PROCEEDINGS

of the 23rd International Society for Music Information Retrieval Conference

ISMIR 2022

Bengaluru, India

(Hybrid Conference)

December 04-08, 2022

Editors

Preeti Rao, Hema Murthy, Ajay Srinivasamurthy,
Rachel Bittner, Rafael Caro Repetto, Masataka Goto,
Xavier Serra, Marius Miron

ISMIR 2022 was organized by the International Society for Music Information Retrieval, Women in Music Information Retrieval (WiMIR) and a diverse international committee of organizers.

Preface

Welcome to ISMIR 2022, the 23rd International Society for Music Information Retrieval Conference. ISMIR is the world's leading research forum on processing, searching, organizing, and accessing music-related data. Our community reflects a diversity of scientific disciplines, seniority levels, professional affiliations, and cultural backgrounds. This year's ISMIR conference is being hosted in Bengaluru, India, making it the first ever ISMIR conference to take place in India. It comes at a very appropriate time, when we are seeing a steadily growing interest in MIR in both academic institutions and in start-ups in the country. Due to the changing global landscape as a result of the COVID-19 pandemic, the 23rd ISMIR conference became the first hybrid ISMIR conference, with both in-person and virtual attendees and presenters. While this posed unique challenges, we took this as an opportunity to bring back the benefits of a physical conference, while maintaining the expanded reach and improved inclusivity that the past two virtual editions of ISMIR have provided. The organizing team, who themselves came together from across the globe, welcomes you to ISMIR 2022.

I. Scientific Program

The Scientific Program Chairs (SPC) of this year's ISMIR are Masataka Goto (National Institute of Advanced Industrial Science and Technology (AIST), Japan), Rachel Bittner (Spotify, France), Rafael Caro Repetto (Kunstuniversität Graz, Austria), and Xavier Serra (Universitat Pompeu Fabra, Spain). Together with the General Chairs and with the participation of many members of the community, mainly as meta-reviewers and reviewers, the SPC coordinated the call for papers, the review process of the conference, and the organization of the scientific sessions.

The core of the ISMIR 2022 Scientific Program is the 113 papers that will be presented during the conference. A total of 305 abstracts were registered of which 264 were submitted as full papers eligible for review. In keeping with the practices of the previous years, a two-tier double-blind review process was conducted involving a total of 241 reviewers and 64 meta-reviewers. Meta-reviewers were instructed to complete a full review of each of their assigned papers, in addition to the final meta-review summarizing the individual reviews. Each paper was assigned to a single meta-reviewer and at least 3 reviewers, with every paper receiving at least 4 reviews in total. A reviewer training session given by Meinhard Muller and Ashley Burgoyne was organized before the review process started. Each meta-reviewer was responsible for between 2 and 5 papers, and each reviewer was responsible for no more than 5 papers, with the average reviewer being responsible for 3.4 papers. The initial reviewing phase was followed by a discussion period, in which reviewers and meta-reviewers could discuss and revise their assessments of each paper. Meta-reviewers were then instructed to summarize the discussion and reviews in the final report, and provide a final recommendation. The SPC rendered final decisions for each paper. The SPC would like to express their thanks to the ISMIR community of reviewers for their wholehearted support to this critical aspect of a successful ISMIR technical program.

Table 1 summarizes the submitted papers by subject area together with the corresponding accepted proportion. Figure 1 illustrates the number of papers accepted with at least one contributing author from each region. Geographic affiliations were inferred from self-reported author affiliations and email addresses. Finally, Table 2 summarizes the publication statistics over the 23-year-history of the conference.

Table 1: Papers submitted and accepted by subject area

Subject Area	Submitted	Accepted	Accept %
Applications	22	5	23
Domain knowledge	50	22	44

Evaluation, datasets and reproducibility	26	11	42
Human-centered MIR	16	3	19
MIR fundamentals and methodology	18	10	56
MIR tasks	94	45	48
Musical features and properties	35	15	43
Philosophical and ethical discussions	3	2	67
Total	**264**	**113**	**42.8**

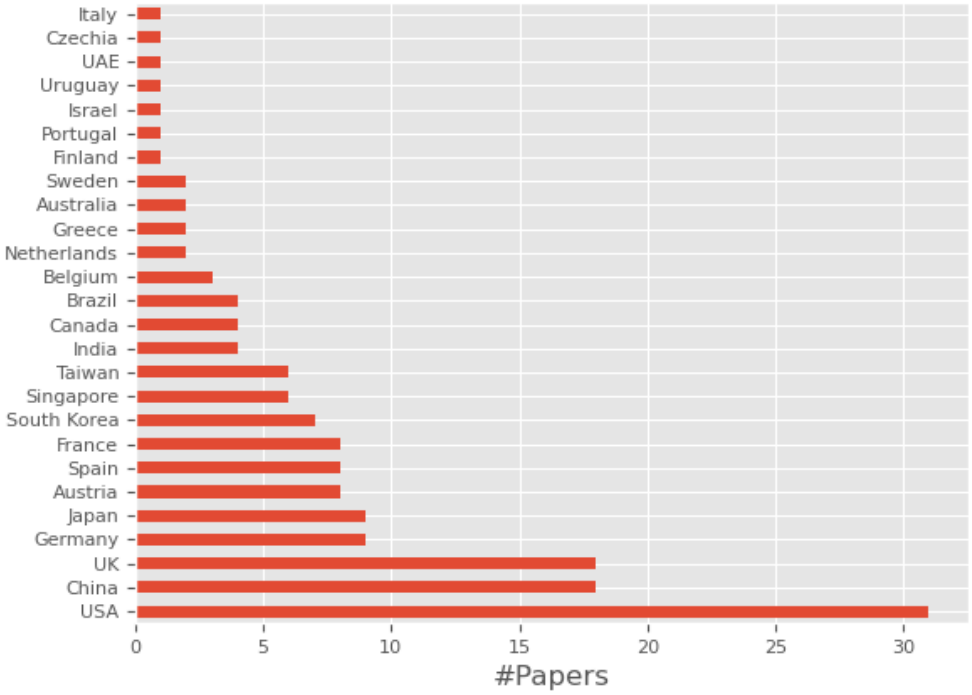

Figure 1: Number of papers accepted with at least one contributing author affiliated to an institution from each country

Table 2: Summary of publication statistics over the 23-year-history of the ISMIR conference

Year	**Location**	**Oral**	**Poster**	**Total**	**Authors**	**Unique Authors**	**Authors / Paper**	**Unique Authors / Paper**
2000	Plymouth	19	16	35	68	63	1.9	1.8
2001	Indiana	25	16	41	100	86	2.4	2.1
2002	Paris	35	22	57	129	117	2.3	2.1

2021	Virtual			104	334	269	3.2	2.6
2022	Bengaluru (Hybrid)			113	423	355	3.8	3.0

Cultural and Social Diversity in MIR (Special Call)

In order to promote the study of music traditions that are still under-represented in MIR, there was a Special Call for Papers on "Cultural and Social Diversity in MIR," continuing the spirit of ISMIR 2021's Special Call for Papers on "Cultural Diversity in MIR." These traditions might not only present music characteristics that would require novel approaches even for standard MIR tasks, but can represent under-studied musical functions and communities. In this regard, this Special Call also encouraged the study of new groups of music makers and users, as well as the development of tools that benefit beyond mainstream music communities. Equally, it encouraged studies from a cross-cultural perspective that cater to this musical and cultural diversity. During the submission process, authors had to indicate that their paper was submitted to this Special Call.

The submissions to the Special Call underwent the same review process as the papers in the main track, with the same number of reviews and a similar number of bids per submission, and with meta-reviewers who were carefully chosen to oversee the review process. In all, 41 papers were submitted to this call, of which 14 were accepted and

verified by the SPC to match the topics of the call. Table 3 shows the distribution of submitted papers across subject areas together with the proportion of accepted papers in each for this special call.

Table 3: Special Call for Papers on "Cultural Diversity in MIR": Papers submitted and accepted by subject area

Subject Area	Submitted	Accepted	Accept %
Applications	5	0	0%
Domain knowledge	14	4	29.6%
Evaluation, datasets, and reproducibility	4	2	50%
Human-centered MIR	2	1	50%
MIR fundamentals and methodology	1	0	0%
MIR tasks	12	4	33.3%
Musical features and properties	2	2	100%
Philosophical and ethical discussions	1	1	100%
Total	**41**	**14**	**34.1%**

Figure 2 depicts the number of Special Call papers accepted with at least one contributing author from each of the specified regions of the world. The geographic affiliations were inferred from self-reported author affiliations. We note an increase of regional diversity in the papers submitted to this year's Special Call, with 7 papers co-authored by researchers from institutions located in 2 or 3 different countries.

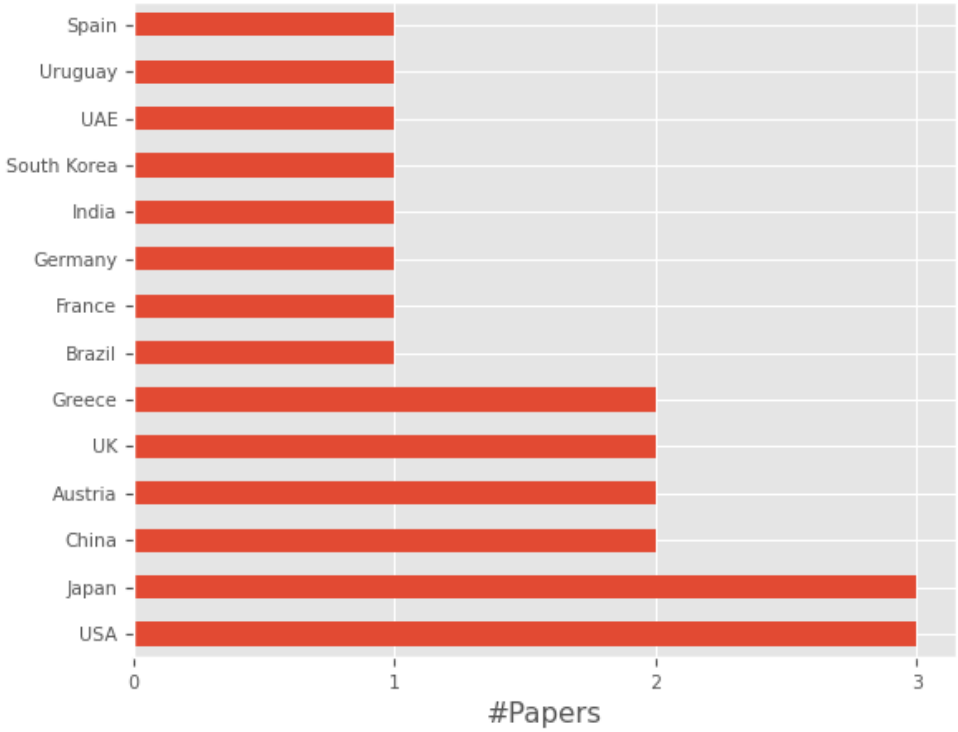

Figure 2: Number of papers in the special call accepted with at least one contributing author affiliated to an institution from each country.

Best Paper Awards

Best paper candidates were selected from the 113 accepted papers. The SPC first short-listed 39 papers based on reviewers' and meta-reviewers' nominations as well as the paper review scores. Of these, the SPC nominated 7 paper candidates under four categories: the Best Paper Award (5 candidates), the Best Student Paper Award (5 candidates), the Best Special Call Paper Award (2 candidates), and the Brave New Idea Award (3 candidates), based on their own judgement of the paper attributes as well as the detailed reviewer comments. This year, the nominations for the Best Paper Award and the Best Student Paper Award are the same. Moreover, we added a criterion,
"Pioneering proposals: This paper proposes a novel topic, task or application. Since this is intended to encourage brave new ideas and challenges, papers rated *Strongly Agree* and *Agree* can be highlighted, but please do not penalize papers rated *Disagree* or *Strongly Disagree*."
to the review form, and thus the Brave New Idea Award was introduced this year to encourage papers with high marks for this criterion. The nominations below are listed in the order of Paper ID for each category. The award winners are underlined.

Best Paper Award Nominations

Yixiao Zhang, Junyan Jiang, Gus Xia, and Simon Dixon, Interpreting Song Lyrics with an Audio-Informed Pre-trained Language Model

Oleg Lesota, Emilia Parada-Cabaleiro, Stefan Brandl, Elisabeth Lex, Navid Rekabsaz, and Markus Schedl, Traces of Globalization in Online Music Consumption Patterns and Results of Recommendation Algorithms

Simeon Rau, Frank Heyen, Stefan Wagner, and Michael Sedlmair, Visualization for AI-Assisted Composing

Mathilde Abrassart and Guillaume Doras, And What If Two Musical Versions Don't Share Melody, Harmony, Rhythm, or Lyrics?

Lele Liu, Qiuqiang Kong, Veronica Morfi, and Emmanouil Benetos, Performance MIDI-to-Score Conversion by Neural Beat Tracking

Best Student Paper Award Nominations

Yixiao Zhang, Junyan Jiang, Gus Xia, and Simon Dixon, Interpreting Song Lyrics with an Audio-Informed Pre-trained Language Model

Oleg Lesota, Emilia Parada-Cabaleiro, Stefan Brandl, Elisabeth Lex, Navid Rekabsaz, and Markus Schedl, Traces of Globalization in Online Music Consumption Patterns and Results of Recommendation Algorithms

Simeon Rau, Frank Heyen, Stefan Wagner, and Michael Sedlmair, Visualization for AI-Assisted Composing

Mathilde Abrassart and Guillaume Doras, And What If Two Musical Versions Don't Share Melody, Harmony, Rhythm, or Lyrics?

Lele Liu, Qiuqiang Kong, Veronica Morfi, and Emmanouil Benetos, Performance MIDI-to-Score Conversion by Neural Beat Tracking

Best Special Call Paper Award Nominations

Martin Clayton, Preeti Rao, Nithya Shikarpur, Sujoy Roychowdhury, and Jin Li, Raga Classification from Vocal Performances Using Multimodal Analysis

Oleg Lesota, Emilia Parada-Cabaleiro, Stefan Brandl, Elisabeth Lex, Navid Rekabsaz, and Markus Schedl, Traces of Globalization in Online Music Consumption Patterns and Results of Recommendation Algorithms

Brave New Idea Award Nominations

Yixiao Zhang, Junyan Jiang, Gus Xia, and Simon Dixon, Interpreting Song Lyrics with an Audio-Informed Pre-trained Language Model

Oleg Lesota, Emilia Parada-Cabaleiro, Stefan Brandl, Elisabeth Lex, Navid Rekabsaz, and Markus Schedl, Traces of Globalization in Online Music Consumption Patterns and Results of Recommendation Algorithms

Jaidev Shriram, Makarand Tapaswi, and Vinoo Alluri, Sonus Texere! Automated Dense Soundtrack Construction for Books Using Movie Adaptations

The final selections were made by specially appointed judges drawn from experienced researchers and were announced during the conference.

Best Reviewer Awards

Based on the scores provided by meta-reviewers on the quality of individual reviews, in relation to the number of papers reviewed by each reviewer, the SPC selected a total of 5 awardees listed below:

Katharina Hoedt
Maximilian Schmitt
Thomas Prätzlich
Silvan Peter
Reinier de Valk

II. Tutorials

T1: **An Introduction to Symbolic Music Processing in Python with Partitura**
Carlos Cancino-Chacón, Francesco Foscarin, Emmanouil Karystinaios, Silvan David Peter

T2: **Computational Methods for Supporting Corpus-Based Research on Indian Art Music**
Thomas Nuttall, Genís Plaja-Roglans, Lara Pearson, Brindha Manickavasakan, Ajay Srinivasamurthy, Kaustuv Kanti Ganguli

T3: **Designing Controllable Synthesis System for Musical Signals**
Hyeong-Seok Choi, Yusong Wu

T4: **Few-Shot and Zero-Shot Learning for Musical Audio**
Yu Wang, Hugo Flores García, Jeong Choi

T5: **Deep learning for Automatic Mixing**
Christian J. Steinmetz, Soumya Sai Vanka, Gary Bromham, Marco A. Martínez Ramírez

T6: **Trustworthy MIR: Creating MIR applications with values**
Christine Bauer, Andrés Ferraro, Emilia Gómez, Lorenzo Porcaro

III. Keynotes

TM Krishna
Karnatik Musician, Author & Activist
Evolution of Performance and Aesthetics in Indian Art Music

Richa Singh
Professor and Head, Dept. of Computer Science and Engineering, Indian Institute of Technology Jodhpur
Adventures of AI: Deepfake and Bias in Audio Processing

IV. Special Sessions

To complement the regular scientific program there were six special sessions, organized as panel discussions, aimed at covering various trending topics of relevance to the ISMIR community. Two of the sessions had a hybrid format and three were fully online.

1. **Enhancing music listening with MIR** (Hybrid)

Moderator: Xavier Serra
Panelists: Anna Gatzioura, Fabien Gouyon, Thomas Lidy, Hugo Rodrigues

In this panel we will discuss the research challenges and opportunities related to the development of new MIR technologies and services to support music listening.

2. **Enhancing music creativity with MIR** (Hybrid)

Moderator: Jan Van Balen
Panelists: Georgi Dzhambazov, Dorien Herremans, Oriol Nieto, Akira Maezawa, Igor Pereira

While audio technology has always had an important role in music production, it is now recognised that MIR tools can provide for workflows that enhance music creativity at every stage of the journey. The panel will discuss the possibilities and challenges of this exciting partnership between music computing and creativity.

3. **Ethics and MIR** (Online)

Moderators: Andre Holzapfel, Fabio Morreale, Bob Sturm

This special session will discuss an action plan towards a code of ethics for the ISMIR community. A code of ethics represents a specific list of values and behaviors that a research community either endorses or objects to. Codes of ethics have been established on the general level of engineering associations (IEEE, ACM), but also more specifically by research communities such as NIME (https://www.nime.org/ethics/).

Whereas ISMIR has seen a series of tutorials on ethics and values, and guidelines have been proposed (https://ismir.net/resources/ethics/), these attempts have not yet manifested into an official code of ethics. Does ISMIR need such a code? What is the function of the code? How can we establish and maintain such a code? What are the main ethical concerns regarding ISMIR research and practice?

4. **PhD in MIR: Challenges and Opportunities** (Online)

Moderator: Meinard Mueller

Music information retrieval (MIR) is an exciting research field related to different disciplines, including signal processing, machine learning, information retrieval, psychology, musicology, and the digital humanities. This diversity opens up many opportunities for challenging, interdisciplinary, and fascinating research projects at the intersection of engineering and humanities. However, younger researchers can also feel overwhelmed by the variety and complexity of MIR research questions. In this session, we will have an informal exchange of ideas and experiences, inviting doctoral candidates and more experienced MIR researchers. Responding to questions from the audience, we hope this interactive session will be helpful for current PhD students and students considering a PhD in MIR.

5. **TISMIR: the open journal of the ISMIR society** (Online)

Moderator: Emilia Gómez

Transactions of the International Society for Music Information Retrieval https://transactions.ismir.net/ was established in 2018 to complement the ISMIR conference proceedings and provide a vehicle for the dissemination of the highest quality and most substantial scientific research in MIR. TISMIR retains the Open Access model of the ISMIR Conference proceedings, encourages reproducibility of the published research papers, and maintains a low publication cost.

Almost 5 years later, this ISMIR 2022 is devoted to discuss and brainstorm on the current status and future perspectives of the journal with a series of TISMIR recent and potential authors, reviewers and editors. We will address the following questions, and others proposed by participants:

What do you appreciate more about TISMIR?

What is the link and complementarity to the ISMIR conference?

Which are the main challenges/limitations that need to be addressed?

How to make TISMIR competitive as a journal in the current publication landscape?

How to engage with more community members in order to make TISMIR a success?

Which are future avenues for conference vs journal outlets in the ISMIR field?

V. Diversity & Inclusion (D&I)

The ISMIR 2022 conference took a broad view of Diversity and Inclusion (D&I). Under the leadership of the conference D&I Chairs, in collaboration with the organizing team at large, ISMIR 2022 offered a variety of initiatives intended to make the conference a positive, welcoming, and supportive environment for a diverse range of presenters and attendees.

The initiatives under ISMIR 2022 D&I included:

1. A new New-to-ISMIR paper mentoring program which was designed for members new to the ISMIR community (early-stage researchers, researchers from areas underrepresented in ISMIR, and/or researchers from other allied fields who wish to submit their work to ISMIR conference). It is envisioned that the program becomes a regular part of the D&I initiatives planned by the society
2. As a part of commitments to foster D&I and to support early-stage researchers, the ISMIR society, WiMIR, local organizers have provided financial support in terms of registration waivers enabled by the generous support of the sponsors. Partial or full waivers have been extended to applicants interested in in-person or virtual participation
3. WiMIR plenary session of ISMIR 2022 invited a panel of four women researchers who are exploring new frontiers and themes in music research, to motivate the audience on their recent research topic, share the challenges and insights and have an interactive session with the audience
4. ISMIR 2022 is made accessible to the local community through open sessions, welcoming the local community to register for free and participate in select sessions

Finally, the ISMIR conference Code of Conduct has been updated to align with this year's hybrid format to provide a harassment-free experience for all participants.

New-to-ISMIR paper mentoring program

The New-to-ISMIR paper mentoring program is designed for members new to ISMIR (early-stage researchers in MIR or researchers from allied fields who wish to consider submitting their work to an ISMIR conference) to share their advanced-stage work-in-progress ISMIR paper drafts with senior members of the ISMIR community (mentors who volunteered for the program) to obtain focused reviews and constructive feedback. The program supplements the generic submission guidelines. The program is being run as a pilot in 2022, closely aligned with the ISMIR 2022 paper submissions deadlines.

We thank the following 24 invited senior members, who were kind enough to sign up as mentors, for their valuable time to review the submitted works with constructive feedback:

Emmanouil Benetos	Cory McKay	David Sears
Jin Ha Lee	Chris Donahue	Ichiro Fujinaga
Cheng-i Wang	Philippe Esling	Juhan Nam
Oriol Nieto	Alexander Lerch	Cynthia Liem
Mitsunori Ogihara	Arthur Flexer	George Fazekas
Carlos Cancino-Chacón	Geoffroy Peeters	Christof Weiss
Justin Salamon	Vipul Arora	Sankalp Gulati
Blair Kaneshiro	Jordan Smith	Xiao Hu

There was an enthusiastic 30 mentee sign-up in the pilot program. 10 out of 15 mentored submissions were submitted to ISMIR 2022. Two of these submissions have been accepted in ISMIR 2022.

Feedback from both mentors and mentees has been collected to establish best practices for future editions of the paper mentoring program.

Women in Music Information Retrieval (WiMIR)

Women in Music Information Retrieval (WiMIR) is a group of people dedicated to promoting the role of, and increasing opportunities for, women in the MIR field. WiMIR's initiatives started as informal gatherings around breakfast or lunch during ISMIR conferences (2011–2014), and moved to formal WiMIR events included in the conference program (2015–today) garnering a high turnout of both women and allies. These events provide occasions for people to network and to discuss several important issues ranging from mentorship and conference support, to improving the representation of women and, more broadly, diversity in the community. In 2018, WiMIR started hosting its own workshop as a satellite event, in which attendees of all genders participated. These workshops aim to offer participants an opportunity for networking, put the spotlight on technical work done by women in the field, and foster collaboration between women and allies by proposing group work led by project guides to try to solve small research problems or to undertake new research projects that could lead to longer-term collaborations. The ISMIR 2022 D&I Chairs gratefully acknowledge the support of this year's WiMIR sponsors, whose contributions support women in the field as well as the broader D&I efforts of this year's conference.

WiMIR Plenary Session

WiMIR plenary session of ISMIR 2022 was a hybrid session, featuring a panel of four women researchers who were invited to motivate the audience about their recent topic of research, while sharing the associated challenges in their journey and valuable insights from their experience. The session also featured an interactive conversation with the audience.

Moderators: Xiao Hu (online), Ranjani H G (in-person)
Panelists:
Xiao Hu (The University of Hong Kong), "Music for learning and well-being"

Emilia Parada-Cabaleiro (Johannes Kepler University), “Working in MIR with a diverse background: A personal view”
Chitralekha Gupta (National University of Singapore), “Automated singing quality analysis: Overview and challenges”
Shahar Elisa (Spotify), “Research on the industrial lane”

Open sessions

As a part of D&I efforts, we had the following events open to the general public and within the IISc community.

The late breaking/demo (LBD) session was proposed to be an open session in ISMIR 2022, and invites students and researchers in the local community. It enabled interested participants to register (without cost) and attend the late-breaking/demo session of the conference and interact with students, experts and senior members of the ISMIR research community.

ISMIR 2022 music track session was proposed to be an open session as a part of outreach to the local community to as a part of efforts to encourage more submissions in future ISMIR editions. The ISMIR 2022 music concert featured a Jugalbandi vocal concert to highlight the commonalities, differences of the two forms of Indian art music - Hindustani and Carnatic music to the ISMIR community. The concert was open to the local community.

Financial support

ISMIR 2022 provided partial and full registration waivers to authors, students, women and other underrepresented minorities in MIR, attendees from low-income countries, new to ISMIR and unaffiliated attendees. The grants included Author Grants (for both accepted full paper and music submissions), WiMIR grants (based on the applicants’ eligibility criteria) to encourage student participants, authors for both in-person or virtual participants. Overall, 25 author grants and more than 50 WiMIR grants have been offered. Almost all applicants have been offered registration grants. Registration waivers were offered to all volunteers who signed up for ISMIR 2022. This is the first edition of the hybrid version of ISMIR conference. Since there were uncertainties around travel due to the pandemic, ISMIR 2022 did not consider providing any travel and accommodation grants.

IV. Late Breaking/Demo Session

Late Breaking/Demo (LBD) session was organised in a hybrid format this year with both local and remote sessions. A light screening process was carried out for each submission by the LBD chairs. Owing to visa application processing times, an earlier submission date was recommended for people requiring visas. To clearly distinguish LBD extended abstracts from main conference papers, a new watermark was introduced on the abstract template. Keeping in line with the cultural and social diversity theme of the conference, the chairs reached out to groups working on Indian music inviting submissions. The local LBD session was an open session for students and independent researchers from the local community, allowing them to attend the event for free (subject to venue capacity constraints). This enabled participants to interact with students, experts and senior members of the ISMIR research community.

VI. Music

The idea of the music program this year was to bring together composers, technologists and performers, demonstrating application of music information retrieval, computational musicology, human computer interaction, machine accompaniment, call-response, or ethical hacking. Keeping in line with the cultural and social diversity theme, submissions on non-Eurogenetic music that could present cultural diversity were also encouraged. The submissions were evaluated on the basis of audio-visual presentation, submission statement, concept clarity while capturing and retaining audience attention. Here is a list of music submissions that were presented:

M1: **Hindustronic Live**
Carlos Guedes

M2: **Conformity 16 for autonomous piano and large ensemble**
Jason Palamara

M3: **Wings for Solo Clarinet and Automated Accompaniment Video Animation**
Kaitlin Pet, Nikki Pet, Christopher Raphael

M4: **AI Phantasy**
Panayiotis Kokoras

M5: **A song with yati Patterns - Visual representation through Kolam**
Saroja TK, Sujatha TKL, Chandrakanth Mamillapalli

M6: **Fantastic AI Sinawi**
Danbinaerin Han, Hannah Park, Chaeryeong Oh, Dasaem Jeong

M7: **Mukti - Kahan Re Aaya Tu (मुक्ति - कहाँ रे आया तू)**
Jyoti Narang, Thomas Nuttall

M8: **The Oratory of Saint Philip Neri**
Luke Dzwonczyk

M9: **Beatboxing with a homespun Sound box**
Ranaprathap Ponnam

M10: **Confluence of Carnatic and Western Music using Grahabedha and Carnatic Gamakas**
Tallapragada Shanmukha Sreevatsa, Suswara Pochampally (Equal contribution)

M11: **Recurrent Variations for String Orchestra**
Hendrik Vincent Koops
M12: 'b_dot_io': an Audio-Visual Miniature for Saxophone and Computer
Mark Hanslip

M13: **Bloom for cello and live electronics**
Austin A Franklin

Music was alive and kicking at hybrid ISMIR 2022!

VII. Industry Presentations Session

With MIR technology playing a prominent role in the present-day industry, we had ISMIR 2022 sponsors making brief presentations about their company profile, the nature of their R&D and the opportunities available to students interested in the field. The participating sponsors were: Spotify, Moises, Adobe, Deezer, Utopia music, Pandora, Smule, Yamaha, and Chordify.

IX. Social Program

After two years of Virtual ISMIR conference, ISMIR 2022 was the first hybrid edition that enabled in-person participants. ISMIR 2022 social program was designed to be engaging to the in-person participants and aimed to

showcase the rich cultural and musical heritage of India. The social program included a performance of Kalidasa's play Mālavikāgnimitram by Dhaatu Puppet Theater (https://www.dhaatupuppets.org/), a Jugalbandi vocal Indian art music concert by Kaustuv Kanti Ganguli and Vignesh Ishwar, an Indian street food themed welcome reception, a banquet dinner in a museum that showcased a model village capturing Karnataka's distinct rural life in all its quaint glory and the traditional ISMIR jam session.

VIII. Satellite Events

In addition to the main conference, five satellite events of ISMIR 2022 were available to participants:

1. **WiMIR workshop**: The WiMIR Workshop comprised two days of talks by eminent researchers in the WiMIR community, and an opportunity to network, socialize, and have discussions with peers ahead of the ISMIR conference. The Workshop was, as ever, free and open to all members of the MIR community. More information: https://wimir.wordpress.com/2022/08/03/wimir-workshop-2022/

2. Music, Mind, Movement and Technology (MMMT) workshop: The MMMT workshop was a hybrid satellite workshop around the 23rd International Society for Music Information Retrieval Conference (ISMIR 2022). MMMT was an attempt to increase the dialogue between the fields of Music Information Retrieval and Music Cognition. This hybrid two-day workshop on Dec 2-3, 2022 brought together leading international researchers for a series of talks highlighting interdisciplinary research and facilitating interaction and exchange of ideas around various themes. More information: https://ismir2022.ismir.net/satellites/mmmt

3. **Indian Music Experience**: As a satellite event for ISMIR 2022, we organized an Indian music experience workshop on the 9th Dec, 2022. The day-long physical-only workshop was hosted at the Indian Music Experience Museum (IME), which is India's first interactive music museum and involved a museum visit, workshops on Indian art music and a music exhibition. More information: https://ismir2022.ismir.net/satellites/ime

4. **Music HackDay India**: The Music Tech Community India is an open community of musicians, developers, researchers and artists with an aim to collaborate, share knowledge and bridge the gap between media, arts and technology as a community. The community conducts talks, workshops, seminars and are currently curating tutorials, resources and interviews with artists, startup founders and researchers. As a satellite event of ISMIR 2022, the community organized a 2-day MusicHackDay India 2022 event on 10-11 Dec, 2022 that included a hackathon, algorave concert, networking, and panel discussions. The event was open to public (with prior registration) and organized in Bengaluru, with a possibility of virtual participation. MusicHackDay India 2022 included the following events:

    - HAMR (Hacking Audio Music Research): Extending on the tradition of past ISMIR conferences, MusicHackDay India included a hackathon with prizes for the best hacks.
    - Algorave concert: Live coding, audio-visual performance from our friends from the Algorave India community, coupled with a social event
    - Networking: A great opportunity to connect the burgeoning tech and music community in Bengaluru, India with the diverse ISMIR community.
    - Panel discussions/Interviews: A panel discussion between individuals from different dimensions of music tech from the Academia, Business and the Musicians.

    More information: https://musichackdayindia.github.io/

5. **CompMusic workshop**: CompMusic Workshop 2022 was a 5-day workshop and a satellite event of ISMIR 2022 to introduce the field of Computational Musicology while focusing on the study of Carnatic Music. By combining theoretical lectures with hands-on labs, the workshop was aimed at giving the participants the conceptual framework and practical tools needed to analyze and understand music signals using a variety of computational methodologies. The workshop was aimed at undergraduate or graduate

students doing engineering, music, or social sciences, without prior experience in the topic but highly interested in acquiring the computational and musicological competencies needed to study music, in particular Carnatic Music. The workshop took place at the Indian Institute of Technology Madras, Chennai during the Madras Music Season, which is the largest music festival of Carnatic Music. In the evenings, the participants were able to attend a wide variety of Carnatic Music concerts. More information: https://compmusic.upf.edu/workshop-ismir-2022

IX. Acknowledgements

We are happy to present to you the proceedings of ISMIR 2022. The conference program was made possible thanks to the hard work of many people, including the ISMIR 2022 conference chairs, the joint host institutes of IIT Bombay, IISc Bangalore and IIT Madras, the administrative staff of the National Science Seminar Complex (NSSC) at IISc, ISMIR Board members, volunteers, and the many reviewers and meta-reviewers from the program committee.

We would also like to thank our sponsors, whose generous support made this conference possible:

Platinum sponsors

- Spotify
- Moises

Gold sponsors

- Adobe
- Deezer
- Utopia Music
- Pandora
- IndSCA
- Steinberg Media Technology
- Smule
- Yamaha
- Chordify
- TikTok

Silver sponsors

- Steinberg Media Technology
- iZotope/Soundwide

Supporters

- ACR Cloud
- Cochl
- School of Information Sciences, University of Illinois Urbana-Champaign

We would like to thank the sponsors that explicitly chose to sponsor WiMIR, its grants, and its initiatives:

Patrons

- Spotify
- Deezer

Contributors

- Adobe

- Pandora
- Soundwide
- TikTok

Supporters

- Steinberg

ISMIR 2022 would not have been possible without the exceptional contributions of our community in response to our call for participation. The biggest acknowledgment goes to you, the presenters and the (in-person and remote) participants.

Keynote Talks

Keynote Talk - 1

Evolution of Performance and Aesthetics in Indian Art Music

TM Krishna
Karnatik Musician, Author & Activist

Abstract

Indian art music continues to evolve in current performance practice, while staying within the framework provided by some of the immutable axiomatic concepts that define the music culture. The changes that lead the evolution of the music culture are guided by practitioners and influenced by the evolving socio-cultural, socio-political or performance and aesthetic considerations. In this talk, we focus on the evolution of Indian art music from the perspective of performance and aesthetics, highlighting some important milestones around the melodic and rhythmic systems in Indian art music. Focusing on recent developments and our own influences on performance practice and aesthetics, we discuss our effort and approaches to create more inclusive roles in music composition and performance. We further aim to provide concrete examples and formulations of the abstractions in current performance and aesthetics. We propose thoughts and ideas that can help current MIR formulations and solutions to go beyond the limiting assumptions based on current music performance practices and (often rigid) structures, and focus on the music abstractions that are more fundamental to our understanding, appreciation and analysis of Indian art music.

Biography

TM Krishna, is one of the pre-eminent vocalists in the rigorous Karnatik tradition of India's classical music. As a public intellectual, Krishna speaks and writes about issues affecting the human condition and about matters cultural. As a vocalist, he has made path-breaking innovations in both the style and substance of his concerts. His award-winning book, A Southern Music – The Karnatik Story, published by Harper Collins in 2013 was a first-of-its-kind philosophical, aesthetic and socio-political exploration of Karnatik music. TM Krishna has partnered with individuals and collectives working at the intersections of social change, a new politics for contemporary India, a fresh new imagining of the wider universe of the Arts. In 2016, TM Krishna received the prestigious Ramon Magsaysay Award in recognition of "his forceful commitment as artist and advocate to art’s power to heal India’s deep social divisions".

Keynote Talk - 2

Adventures of AI: Deepfake and Bias in Audio Processing

Richa Singh
Professor and Head, Dept. of Computer Science and Engineering, Indian Institute of Technology Jodhpur

Abstract

The increasing capabilities for machine learning algorithms is enabling the usage of ML models for a variety of tasks including for creativity such as generating new music and modifying existing music. Similar applications are present in different kinds of audio signals such as voice biometrics, speaker and speech recognition. However, these technologies that support creativity can also be used for malicious purposes. Deepfake audios are one such technology which enable flawlessly altering existing audio signals or creating new signals from any given text. Audio can also be integrated with videos to provide a complete multimodal experience, which can be purely synthetic and fake. While there is significant research ongoing in image and video, the space of detecting these anomalies in audio processing is relatively unaddressed. We will discuss some of these possible adventures of machine learning in audio processing and the research efforts that we are undertaking to detect them. In addition, we will also discuss the bias and fairness issues in audio processing where we will highlight "out of distribution" behavior of popular approaches and some strategies to address them.

Biography

Richa Singh received her Ph.D. degree in computer science from West Virginia University, Morgantown, USA, in 2008. She is currently a Professor and Head at Department of CSE, IIT Jodhpur. She has co-edited the book Deep Learning in Biometrics and has delivered keynote talks/tutorials on deep learning, trusted AI, and domain adaptation in NVIDIA GTC 2021, BIOSIG2021, ICCV 2017, AFGR 2017, and IJCNN 2017. Her areas of interest are pattern recognition, machine learning, and biometrics. She is a Fellow of IEEE, IAPR and AAIA, and a Senior Member of ACM. She was a recipient of the Kusum and Mohandas Pai Faculty Research Fellowship at the IIIT-Delhi, the FAST Award by the Department of Science and Technology, India, and several best paper and best poster awards in international conferences. She is/was served as the Program Co-Chair of CVPR2022, ICMI2022, IJCB2020, AFGR2019 and BTAS 2016, and a General Co-Chair of FG 2021 and ISBA 2017. She is also the Vice President (Publications) of the IEEE Biometrics Council and an Associate Editor-in-Chief of Pattern Recognition.

Tutorials

Tutorial 1

An Introduction to Symbolic Music Processing in Python with Partitura

Carlos Cancino-Chacón, Francesco Foscarin, Emmanouil Karystinaios, Silvan David Peter

Abstract

Symbolic music formats (e.g., MIDI, MusicXML/MEI) can provide a variety of high-level musical information like note pitch and duration, key/time signature, beat/downbeat position, etc. Such data can be used as both input/training data and as ground truth for MIR systems.

This tutorial aims to provide an introduction to symbolic music processing for a broad MIR audience, with a particular focus on showing how to extract relevant MIR features from symbolic musical formats in a fast, intuitive, and scalable way. We do this with the aid of the Python package Partitura. To target different kinds of symbolic data, we use an extended version of the ASAP Dataset, a multi-modal dataset that contains MusicXML scores, MIDI performances, audio performances, and score-to-performance alignments.

The tutorial will be structured in four parts: The first part provides an introduction to the topic of symbolic music processing. The second, third, and fourth parts are hands-on tutorials that showcase the structure of the Partitura package (including its relation to other popular Python packages for symbolic music processing), how to extract common MIR features, and how to work with symbolic multimodal datasets, respectively.

The motivation behind this tutorial is to promote research on symbolic music processing in the MIR community. Therefore, we target a broad audience of researchers without requiring prior knowledge of this particular area. For the hands-on parts of the tutorial, we presuppose some practical experience with the Python language, but we will provide well-documented step-by-step access to the code in the form of Google Colab notebooks, which will be made publicly available after the tutorial. Furthermore, some familiarity with the basic concepts of statistics and machine learning is useful.

This work receives funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme, grant agreement No 101019375 (Whither Music?).

Biographies of Presenters

Carlos Cancino-Chacón is an Assistant Professor at the Institute of Computational Perception, Johannes Kepler University, Linz, Austria, and a Guest Researcher at the RITMO Centre for Interdisciplinary Studies in Rhythm, Time and Motion, University of Oslo, Norway. His research focuses on studying expressive music performance, music cognition, and music theory with machine learning methods. He received a doctoral degree in Computer Science at the Institute of Computational Perception of the Johannes Kepler University Linz, a M.Sc. degree in Electrical Engineering and Audio Engineering from the Graz University of Technology, a degree in Physics from the National Autonomous University of Mexico, and a degree in Piano Performance from the National Conservatory of Music of Mexico.

Francesco Foscarin is a postdoctoral researcher at the Institute of Computational Perception, Johannes Kepler University, Linz, Austria. He completed his Ph.D. at CNAM Paris on music transcription, with a focus on the production of musical scores, and holds classical and jazz piano degrees from the Conservatory of Vicenza. His research interests include post-hoc explainability techniques for DL models, grammar-based parsing of hierarchical chord structures, piano comping generation for jazz music, and voice separation in symbolic music.

Emmanouil Karystinaios is a Ph.D. student at the Institute of Computational Perception, Johannes Kepler University, Linz, Austria. His research topics encompass graph neural networks, music structure segmentation, and automated music

analysis. He holds an M.Sc. degree in Mathematical Logic from Paris Diderot University, an M.A. in Composition from Paris Vincennes University, and an integrated M.A. in Musicology from the Aristotle University of Thessaloniki.

Silvan David Peter is a University Assistant at the Institute of Computational Perception, Johannes Kepler University, Linz, Austria. His research interests are the evaluation of and interaction with computational models of musical skills. He holds an M.Sc. degree in Mathematics from the Humboldt University of Berlin.

Tutorial 2

Computational Methods For Supporting Corpus-Based Research On Indian Art Music

Thomas Nuttall, Genís Plaja-Roglans, Lara Pearson, Brindha Manickavasakan

Abstract

Culture-aware approaches to computational musicology and music information research (MIR) have been shown to be effective for a musically relevant analysis of a music culture. Projects such as CompMusic (2011-2017), MusicalBridges (2018-2022) or the initiatives funded by SPARC (2019-2022) have demonstrated the importance of considering sociocultural specifics of a music tradition to effectively define research problems, collect data and propose methods for analysis. These projects have made particularly notable contributions to the analysis of Indian Art Music (IAM), leading to a collective body of bespoke computational methods for analyzing these traditions.

Through this tutorial we aim to compile and present such works, making openly available a number of software tools and materials developed by MIR researchers working on the two main IAM traditions, Carnatic and Hindustani. The content will be organized into five sections: (1) datasets and corpora, (2) melodic analysis, (3) rhythmic analysis, (4) timbral analysis and (5) structural analysis. Each topic will include an introduction covering the basic musical concepts required to understand its constituent tasks, followed by a practical presentation of the materials and software tools compiled.

This tutorial is the result of an ongoing collaborative effort involving many contributors. The software will be available in Python through a single Github repository, containing clear and reproducible implementations of the presented methodologies. A Jupyter WebBook will be the main tutorial reference, in which we will introduce all the materials, contextualize the software tools, and include Jupyter Notebook examples for most of the research tasks covered.

Biographies of Presenters

Thomas Nuttall is a Research Engineer in the Music Technology Group (MTG) of Universitat Pompeu Fabra in Barcelona, Spain. His research focus is on melodic pattern analysis in musical traditions under-represented in the music computation and computational musicology fields, such as Arab-Andalusian or Indian Art Music, and on building tools that bridge the gap between the music information retrieval and musicology research communities.

Genís Plaja-Roglans is a Ph.D student in the Music Technology Group (MTG) of Universitat Pompeu Fabra in Barcelona, Spain. His research focus is on creation of bespoke machine learning models for the understanding of musical traditions under-represented in Music Information Research, currently focusing on Carnatic and Hindustani music. Recent work includes vocal melody estimation, singing voice source separation and repeated pattern discovery.

Lara Pearson is a musicologist at the Max Planck Institute for Empirical Aesthetics (MPIEA), Frankfurt am Main, Germany. Her work explores bodily and movement dimensions of music experience and meaning, often combining sonic and kinetic analyses. Her stylistic focus lies in South Indian music practices, in particular Carnatic music. She has also published on cross-cultural aesthetics, cultural heritage, music notation and the concept of improvisation.

Brindha Manickavasakan is a Carnatic Music vocalist, and is among the foremost, popular young performing Carnatic musicians in India. She has been performing for the past 21 years, and is currently learning from Vidushi Suguna Varadachari. She is an ‘A’ graded vocal artist of All India Radio. Brindha holds a Master’s degree in Biostatistics from Georgetown University, USA, a Master’s degree in Music and is a PhD candidate in Music from Madras University with a thesis on the contribution of Tañjāvūr K Ponnayyā Piḷḷai. She is a constant feature in all the major sabhas in Chennai, and performs regularly across India and abroad.

Tutorial 3
Designing Controllable Synthesis System for Musical Signals

Hyeong-Seok Choi, Yusong Wu

Abstract

Advances in deep learning and signal processing research have made it possible to generate signals that at times can be difficult to distinguish from real samples. Despite the realistic output the models can produce, however, the controllability of the models is still constrained because of the black-box-like nature of many models.

In this tutorial, we aim to introduce considerations researchers can take into account for a better end-user experience. We would like to focus in particular on how to design deep generative models with intuitive control of music audio signals, specifically vocal and instrumental performance. To this end, we will first present a broad review of up-to-date generative models for singing voices and musical instrument performance. Then, we will share our own research results and insights regarding both the implicit and explicit controllability of the deep learning models. In the section on presenting controllable models for instrumental performance synthesis, we will include a walk-through of the building, training, and control of the DDSP and MIDI-DDSP models via Jupyter (Colab) Notebook with Python and Tensorflow.

The target audience for this tutorial is researchers who are interested in deep generative models for monophonic signals, especially for singing voice and musical instruments. We expect the audience to have a basic understanding of machine learning concepts for audio signal processing.

Biographies of Presenters

Hyeong-Seok Choi received his PhD from Seoul National University, South Korea, in 2022, with a thesis titled, “A Controllable Generation of Signals from Self-Supervised Representations” under the supervision of Prof. Kyogu Lee. His recent research interest is mainly in representation learning and controllable synthesis of speech and singing voices. He co-founded the audio technology startup company, Supertone, where he has been working as the lead of their research team. He contributed to the winning of the CES 2022 Innovation Awards Honoree: Software & Mobile Apps by proposing a real-time voice conversion technology.

Yusong Wu is a final-year research master at the University of Montreal and Mila in Montreal, Canada. He is co-advised by Prof. Aaron Courville and Prof. Cheng-Zhi Anna Huang and will become a Ph.D. student under the same advisors shortly. His research focuses on making better generative models for music creativity. His recent work ``MIDI-DDSP: Detailed Control of Musical Performance via Hierarchical Modeling”, collaborating with Google Magenta, was accepted by ICLR 2022 for oral presentation.

Tutorial 4

Few-Shot and Zero-Shot Learning for Musical Audio

Yu Wang, Hugo Flores García, Jeong Choi

Abstract

While deep neural networks achieved promising results in many MIR tasks, they typically require a large amount of labeled data for training. Rare, fine-grained, or newly emerged classes (e.g. a rare musical instrument, a new music genre) where large-scale data collection is hard or simply impossible are often considered out-of-vocabulary and unsupported by MIR systems. To address this, few-shot learning (FSL) and zero-shot learning (ZSL) are learning paradigms that aim to train a model that can learn a new concept based on just a handful of labeled examples (few-shot) or some auxiliary information (zero-shot), mimicking human ability. By doing so, the trained model is no longer limited to a pre-defined and fixed set of classes but ideally can generalize to any class of interest with the cost of little human intervention. In addition, few-shot and zero-shot models naturally incorporate human input without asking for significant effort, making them useful tools when developing MIR systems that can be customized by individual users.

In this tutorial, we will go over

- FSL/ZSL foundations - Task definition and existing approaches.
- Recent advances of FSL/ZSL in MIR - Techniques and contributions in recent studies. We will also discuss the remaining challenges and future directions.
- Coding examples - Showcasing the training and evaluation pipeline of FSL and ZSL models on specific MIR tasks. Code and references to the tools and datasets will be provided.

We aim for this tutorial to be useful to researchers and practitioners in the ISMIR community who are facing labeled data scarcity issues, looking for new interaction paradigms between users and MIR systems, or generally interested in the techniques and applications of FSL and ZSL. We assume the audience is familiar with the basic machine learning concepts.

Biographies of Presenters

Yu Wang Yu is a Ph.D. candidate in Music Technology at the Music and Audio Research Laboratory at New York University, working under Prof. Juan Pablo Bello. Her research interests focus on machine learning and signal processing for music and general audio. Specifically, she is interested in adaptive and interactive machine listening with minimal supervision. She has interned with Adobe Research and Spotify. Before joining MARL in 2017, she was in the Music Recording and Production program at the Institute of Audio Research. She holds two M.S. degrees in Materials Science & Engineering from Massachusetts Institute of Technology (2015) and National Taiwan University (NTU) (2012), and a B.S. in Physics from NTU (2010). Yu is a guitar player and also enjoys sound engineering. Japanese math rock is her current favorite music genre.

Hugo Flores García is a Ph.D. student in Computer Science at Northwestern University, working under Prof. Bryan Pardo in the Interactive Audio Lab. Hugo's research interests lie at the intersection of machine learning, signal processing, and human computer interaction for music and audio. Hugo has previously worked on a deep learning framework for Audacity, an open source audio editor, and will be a research intern at Spotify and Descript during the latter half of 2022. Hugo holds an B.S. in Electrical Engineering from Georgia Southern University (2020). He is a jazz guitarist, and can be seen playing with various groups local to the Chicago area. Hugo enjoys augmenting musical instruments with technology, as well as making interactive music and art in SuperCollider and Max/MSP.

Jeong Choi is a machine learning researcher at Naver, where he leads NOW AI team that's working on a multi-modal recommendation system for a video streaming service, Naver NOW. Before joining Naver, he was a researcher at

NCSOFT, working on a recommendation system in a music game FUSER. He also interned at Deezer Research. He received a M.S. in Culture Technology at Korea Advance Institute of Science and Technology, under the supervision of Prof. Juhan Nam. His research interest is on representational learning of various signals that can further contribute to diverse music recommendation strategies. Previously, he pursued a long music career as a composer and a bassist. His passion for music research originates from the experience. He also received a M.S. and a B.E. in Digital Media at Ajou University, and majored in French at Daewon Foreign Language High School.

Tutorial 5

Deep learning for automatic mixing

Christian J. Steinmetz, Soumya Sai Vanka, Gary Bromham, Marco A. Martínez Ramírez

Abstract

Mixing is a central task within audio post-production where expert knowledge is required to deliver professional quality content, encompassing both technical and creative considerations. Recently, deep learning approaches have been introduced that aim to address this challenge by generating a cohesive mixture of a set of recordings as would an audio engineer. These approaches leverage large-scale datasets and therefore have the potential to outperform traditional approaches based on expert systems, but bring their own unique set of challenges. In this tutorial, we will begin by providing an introduction to the mixing process from the perspective of an audio engineer, along with a discussion of the tools used in the process from a signal processing perspective. We will then discuss a series of recent deep learning approaches and relevant datasets, providing code to build, train, and evaluate these systems. Future directions and challenges will be discussed, including new deep learning systems, evaluation methods, and approaches to address dataset availability. Our goal is to provide a starting point for researchers working in MIR who have little to no experience in audio engineering so they can easily begin addressing problems in this domain. In addition, our tutorial may be of interest to researchers outside of MIR, but with a background in audio engineering or signal processing, who are interested in gaining exposure to current approaches in deep learning.

Biographies of Presenters

Christian J. Steinmetz is PhD researcher working with Prof. Joshua D. Reiss within the Centre for Digital Music at Queen Mary University of London. He researches applications of machine learning in audio with a focus on differentiable signal processing. Currently, his research revolves around high fidelity audio and music production, which involves enhancing audio recordings, intelligent systems for audio engineering, as well as applications that augment and extend creativity. He has worked as a Research Scientist Intern at Adobe, Facebook Reality Labs, and Dolby Labs. Christian holds a BS in Electrical Engineering and BA in Audio Technology from Clemson University, as well as an MSc in Sound and Music Computing from the Music Technology Group at Universitat Pompeu Fabra.

Soumya Sai Vanka is a first year PhD researcher at the Centre for Digital Music, Queen Mary University of London. She is part of the AI and Music, Centre for Doctoral Training. Her research focus is mainly on exploring the idea of Music Mix similarity, Music Mix Style transfer, and Intelligent Multitrack Mixing using Self-Supervised, Semi-Supervised, and Unsupervised Learning architectures. She also writes music, produces and plays saxophone. Her educational background is a mixture of Masters in Physics and Courses in Music Production.

Gary Bromham is a part-time PhD researcher at Queen Mary University of London, researching the role that traditional studio paradigms and retro aesthetics play in intelligent music production systems (2016 -). He has several publications in this field and has contributed a chapter to the recent Routledge publication, ‘Perspectives on Music Production: Mixing Music’ (2017). He was also a research assistant on the EPSRC funded project called FAST (Fusing Audio and Semantic Technologies) where he is employed as an industry advisor (2017 - 2020). In addition to his research interests, Gary is a practising music producer, songwriter and audio engineer, with over 30 years’ experience (1989 - 2020). He has worked with artists as diverse as Bjork, Wham, Blur and U2, during a period that has witnessed several technological changes. Gary is well versed in most popular music making software and has extensive knowledge of using analog hardware, acting as a product designer and specialist for the renowned mixing desk company, Solid State Logic. He is also a frequent guest lecturer and external advisor at several universities in the UK, Norway and Sweden; speaking on songwriting, music production aesthetics and audio engineering and bringing some of his extensive knowledge and experience to both Undergraduate and Master’s degree level programs.

Marco A. Martínez Ramírez is music technology researcher at Sony in the Tokyo R&D center, where he is part of the Creative AI Lab. His research interests lie at the intersection of machine learning, digital signal processing, and intelligent music production, with a primary focus on deep learning architectures for music processing tasks. Previously, he was an audio research intern at Adobe and received his PhD from the Centre for Digital Music at Queen Mary University of London. He has a MSc in digital signal processing from the University of Manchester, UK, and a BSc in electronic engineering from La Universidad de Los Andes, Colombia. Marco also has a background in music production and mixing engineering.

Tutorial 6

Trustworthy MIR: Creating MIR applications with values

Christine Bauer, Andrés Ferraro, Emilia Gómez, Lorenzo Porcaro

Abstract

The MIR community shows an increasing interest in understanding how current technologies affect the everyday experience of people all over the world, e.g., how we listen to music, compose songs, or learn to play an instrument. As it was introduced in the FAT-MIR tutorial held at ISMIR 2019, a great discussion has aroused around the ethical, social, economic, legal, and cultural implications that the use of MIR systems have in our life.

In this tutorial, we aim at building upon and expanding the aforementioned debate, discussing the more recent results obtained by the MIR community and beyond. The goal of the tutorial is to show how values, such as fairness and diversity, can be embedded in the life cycle of MIR systems to make them trustworthy: from algorithmic design to evaluation practices and regulatory proposals. To achieve that, we will discuss examples of, among the others, popularity bias, gender bias, algorithmic bias, music styles underrepresentation, and diversity-related phenomena (e.g. filter bubbles).

This tutorial is suitable for researchers and students in MIR working in any domain, as these issues are relevant for all MIR tasks. The examples will mostly focus on music information retrieval and recommendation, but there are no prerequisites for taking this tutorial. Besides presenting recent research insights, the tutorial will integrate two hands-on sessions, where we will involve the participants in reflecting on the design of evaluation methods that take into account values for which MIR systems should be accountable.

Biography of the Presenter

Christine Bauer is an assistant professor at the Department of Information and Computing Sciences at Utrecht University, The Netherlands. Her research activities center on interactive intelligent systems. Recently, she focuses on context-aware (music) recommender systems. A core interest in her research activities are fairness in algorithmic decision-making and multi-method evaluations. Her research and teaching activities are driven by her interdisciplinary background. She holds a Doctoral degree in Social and Economic Sciences, a MSc in Business Informatics, and a Diploma degree in International Business Administration. In addition, she pursued studies in jazz saxophone. Christine holds several best paper awards and awards for her reviewing activities. Furthermore, she received the Elise Richter grant by the Austrian Science Fund. Before joining Utrecht University, she was a researcher at Johannes Kepler University Linz, WU Wien, and EC3 (Austria), and University of Cologne (Germany). In 2013 and 2015, she was a Visiting Fellow at Carnegie Mellon University (PA, USA). Christine has co-organized the workshop PERSPECTIVES 2021 at RecSys 2021 and IUadaptMe 2019 at UMAP 2019. At UMAP 2021, she gave a tutorial on Multi-Method Evaluation of Adaptive Systems. Furthermore, she was a co-chair for the Doctoral Symposium at RecSys 2021.

Andrés Ferraro (BSc/MSc in Software Engineering) is a Postdoctoral Fellow at McGill University and Mila (Quebec AI Institute), Canada. He completed his PhD at the Department of Information and Communication Technologies and Engineering of the Universitat Pompeu Fabra, Spain. His thesis uncovers multiple dimensions in which music recommender systems affect the artists and proposes alternatives to mitigate such problems. He is currently part of an interdisciplinary project, rethinking music recommender systems by considering new and alternative conceptions from the social sciences and humanities, informed by non-profit systems and critical debates over bias and discrimination. He is co-organizer of LatAm Bish Bash, a series of meetings and networking events that connect engineers, researchers, and students working on music and audio signal processing.

Emilia Gómez (BSc/MSc in Electrical Engineering, PhD in Computer Science) is Principal Investigator on Human and Machine Intelligence (HUMAINT) team at the Joint Research Center (European Commission). She is also a Guest Professor at the Music Technology Group, Universitat Pompeu Fabra, Barcelona. Her research is grounded on the Music

Information Retrieval field, where she has developed data-driven technologies to support music listening experiences. Starting from music, she studies the impact of artificial intelligence (AI) on human decision making, cognitive and socio-emotional development. Her research interests include fairness and transparency in AI, the impact of AI on jobs, and how it affects children development.

Lorenzo Porcaro (MSc Sound and Music Computing and Intelligent Interactive Systems) is a PhD candidate at the Music Technology Group, Universitat Pompeu Fabra (UPF), Spain. His research is at the intersection between Music Information Retrieval and Social Computing, and he is currently working on the assessment of the impact of music recommender systems on cultural diversity. He has collaborated in several initiatives focused on the analysis of ethical dimensions of algorithmic systems (Mechanism Design for Social Good (MD4SG); divinAI project, HUMAINT / UPF). He has also been part of national and international research projects aiming at making music more accessible through the use of technology (Musical AI, TROMPA).

Papers - Session I

INTERPRETING SONG LYRICS WITH AN AUDIO-INFORMED PRE-TRAINED LANGUAGE MODEL

Yixiao Zhang[1] **Junyan Jiang**[2,3] **Gus Xia**[2,3]

ABSTRACT

Lyric interpretations can help people understand songs and their lyrics quickly, and can also make it easier to manage, retrieve and discover songs efficiently from the growing mass of music archives. In this paper we propose BART-fusion, a novel model for generating lyric interpretations from lyrics and music audio that combines a large-scale pre-trained language model with an audio encoder. We employ a cross-modal attention module to incorporate the audio representation into the lyrics representation to help the pre-trained language model understand the song from an audio perspective, while preserving the language model's original generative performance. We also release the Song Interpretation Dataset, a new large-scale dataset for training and evaluating our model. Experimental results show that the additional audio information helps our model to understand words and music better, and to generate precise and fluent interpretations. An additional experiment on cross-modal music retrieval shows that interpretations generated by BART-fusion can also help people retrieve music more accurately than with the original BART. [1]

1. INTRODUCTION

Lyrics play a key role in the understanding and creation of songs, expressing emotions and delivering messages in the form of natural language [1]. Lyrics have both linguistic and musical characteristics: the field of Lyric Information Processing (LIP) can consequently be seen as a bridge between Music Information Retrieval (MIR) and Natural Language Processing (NLP), encompassing a range of new challenges such as lyric structure analysis [2], lyric semantic analysis [3], automatic lyric generation [4], and lyric understanding [5]. In this paper, we focus on the task of multimodal lyric interpretation, which requires the model to understand both the words and music of a song, and to produce a natural, concise and human-like description of its lyrics.

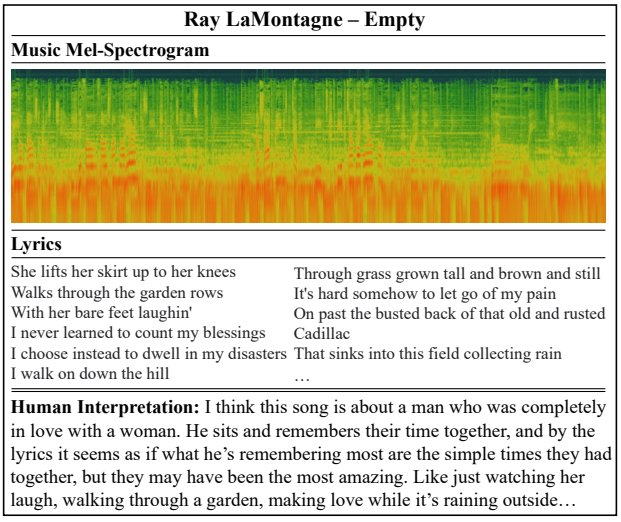

Figure 1. An example of lyrics and their interpretation in real-life, where the interpretation is written by a human. Information from the audio modality includes the representations of instruments, styles, chords, etc., which may help the model to understand the meaning of the lyrics.

In real life, human interpretations of lyrics often contain both a general summary of the lyrical theme and a detailed analysis in relation to specific lines. Figure 1 shows such an example. Considering that the human interpretation of the lyrics contains subjective elements, the lyrics interpretation task is like an extension of the lyrics summarisation task. The task requires the model to be able to (1) select an excerpt from the lyrics, as in extractive text summarisation; (2) generate explanatory text from lyrics, which is similar to abstractive text summarisation. However, previous summarisation methods for general texts [6, 7] are not necessarily applicable in the context of lyrics, because song lyrics often contain rich metaphors, poetic themes, and a high degree of rhythm [2]. Previous studies have attempted to apply extractive summarisation to song lyrics using TextRank algorithms [8] and audio-text alignment algorithms [9]. The drawback of such approaches is that the summary by itself is not enough to explain the lyrics.

Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

To the best of our knowledge, this paper is the first study to use both extractive and abstractive methods to generate lyric interpretations.

Compared to unimodal lyric interpretation models, multimodal models can use information from the music audio domain, such as style, emotion and instrument representations, to reduce the difficulty of understanding lyrics and to improve the quality of the generated text. In recent years, Transformer-based multimodal generative pre-training models have performed well for tasks such as text understanding [10, 11] and text generation [12, 13]. Some related works have attempted to adapt existing pre-trained language models to multimodal tasks [14] or conditional generation tasks [13, 15]. The model we introduce in this paper is inspired by Yu *et al.* [14] and we choose to adapt it from a pre-trained language model (BART) [7]. Our model makes use of two modalities: the text of the song lyrics and the corresponding music audio. We add a convolutional encoder (CNN-SA) [16] to extract a representation of the audio and transfer it to the text domain by computing the similarity between the semantics of the song lyrics and the audio representation through a cross-modal attention mechanism, implemented by a multi-headed attention layer [17]. The transformed music audio representation is then fused into the semantic representation of the lyrics as an additional embedding. We discuss more details of the model in Section 2. To train and evaluate our model, we propose a new dataset, the Song Interpretation Dataset, which contains 27,834 songs with 490,000 corresponding user interpretations. This is the first large-scale open-source dataset for lyric interpretation. We describe the dataset in detail in Section 3.

We evaluate our model against the original BART model (as a baseline) on the Song Interpretation Dataset, as described in Section 4. On the lyric interpretation task, our model outperforms the baseline model according to the standard text summarisation metrics ROUGE, METEOR, and BERT-Score. Ablation experiments show that our dataset filtering techniques also improve model performance. To show the value of our model for other tasks, we also present experimental results demonstrating that it performs better than the baseline on a cross-modal retrieval task.

The main contributions of this work can be summarised as follows:

1. We present BART-fusion, the first multimodal generative model for lyric interpretation. We investigate the integration of audio representations with lyric representations and show that audio representations can improve the performance of lyric interpretation models;
2. We contribute a large-scale multimodal dataset containing paired audio, lyrics, and lyric interpretations that can be used for music understanding tasks such as lyric interpretation.

2. METHOD

In this section, we first revisit the original BART model in Section 2.1. We then discuss the approach to extract musical features from an audio spectrogram in Section 2.2. Finally, we introduce the music-text representation fusion mechanism in Section 2.3. We identify text-domain features with the subscript t and music-domain features with m.

2.1 BART Model for the Generative Task

Transformer-based pre-trained encoder-decoder language models such as BART [7], MASS [18] and T5 [19] generalize BERT [20] (due to the bidirectional encoder) and GPT [21] (with the left-to-right decoder), achieving good results on sequence-to-sequence tasks such as text summarisation and machine translation. Our model takes advantage of the text generation ability of BART, the structure of which is shown on the right side of Figure 2.

The lyric text input is firstly tokenized and embedded. We assume the lyric text sequence has L_t tokens, and the embedding dimension is d_t, resulting in an embedding $X_t \in \mathbb{R}^{L_t \times d_t}$. Following Vaswani *et al.* [22], we add an absolute positional embedding E_{pe} to get the final input features H_t^0:

$$H_t^0 = X_t + E_{\text{pe}}. \tag{1}$$

These input features are then passed to the encoder. The encoder has a stack of six layers, as illustrated in Figure 2, where a single Transformer layer is shown by a yellow box. Each Transformer layer contains a multi-head Self-Attention (SA) module and a Feed-Forward Network (FFN), each followed by a Layer Normalization (LN) module. For the i-th layer, the representation is calculated as:

$$\widetilde{H}_t^i = \text{LN}(\text{SA}(H_t^{i-1}W_Q, H_t^{i-1}W_K, H_t^{i-1}W_V)W_a + H_t^{i-1}) \tag{2}$$

$$H_t^i = \text{LN}(\text{FFN}(\widetilde{H}_t^i) + \widetilde{H}_t^i), \tag{3}$$

where $H_t^i \in \mathbb{R}^{L_t \times d_t}$, and $W_Q \in \mathbb{R}^{d_t \times d_a}$, $W_K \in \mathbb{R}^{d_t \times d_a}$ and $W_V \in \mathbb{R}^{d_t \times d_a}$ denote linear transformation matrices which map the representations to a common space. $W_a \in \mathbb{R}^{d_a \times d_t}$ linearly projects the attention value back to the desired dimensionality.

The decoder also consists of a stack of six Transformer layers, which is similar to the encoder. But the multi-head self-attention module in the decoder is masked to respect causality, and an additional multi-head encoder-decoder attention is introduced to incorporate the encoder representation.

2.2 Audio Encoder

For the multimodal lyric interpretation model, we expect the music audio modality to provide some additional semantic information, such as style, mood, instrumentation, etc., to help the model understand the lyrics better. We

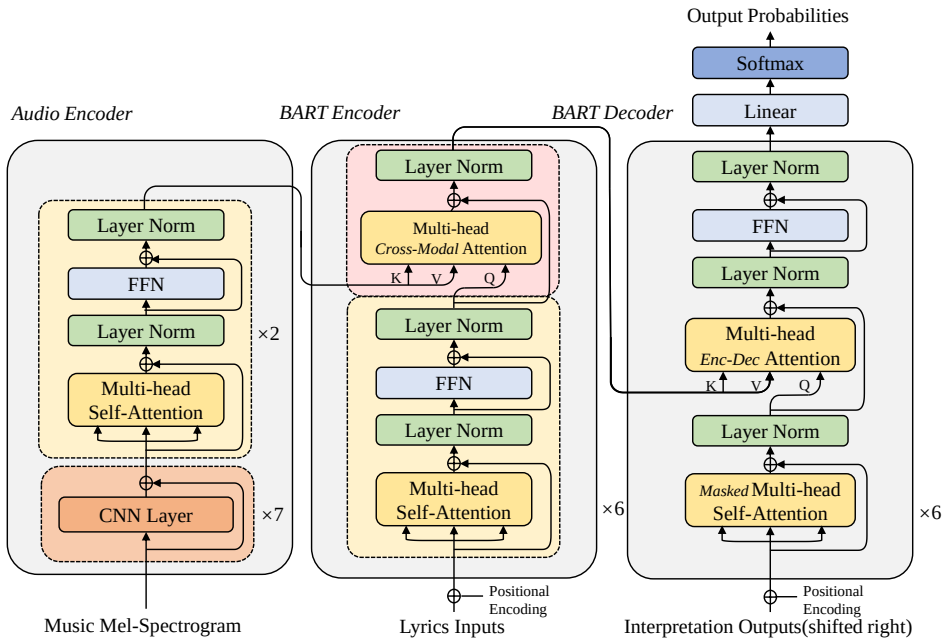

Figure 2. An overview of our proposed model. The model is divided into three parts from left to right: the audio encoder, the BART encoder, and the BART decoder. The fusion of the semantic representation of music audio and lyric text occurs in the upper part of the middle module (pink background). Only at the last two layers of the BART encoder, the music audio representation and the lyric text representation are semantically fused: the music audio representation and the lyric text representation are fed into the cross-modal attention module, and the result is added as an additional embedding to the original lyric text representation. The fused representation is fed into the BART decoder to generate an interpretation.

design an audio encoder to extract a representation following Won *et al.* [16]. The audio encoder uses a stack of CNN layers as a filter to extract local features, followed by a self-attention module to capture the global and temporal features of the audio.

The audio encoder receives an audio clip X_m and transforms it to a mel spectrogram H_m^0 as input. We compute the feature map of the i-th layer of the encoder as follows:

$$\widetilde{H}_m^i = \text{BN}(\text{CNN}_2(\text{ReLU}(\text{CNN}_1(H_m^{i-1})))) \quad (4)$$

$$H_m^i = \widetilde{H}_m^i + \text{BN}(\text{CNN}_3(H_m^{i-1})), \quad (5)$$

where BN is the Batch Normalization operation, and the CNNs are convolutional modules with different parameters. We add a residual connection to each CNN layer.

We then add two Transformer layers, identical to those in the BART encoder, to extract the final representation of music audio. Finally, we get the music audio representation $Z_m \in \mathbb{R}^{L_m \times d_m}$, where L_m and d_m denote the shape of the music audio feature map at the last CNN layer.

2.3 Representation Fusion

As shown in Figure 2, we insert a representation fusion module into the BART encoder to incorporate musical information. Inspired by Tsai *et al.* [17] and Yu *et al.* [14], we apply cross-modal attention to enable the music audio representation to be transferred to the lyric text domain. Jawahar *et al.* [23] have shown that BART encoders tend to extract semantic information in the last few layers, so we only fuse semantic representations at the final two Transformer layers.

For a specific Transformer layer i, we have the lyric text representation $H_t^i \in \mathbb{R}^{L_t \times d_t}$ and the music audio representation $Z_m \in \mathbb{R}^{L_m \times d_m}$, which is the same for each layer. We calculate the domain-adapted music audio representation with a multi-head Cross-Modal Attention (CMA) module:

$$H_{m \to t}^i = \text{CMA}(H_t^i W_Q', Z_m W_K', Z_m W_V') W_a', \quad (6)$$

where $H_{m \to t}^i \in \mathbb{R}^{L_t \times d_t}$ and the symbol $m \to t$ denotes cross-modal attention from music audio to the lyric domain. $d_{a'}$ is the dimensionality of the attention module, and similar to Eq. 3, $W_Q' \in \mathbb{R}^{d_t \times d_{a'}}$, $W_K' \in \mathbb{R}^{d_m \times d_{a'}}$ and $W_V' \in \mathbb{R}^{d_m \times d_{a'}}$ denote linear transformation matrices which map the representations to a common space. $W_a' \in \mathbb{R}^{d_{a'} \times d_t}$ linearly projects the attention value back to the lyric text dimension.

We add the cross-domain representation as an additional embedding [24] to the lyric text representation to get the final representation for the last two layers of the BART encoder:

$$H_{\text{fusion}}^i = H_t^i + H_{m \to t}^i. \quad (7)$$

3. SONG INTERPRETATION DATASET

The lack of suitable datasets has prevented deep learning models from learning to describe songs in natural lan-

guage. Related studies [25, 26] refer to some datasets, but they share two common problems: 1) the amount of data is small and 2) the datasets are not open-sourced. We propose a new dataset, the Song Interpretation Dataset, for the lyric interpretation task. [2]

The Song Interpretation Dataset combines data from two sources: (1) music and metadata from the Music4All Dataset [27], and (2) lyrics and user interpretations from SongMeanings.com [3] . We design a music metadata-based matching algorithm that aligns matching items in the two datasets with each other. In the end, we successfully match 25.47% of the tracks in the Music4All Dataset.

The dataset contains audio excerpts from 27,834 songs (30 seconds each, recorded at 44.1 kHz), the corresponding music metadata, about 490,000 user interpretations of the lyric text, and the number of votes given for each of these user interpretations. The average length of the interpretations is 97 words. Music in the dataset covers various genres, of which the top 5 are: Rock (11,626), Pop (6,071), Metal (2,516), Electronic (2,213) and Folk (1,760).

To the best of our knowledge, this is the first large-scale open-source dataset for lyric interpretation. A comparison with similar datasets is shown in Table 1.

Dataset	Music	Interpretation	Public
Choi *et al.* [25]	800	2000	×
Manco *et al.* [26]	17,354	17,354	×
Ours	**27,384**	**490,000**	✓

Table 1. A comparison of our dataset with previous music description datasets.

We observe three main issues with interpretations written by real users: (1) some interpretations are very short or very long; (2) interpretations can contain content unrelated to the lyrics themselves, and (3) some interpretations are of low quality. We therefore preprocess the dataset using two techniques:

1. We **remove overly short interpretations** with length less than 256 characters to improve data representativeness, since we find that sentences below this length are often meaningless interpretations. For interpretations longer than 2048 characters, we keep only the first 2048 characters, but ensure that the last word is complete.
2. We use a **voting-based filtering mechanism** to improve data quality. Every interpretation on SongMeanings.com has a voting result attached, indicating how much the community approves of it, so an interpretation with a higher vote is more likely to be a high-quality interpretation. We therefore create two subsets, keeping only interpretations with positive votes and interpretations with non-negative votes.

[2] The Song Interpretation Dataset is anonymously open for downloading: `https://doi.org/10.5281/zenodo.7019124`.

[3] `https://songmeanings.com/`

To enable the model to be comparable across datasets, we manually select 800 interpretations and use them as a test dataset after excluding them from the original dataset. We have specifically removed all songs that appeared in the test set from the training set to avoid data leakage issues. After the above preprocessing, the dataset has 3 different subsets with the information shown in Table 2.

Dataset Name	Train	Valid.	Test
Raw dataset	440,000	50,000	800
Dataset Full	279,283	31,032	800
Dataset w/vote ≥ 0	265,360	29,484	800
Dataset w/vote > 0	49,736	5,526	800

Table 2. A comparison of dataset sizes (in number of interpretations) with different filtering methods.

4. EXPERIMENTAL SETTINGS

4.1 Implementation Details

We pre-process the lyric text input data by truncating or padding text to 2048 tokens. All the audio signals are downsampled to 16,000 Hz sample rate and converted to short-time Fourier transform representations with a 512-point FFT and 50%-overlapping Hann window. Finally, we convert these to log mel spectrograms with 128 bins.

We use `BART-base` [7] as the pre-trained language model to construct BART-fusion, which has a 6-layer encoder and decoder. For the audio encoder (CNNSA), we use 3×3 kernels for all layers with [128, 128, 256, 256, 256, 256, 256] channels and [(2, 2), (2, 2), (2, 2), (2, 1), (2, 1), (2, 1), (2, 1)] strides. The cross-modal attention module has 1 head and 1 layer, with $d_a = 768$.

We use AdaFactor [28] as the optimizer. We set the learning rate to 6×10^{-4} and reduce it to 6×10^{-5} from the 11th epoch. For all experiments, we use a batch size of 8. We train all models for 20 epochs with early stopping of 3 epochs using the ROUGE-1 score on the validation set.

4.2 Evaluation Metrics

Since there are no existing metrics for the lyric interpretation task, we borrow several complementary metrics from similar tasks to evaluate the performance level of the model in a comprehensive manner. We use ROUGE, METEOR and BERT-Score to evaluate the generated interpretations. ROUGE is considered as the main metric for evaluation, because our task is closest to the text summarisation task.

4.2.1 ROUGE-{1, 2, L}

ROUGE [29] is a common metric for evaluating abstractive text summaries. It calculates the overlap of 1-gram phrases (R-1), 2-gram phrases (R-2) and their weighted results (R-L). In the context of lyrics, a higher ROUGE score indicates that the generated explanatory text leaves out less necessary information, which is better.

Training dataset	Method	Data size	R-1	R-2	R-L	METEOR	BERT-Score
Dataset w/random	BART	56,470	40.0	12.5	21.7	21.1	**83.7**
Dataset w/random	BART-fusion	56,470	**42.1***	**13.6***	**23.4***	**22.0***	83.3
Dataset w/voting > 0	BART	56,470	41.2$_{+}$	13.0$_{+}$	22.8$_{+}$	22.0$_{+}$	**83.6**
Dataset w/voting > 0	BART-fusion	56,470	**44.3**$^{*}_{+}$	**14.6**$^{*}_{+}$	**24.7**$^{*}_{+}$	**22.6**$^{*}_{+}$	83.3
Dataset Full	BART	316,478	44.1	14.0	24.5	22.5$_{+}$	**83.5**
Dataset Full	BART-fusion	316,478	**46.1***	**15.0***	**25.1***	**23.0***	**83.5**

Table 3. Evaluation results of BART-fusion and BART (baseline) on the Song Interpretation Dataset with different settings. $*$: BART-fusion outperforms BART with $p < 0.05$; $+$: the filtered dataset outperforms the unfiltered dataset with $p < 0.05$.

4.2.2 METEOR

METEOR [30] takes into account similar semantic information such as synonyms through WordNet and calculates the similarity score based on F-measure. It complements ROUGE by jointly measuring how semantically similar the model-generated lyric interpretation is to the reference text.

4.2.3 BERT-Score

BERT-Score [31] is mainly used to evaluate the naturalness and fluency of the generated text. We expect that incorporating the audio modality should not sacrifice the generative performance of the language model.

We use `rouge` [4], `nltk` [5] and `bert-score` [6] respectively to compute these metrics.

5. RESULTS AND ANALYSIS

5.1 Main Results

We train BART-fusion and the corresponding original BART on several different dataset settings. Results are shown in Table 3, where all values are the means of multiple independent repeated experiments. We perform a *paired Student's t-test* on the results of BART-fusion and BART, and the results on the filtered datasets and unfiltered datasets respectively, where p-value is 0.05.

Our first finding is that applying a voting-based filtering mechanism to the dataset significantly improves the performance of the models (both BART-fusion and baseline) on this task. For fairness, we take a random subset of *Dataset Full*, which we call *Dataset w/random*, to match the size of *Dataset w/voting* > 0. (We still use *Dataset Full* to compare *Dataset w/voting* ≥ 0.) The experimental results show that the performances of both BART-fusion and the baseline are significantly improved on the filtered datasets.

The experimental results also show that BART-fusion significantly outperforms the baseline, and generates more precise interpretion text for lyrics. For all dataset settings, our BART-fusion models show better performance on the ROUGE and METEOR scores.

Finally, we find that BART-fusion preserves the generative performance of the pre-trained language model while improving the generation accuracy. The performance of BART-fusion is essentially equal to that of baseline on the BERT-Score metric, which is the metric of text quality. It means that the introduction of audio modal information affects the model mainly semantically and does not affect the naturalness or fluency.

5.2 Case Study and Error Analysis

We observe that adding music modality information usually brings the benefits of accurate understanding of the theme, selecting highlighted lyric lines, and emotive sentences from the generated samples. In the case study, we select a representative example showing the generation results from different models with the same lyric input, as shown in Table 4. In the first lines, BART-fusion explains the theme of the lyrics more accurately than BART. Then, BART-fusion selects the highlighted lyric lines and gives further detailed interpretation, while the text generated by BART lacks a clear explanation of them. We find that BART-fusion talks about the mood of the song at the end, which is not present in the original BART example. [7]

We have noticed that when the lyrics are about complex topics, such as religious and philosophical topics, BART-fusion and BART sometimes fail to understand the meaning correctly and generate text that is only superficially correct, which we interpret as a lack of common sense often observed in this class of deep learning models.

5.3 Cross-Modal Retrieval Analysis

In addition, we design a cross-modal retrieval experiment to test the retrieval capability of our models. We randomly extract a sentence from the real interpretation in the test set as a query string, use this to search over a database of lyric text and musical audio on a semantic level, and return a ranked list of all possible results. We expect the correct result corresponding to the query to be as close to the top of this ranking as possible.

To accomplish this task, the model generates interpretations for all song lyrics in the database, calculates their semantic features using Sentence-BERT [32], and stores

Lyrics: I cannot find a way to describe it / It's there inside, all I do is hide / I wish that it would just go away / What would you do, you do, if you knew? / What would you do? / / All the pain I thought I knew / All the thoughts lead back to you / Back to what was never said / Back and forth inside my head / I can't handle this confusion / I'm unable, come and take me away / / I feel like I am all alone / All by myself, I need to get around this / My words are cold, I don't want them to hurt you / If I show you, I don't think you'd understand / 'Cause no one understands / / All the pain I thought I knew / All the thoughts lead back to you / Back to what was never said / Back and forth inside my head / I can't handle this confusion / I'm unable, come and take me away / ...
Reference: I think this song is about a crush that the singer is afraid to tell the person they are in love with. She wonder if maybe the other person feels the same, but is also too afriad to tell her. Thinking "what if". Since, she won't admit it she'll never know and this not knowing ends up eating her up inside. Each day she wonders if she could be with this person who she really loves, but she just gets frustrated and eventually wishes that she never even fell in love with the person since it would make her life so much easier. It builds up so much that she just wishes someone would "come and take me away". That could mean two things. It could be death/suicide because she decides it's not worth it or she could just wish for someone else to date so she can just say she's taken and not have to worry about this crush.
BART: I think this song is about a girl who is in love with a guy, but she doesn't know how to tell him because she's afraid he'll hurt her. She's trying to convince herself that he loves her, but he doesn't understand how she feels about him. She wants him to come and take her away from all the pain she's caused and make her feel better about herself. This is what I think of when I listen to this song. I think it's about someone who is trying to tell someone they love them, but they don't want to tell them because they're afraid that they'll hurt them. I love this song, it's one of my favorites on the album.
BART-fusion: I think this song is about a girl who is in love with a guy but she is afraid to tell him because she doesn't want to ruin the friendship. In the first verse she is talking about how she can 't find a way to describe how she feels and how she wishes it would just go away. The second verse is about how the guy is telling her how he feels but she isn't sure if he really feels the same way. The chorus is her saying how she is confused about what to say and how to tell the guy. "I'm unable, come and take me away" means that she is unable to tell her feelings and she is trying to get the guy out of her head. The last verse is her telling the guy that she feels like she is going nowhere in her life, and she just wants him to take her away from all of this. That's just my take on it. I can totally relate to this song. It's a very powerful song.

Table 4. A generation example for Avril Lavigne - *Take Me Away*.

features in advance. At query time, we also use Sentence-BERT to compute the semantic feature for the query string. We return the song whose feature is most similar to the query feature by computing the cosine similarities between the query feature and features in the database.

We use Mean Reciprocal Rank (MRR) [33], a common metric for information retrieval tasks, to measure the performance of the models on this task. Formally, for a set of query strings $Q = \{q_1, q_2, ..., q_m\}$ and the corresponding database $S = \{s_1, s_2, ..., s_n\}$, the model outputs a list of songs sorted by probability for the i-th query, where the correct song is ranked k_i-th, and the model is scored as:

$$\text{score}_i = \frac{1}{k_i}, \text{where } k_i \leq n. \tag{8}$$

The final MRR is calculated by averaging the scores:

$$\text{MRR} = \frac{1}{m}\sum_{i=1}^{m}\text{score}_i = \frac{1}{m}\sum_{i=1}^{m}\frac{1}{k_i}. \tag{9}$$

From Table 5, we find that BART-fusion outperforms the original BART on all 4 dataset settings, i.e., the interpretations generated by BART-fusion can help users find music more accurately. If we return a random ranking result, the MRR value is about 0.9%, which is much lower than the model performance.

Dataset	Method	MRR (%)
Dataset w/random	BART	25.3
Dataset w/random	BART-fusion	**27.5***
Dataset w/voting > 0	BART	26.1_+
Dataset w/voting > 0	BART-fusion	$\mathbf{28.2}^*_+$
Dataset Full	BART	26.2
Dataset Full	BART-fusion	**30.5***
Dataset w/voting ≥ 0	BART	26.4
Dataset w/voting ≥ 0	BART-fusion	$\mathbf{32.5}^*_+$

Table 5. Evaluation results for the music retrieval task. $*$: BART-fusion outperforms BART with $p < 0.05$; $+$: the filtered dataset outperforms the unfiltered dataset with $p < 0.05$.

6. CONCLUSION AND FUTURE WORK

In this paper, we have proposed a novel model to generate interpretations from song lyrics and musical audio. Our modelis based on a pre-trained language model and generates better lyric interpretations by fusing text and music semantic representations. We also have proposed a new dataset and explored the process of dataset creation, and have investigated how different treatments of the dataset can affect the performance of the model. We have designed an additional experiment that shows that our model outperforms BART on cross-modal music retrieval tasks. Our work has a range of potential applications, such as helping people better understand English lyrics (especially for non-native English speakers) and natural language based music discovery.

The current model still has shortcomings, such as difficulty in understanding complex topics and lack of general common sense. In future work, we will try to improve the model by adding metadata and knowledge base inputs. We also plan to extend the model to describe the musical content of a song in natural language. In addition, large-scale language models may be biased, reinforce stereotypes and introduce harms, which deserves our attention in the future.

7. ACKNOWLEDGEMENT

We want to thank Mark Levy for his great contribution to this work. We also thank Yin-Jyun Luo and Liming Kuang for their enthusiastic help during the writing process of the paper. TOWARD POSTPROCESSING-FREE NEURAL NETWORKS FOR JOINT BEAT AND DOWNBEAT ESTIMATION

Tsung-Ping Chen **Li Su**
Institute of Information Science, Academia Sinica, Taiwan
{tearfulcanon, lisu}@iis.sinica.edu.tw

ABSTRACT

Recent deep learning-based models for estimating beats and downbeats are mainly composed of three successive stages—feature extraction, sequence modeling, and post processing. While such a framework is prevalent in the scenario of sequence labeling tasks and yields promising results in beat and downbeat estimations, it also indicates a shortage of the employed neural networks, given that the post-processing usually provides a notable performance gain over the previous stage. Moreover, the assumption often made for the post-processing is not suitable for many musical pieces. In this work, we attempt to improve the performance of joint beat and downbeat estimation without incorporating the post-processing stage. By inspecting a state-of-the-art approach, we propose reformulations regarding the network architecture and the loss function. We evaluate our model on various music data and show that the proposed methods are capable of improving the baseline approach without the aid of a post-processing stage.

1. INTRODUCTION

Beat and downbeat trackings have been of long-standing interests in the communities of signal processing and music information retrieval (MIR) [1–5]. The two tasks inherently possess the class imbalance issue [6], i.e., the highly imbalanced numbers of beat (downbeat) and non-beat (non-downbeat) frames in music data, and hence remain challenging in many cases even nowadays. To tackle the beat and downbeat tracking problems, early signal processing approaches have developed a three-stage framework which consists of *feature extraction*, *sequence modeling*, and *post-processing* [7–9]. Over the past few years, great progresses on the two tasks have been made through the combination of the three-stage pipeline and deep learning models such as recurrent neural networks (RNNs) [10–12], convolutional-recurrent neural networks (CRNNs) [13], and Transformer-based networks [14]. Among the thriving research, a convolutional approach achieves the state-of-the-art performance on joint estimation of tempo, beat, and downbeat [15], in which convolutional neural networks (CNNs) and temporal convolutional networks (TCNs) [16] are placed in charge of the feature extraction and of the sequence modeling, respectively, while dynamic Bayesian networks (DBNs) [17] are used for the post-processing.

In spite of the promising results obtained by this approach, the employed networks raise three concerns. First, the CNNs for feature extraction convolve an input spectrogram with small kernels at the very beginning, and a max-pooling layer is followed immediately. Therefore, the spectro-temporal patterns might not be well-captured [18]. Second, the dilated convolutions [19] of the TCNs involve a small kernel size and an exponentially increasing dilation rate. Despite the large receptive fields obtained at higher layers, this design leads to extremely sparse samplings which join distantly-separated frames, and consequently the contextual information could be irrelevant [20]. Lastly, the assumptions made for the DBNs that the meter is unchanged or the rhythmic patterns are known [11, 21] are not always applicable to various music genres, even to popular music. For example, the Hainsworth dataset [22], which is often employed for evaluation, includes several clips of pop or rock songs with changing meter. Moreover, the DBNs involve intricate design and assumptions for representing the state and the transition throughout a piece of music, and hence introduce non-trivial works in addition to the training of the preceding neural networks.

In this paper, we cope with the joint beat and downbeat estimation task by addressing the aforementioned issues. To get rid of the post-processing DBNs while maintaining the performance, we consider to improve the network architecture and the loss function. Precisely, we propose to use scaled depthwise separable convolutions [23–25] to aggregate rich contextual information at multiple time scales. To address the class imbalance issue, the focal loss [26] and the Dice loss [27] are employed in place of the commonly used cross entropy loss. Besides, we make our model aware of the periodic structure of beat or downbeat sequences by including a label embedding network [28] during training. We evaluate the proposed architecture on various music data, including both audio and MIDI files, and demonstrate a state-of-the-art performance on the Ballroom dataset. The main contribution of this work is that we thoroughly address the architectural issues for beat and downbeat estimations. Most of the problems are shared by sequence models in general, and therefore the proposed methods could be applied to many other MIR-related tasks.

2. OVERVIEW OF THE STATE-OF-THE-ART

The model of [15] without the DBNs is taken as our baseline upon which we build our new model to address the architectural issues mentioned beforehand. In the following, we briefly introduce the baseline model using the three-stage framework, and present the new model thereafter. We skip the post-processing stage for we aim to expel the DBNs from the system in this work. An overview of the baseline model is illustrated at the top of Figure 1.

2.1 Feature extraction

Given an audio signal represented as a log-magnitude spectrogram of size $T \times J$, where T denotes the number of time steps and J the number of frequency bins, the CNNs of the baseline model extract high-level features using three groups of 2-D convolution and max-pooling layers. The three convolutional layers (with a kernel size of 3×3, 1×12, and 3×3, respectively) [1] capture harmonic content at different frequency scales, while the max-pooling operations (with a kernel size of 1×3) reduce the frequency dimension in three steps. In other words, the CNNs gradually transcribe the harmonic information into high-level features, and output a sequence of size $T \times D$ with D indicating the dimension of high-level features.

2.2 Sequence modeling

The high-level feature sequence from the previous stage is then passed to the TCNs for learning temporal structure. As depicted at the top of Figure 1, each TCN layer performs two 1-D dilated convolutions in parallel with a kernel of size 5 and an exponentially increasing dilation rate 2^l (resp. 2^{l+1}), where l is the layer number. The outputs of the two dilated convolutions are concatenated and reprojected to keep the feature dimensionality constant. As a result, the TCNs efficiently enlarge the receptive field within a few layers with the amount of learnable parameters increasing linearly to the number of layers. Given that the TCNs has 11 layers, the two convolutions at the last layer will expand the kernels across over 4000 (resp. 8000) time frames with each element of the two kernels being spaced 1024 (resp. 2048) frames apart. Therefore, the temporal context modelled by the TCN is more than 80 seconds (assume a frame rate of 100 fps). Afterwards, the output of the TCNs is processed by the DBNs to obtain a sequence of beat or downbeat estimates.

2.3 Potential issues

In the community of computer vision, it has been shown that stacking small convolutional kernels followed by pooling layers is effectual for extracting high-level features of an image [29–31]. Such a architecture is often adopted by audio-based, or more specifically spectrogram-based research [32–34]. Considering the nature of images, it is reasonable to aggregate information hierarchically from spatial associations. However, it is questionable that a spectrogram could be well-represented with the same architecture. The characteristic spectral information of a musical piece does not necessarily reside in the adjacent frequency bins within a small kernel. Moreover, it is also suspicious that the *compressed* frequency dimension after pooling operations is as meaningful as a downsampled image.

On the other hand, it has been observed that dilated convolutions result in the so-called *gridding artifacts* [35, 36], due to that adjacent elements in the output are calculated from completely different sets of elements in the input. Additionally, small convolutional kernels with high dilation rates relate input elements which are highly sparsely distributed and hence might lack of correlations. In the scenario of beat or downbeat estimation, stacked 1-D dilated convolutions could be preferable for they are able to encode periodic structure of the beat (downbeat) through equidistant elements of dilated kernels. However, it is not guaranteed that an inquired musical piece has a steady tempo as well as a constant rhythm. Hence, a network equipped with dilated convolutions for modeling temporal information may have limitations on expressive music.

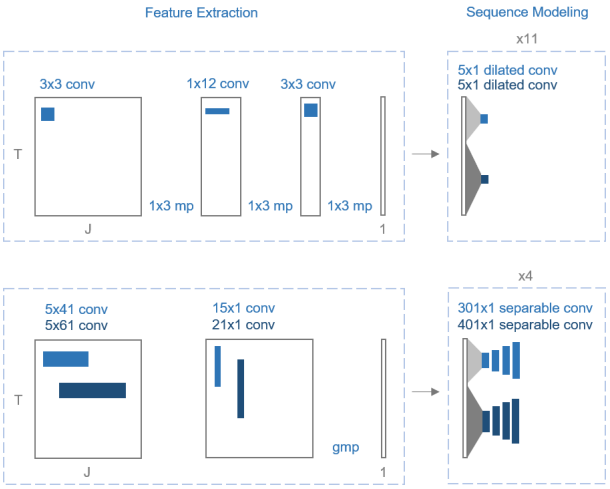

Figure 1: Architecture reformulation with respect to convolution (conv) and max pooling (mp) layers . Top: model of [15] without DBNs. Bottom: proposed architecture. The feature dimension is not shown in the figure.

3. APPROACH

3.1 Task formulation

We treat the joint beat and downbeat estimation task as a sequence labeling problem [37, 38]. Given an input spectrogram $\mathbf{X} \in \mathbb{R}^{T \times J}$, the task involves the assignment of a categorical label $\in \{\texttt{downbeat}, \texttt{xbeat}, \texttt{neither}\}$ [2] to each time step $t \in \mathrm{T}$. We employ a model architecture which mainly consists of a feature extraction network (f_{ex}), a sequence modeling network (f_{seq}), and an estima-

[1] A kernel size $M \times N$ specifies a convolution window across M time frames and N frequency bins.

[2] The label `xbeat` refers to a beat which is not a downbeat.

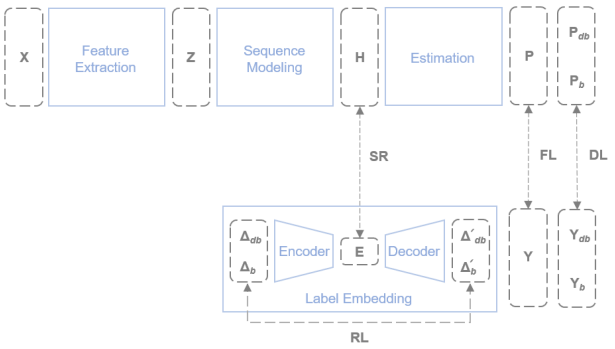

Figure 2: Proposed architecture. Dashed borders indicate data sequences, and solid ones denote neural networks. The losses includes focal loss (FL), Dice loss (DL), reconstruction loss (RL), and structural regularization (SR).

tion network (f_{est}) for the task:

$$\begin{aligned} \mathbf{P} &= f_{est}(\mathbf{H}), \\ \mathbf{H} &= f_{seq}(\mathbf{Z}), \\ \mathbf{Z} &= f_{ex}(\mathbf{X}), \end{aligned} \tag{1}$$

where $\mathbf{Z}$, $\mathbf{H} \in \mathbb{R}^{T \times D}$ are higher-level feature sequences, and $\mathbf{P} \in \mathbb{R}^{T \times 3}$ is a sequence of model estimates indicating the probabilities of the three categorical labels across all time steps. The overall model architecture is schematically shown in Figure 2.

3.2 Reformulation of feature extraction

We propose to use kernels of larger sizes for the 2-D convolution layers and remove the intermediate pooling layers in f_{ex}. As shown at the bottom of Figure 1, the feature extraction network consist of two layers, denoted as $f_{ex}^{(1)}$ and $f_{ex}^{(2)}$. The first layer captures harmonic information distributed across the frequency bins of an input spectrogram, while the second layer aggregates the harmonic information along the temporal dimension. Within each layer l, we employ two parallel convolutions with kernel sizes of $w_{ex,1}^{(l)}$ and $w_{ex,2}^{(l)}$. For these convolution operations, we keep the frequency dimension of the input spectrogram uncompressed, and thus the output shape will be $T \times J \times D$. Finally, we employ a global max pooling layer (GMP) [39] to reduce the frequency dimension (J) of the output, yielding the feature sequence $\mathbf{Z} \in \mathbb{R}^{T \times D}$. Let $f_c(\cdot, d, w)$ denote a standard convolution parameterized by the number of filters d and the kernel size w. The feature extraction network can be formulated as follows:

$$\begin{aligned} \mathbf{Z} = f_{ex}(\mathbf{X}) &= \underset{j \in J}{\mathrm{GMP}}(f_{ex}^{(2)}(f_{ex}^{(1)}(\mathbf{X}))), \\ f_{ex}^{(l)}(\cdot) &= [f_c(\cdot, D, w_{ex,1}^{(l)}), f_c(\cdot, D, w_{ex,2}^{(l)})]\mathbf{W}_{ex}^{(l)}, \end{aligned} \tag{2}$$

where $\mathbf{W}_{ex}^{(l)} \in \mathbb{R}^{2D \times D}$ is a learnable parameter matrix at the l-th layer, and $[\cdot, \cdot]$ indicates a concatenation operation.

3.3 Reformulation of sequence modeling

To maintain a large receptive field while get rid of the sparse sampling issue introduced by dilated convolutions, we use depthwise separable convolutions [23] (hereafter separable convolutions) instead. Separable convolution, denoted as $f_{sc}(\cdot, d, w)$, factorizes a standard convolution into a depthwise convolution and a pointwise convolution. This factorization allows a network to expand the receptive field using a large kernel size without drastically increasing the number of parameters. Similarly to the TCNs, we use two separable convolutions with kernel sizes of $w_{seq,1}$ and $w_{seq,2}$, as shown in Figure 1. Each sequence modeling layer, denoted as $f_{seq}(\cdot)$, is thus formulated as below:

$$f_{seq}(\cdot) = f_{sc}(\cdot, D, w_{seq,1}) + f_{sc}(\cdot, D, w_{seq,2}). \tag{3}$$

Considering that rhythmic patterns are tempo-dependent, that is, the inter-beat or the inter-downbeat interval will vary according to the current tempo, it is crucial for a network to learn tempo-invariant, or *scale-invariant* patterns [40]. To achieve scale invariance, we simply introduce a set of dilation rates, or *scale factors* $\mathbf{s} = \{r_s\}_{s=1}^{S}$ to each separable convolution. The *scaled* separable convolution, accordingly, will operate S times on the same input with the kernel being expanded by the given set of dilation rates:

$$\underset{\mathbf{s}}{f_{sc}}(\cdot, d, w) = (f_{sc}(\cdot, d, w, r_1), \ldots, f_{sc}(\cdot, d, w, r_S)), \tag{4}$$

where $(\cdot, \ldots, \cdot)$ denotes a stacking operation. Therefore, the scaled separable convolution is capable of capturing rhythmic patterns at different tempi simultaneously. Note that the dilation employed here differs from that of the original TCNs in two aspects. First, we employ the dilation for modeling tempo variance rather than for expanding the receptive field. Second, the parameters of a scaled separable convolution are shared among the S operations.

By introducing the scale factors, we add a new dimension to the output of the scaled separable convolution, whose shape thus becomes $T \times D \times S$. We summarize the scale information by applying a gating mechanism, termed *scale summarization* (SS), which is similar to the *Squeeze-and-Excitation* operation of the SENet [41]. Let $\mathbf{U} \in \mathbb{R}^{T \times D \times S}$ denote the output of a scaled separable convolution. We use global average pooling (GAP) along both the time and the feature dimensions to calculate scalewise statistics $\mathbf{z} \in \mathbb{R}^{S}$. Subsequently, a gating function $\mathbf{g} \in \mathbb{R}^{S}$ is generated by using a projection layer with learnable parameters $\mathbf{W} \in \mathbb{R}^{S \times S}$ and a softmax activation. Lastly, we apply the gate function to $\mathbf{U}$ for obtaining the summarized output $\mathbf{U}' \in \mathbb{R}^{T \times D}$:

$$\begin{aligned} \mathbf{U}' = \mathrm{SS}(\mathbf{U}) &= \sum_{s=1}^{S} \mathbf{U}\mathbf{g}, \\ \mathbf{g} = \underset{s \in S}{\mathrm{softmax}}(\mathbf{W}\mathbf{z}), \quad \mathbf{z} &= \underset{t \in T, d \in D}{\mathrm{GAP}}(\mathbf{U}). \end{aligned} \tag{5}$$

In conclusion, the L-layer sequence modeling network can be formally expressed as follows:

$$\begin{aligned} \mathbf{H}^{(l)} &= f_{seq}^{(l)}(\mathbf{H}^{(l-1)}), \\ f_{seq}^{(l)}(\cdot) &= \mathrm{SS}(\underset{\mathbf{s}}{f_{sc}}(\cdot, D, w_{seq,1}) + \underset{\mathbf{s}}{f_{sc}}(\cdot, D, w_{seq,2})), \end{aligned} \tag{6}$$

with boundaries $\mathbf{H}^{(0)} = \mathbf{Z}$ and $\mathbf{H}^{(L)} = \mathbf{H}$.

3.4 Estimation

We employ a convolutional layer with a kernel size of w_{est} followed by a softmax activation function to estimate the probabilities of being `downbeat` (db), `xbeat` (xb), and `neither` (n) at each time step:

$$\begin{aligned}[\mathbf{P}_{db}, \mathbf{P}_{xb}, \mathbf{P}_{n}] = \mathbf{P} &= f_{est}(\mathbf{H}) \\ &= \underset{d}{\text{softmax}}(f_c(\mathbf{H}, d=3, w_{est})),\end{aligned} \tag{7}$$

where $\mathbf{P}_{db}, \mathbf{P}_{xb}, \mathbf{P}_{n} \in \mathbb{R}^T$ indicate the estimated probabilities of the three categorical labels across T time steps. During inference, we generate a downbeat sequence ($\mathbf{I}_{db}$) and a beat sequence ($\mathbf{I}_b$) from $\mathbf{P}_{db}$ and $\mathbf{P}_{xb}$ by finding the local maximums (LM):

$$\begin{aligned}\mathbf{I}_{db} &= \text{LM}(\mathbf{P}_{db}), \\ \mathbf{I}_b &= \text{LM}(\mathbf{P}_b) = \text{LM}(\mathbf{P}_{db} + \mathbf{P}_{xb}).\end{aligned} \tag{8}$$

3.5 Loss function

Cross entropy is often used as the loss function in the beat and the downbeat estimation tasks. Since the cross entropy loss treats all samples equally, the network optimization will be dominated by vast amount of easy samples, i.e., time frames not belonging to the beat and the downbeat. Similar cases can be found in computer vision-related tasks such as object detection, where exists an extreme foreground-background disproportion. The focal loss (FL) [26] is therefore proposed to weigh more on hard or easily mis-classified samples by introducing a modulating term to the cross entropy loss:

$$\text{FL} = -\frac{1}{N}\sum_{i=1}^{N} m_i \times y_i \times \log(p_i), \tag{9}$$

where p_i is the estimated probability of sample i being classified as the ground truth y_i, and $m_i = (1-p_i)^{\gamma_i}$ is the modulating term with γ_i being a controllable factor. It is noteworthy that the FL, as same as the cross entropy, is calculated on individual samples and hence unable to reflect spatial or temporal relations between samples. On the other hand, the Dice loss (DL) [27], which has been applied to semantic segmentation of images, measures the overlap between the estimations of N samples and the ground truths, and thus can delineate the regions of interest, e.g., beat positions in a given musical sequence:

$$\text{DL} = 1 - \frac{2\sum_{i=1}^{N} p_i \times y_i}{\sum_{i=1}^{N} p_i^2 + \sum_{i=1}^{N} y_i^2}. \tag{10}$$

We propose to use a hybrid of the FL and the DL in place of the cross entropy loss, for they address the class imbalance issue from two complementary aspects: the FL accentuates *individual* hard samples whereas the DL underlines *collective* similarity of the minority samples. In practice, we compute the FL on $\mathbf{P}$ while the DL on both $\mathbf{P}_{db}$ and $\mathbf{P}_b$. By combining the two losses, we urge our network to focus on the minority classes, i.e., beats and downbeats, both at the frame level and at the sequence level.

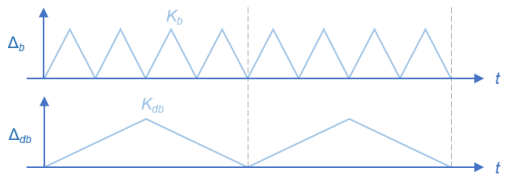

Figure 3: Representations of beat (top) and downbeat (bottom) for label embedding (assume a meter of `4/4`). The horizontal axes are the time dimensions while the vertical axes indicate the phase classes. K_b and K_{db} are the numbers of classes for beat and downbeat, respectively.

3.6 Label embedding

Another concern in regard to the loss function is that the periodic structure of a beat or downbeat sequence is not considered. A recent work deals with the periodicity by estimating beat *phase* instead of beat presence at each frame [42]. Accordingly, the beat estimation task is reformulated as a sequence labeling problem in which the beat phase is represented as a discrete sawtooth wave with period equal to the interbeat interval. This reformulation, however, enlarges the estimation space as the beat phase is categorized into K classes with K being the phase resolution.

Alternatively, we leverage the label embedding approach [28] for learning the periodic structure. As illustrated in Figure 3, a sequence of ground-truth annotations is represented as a discrete triangular wave $\mathbf{\Delta}_{\{db,b\}} \in \mathbb{R}^{T \times K_{\{db,b\}}}$ whose troughs locate at the beat or downbeat frames. We then employ a vanilla autoencoder to encode the represented annotations in an unsupervised manner. The encoder (f_{enc}) and the decoder (f_{dec}) used are both a simple 1-D convolution layer with a kernel size of w_e, i.e., $f_{enc}(\cdot) = f_{dec}(\cdot) = f_c(\cdot, D, w_e)$. The label embedding network is formulated as follows:

$$\begin{aligned}[\mathbf{V}'_{db}, \mathbf{V}'_{b}] &= f_{dec}(\mathbf{E}), \\ \mathbf{E} &= f_{enc}([\mathbf{V}_{db}, \mathbf{V}_{b}]), \\ \mathbf{V}_{db} &= \mathbf{\Delta}_{db}\mathbf{W}_{db}, \mathbf{V}_{b} = \mathbf{\Delta}_{b}\mathbf{W}_{b},\end{aligned} \tag{11}$$

where $\mathbf{W}_{\{db,b\}} \in \mathbb{R}^{K_{\{db,b\}} \times D}$ are learnable phase embedding matrices, $\mathbf{V}_{\{db,b\}} \in \mathbb{R}^{T \times D}$ are sequences of embeddings, $\mathbf{E} \in \mathbb{R}^{T \times D}$ is a sequence of joint embeddings, and $\mathbf{V}'_{\{db,b\}} \in \mathbb{R}^{T \times D}$ are the reconstructions of $\mathbf{V}_{\{db,b\}}$. We compute the reconstruction loss (RL) as follows:

$$\begin{aligned}\text{RL} &= \text{FL}(\mathbf{\Delta}_{db}, \mathbf{\Delta}'_{db}) + \text{FL}(\mathbf{\Delta}_{b}, \mathbf{\Delta}'_{b}), \\ \mathbf{\Delta}'_{db} &= \underset{k \in K}{\text{softmax}}(\mathbf{V}'_{db}\mathbf{W}_{db}^{\top}), \\ \mathbf{\Delta}'_{b} &= \underset{k \in K}{\text{softmax}}(\mathbf{V}'_{b}\mathbf{W}_{b}^{\top}).\end{aligned} \tag{12}$$

As illustrated in Figure 2, the joint embedding $\mathbf{E}$ is taken as a structural regularization (SR) of $\mathbf{H}$ (the output of the sequence modeling network) by minimizing the mean squared error (MSE):

$$\text{SR} = \text{MSE}(\mathbf{E}, \mathbf{H}). \tag{13}$$

Hence, the total loss $\mathscr{L} = \text{FL} + \text{DL} + \text{RL} + \text{SR}$. We train the whole networks in an end-to-end fashion. As the

contextual information of the annotations is encoded in $\mathbf{E}$, adding this *topology-aware* regularization term (SR) to the loss computation enables the network to explicitly learn the structural characteristics [43]. The source code of the proposed model is available online. [3]

4. EVALUATION

4.1 Data preparation

Four datasets are employed in the evaluation, including the Ballroom [44], the Hainsworth [22], the GTZAN [45], and the ASAP [46]. Each audio file (with a sampling rate of 44,100 Hz) in the datasets is transformed into a log-magnitude spectrogram with a total of 81 frequency bins from 30 Hz to 17,000 Hz, by using the Python package *librosa* [47]. Specifically, the short-time Fourier transform (STFT) with a window size of 92.9 ms (4,096 samples) and a hop size of 23.2 ms (1,024 samples) is applied, and the output spectrogram is mapped onto the Mel scale. The per-bin first-order difference is calculated for each spectrogram as an additional feature (only the positive differences are retained) [16]. In consequence, each audio file is represented as $\mathbf{X} \in \mathbb{R}^{T\times 81\times 2}$ with T being the time steps of the corresponding spectrogram. Besides, the MIDI data of the ASAP are also used for evaluation. Following [48], we represent each MIDI file by four features: the *pitch profile* $\in \mathbb{R}^{T\times 88}$ (i.e., pianoroll), the *onset profile* $\in \mathbb{R}^{T\times 88}$, the *spectral flux* $\in \mathbb{R}^{T}$, and the *inter-onset interval* $\in \mathbb{R}^{T}$. We modify our feature extraction network accordingly for the MIDI representation, and keep the other parts of the architecture unchanged. Specifically, the pitch profile and the onset profile are concatenated together and fed into the feature extraction network. The output of the feature extraction network is then concatenated with the other two features and taken as the input of the succeeding layer.

On the other hand, the beat and downbeat annotations are represented as binary sequences, $\mathbf{Y}_b, \mathbf{Y}_{db} \in \{0,1\}^T$, where a time step $t \in T$ has a value of 1 if it belongs to the beat or the downbeat, and 0 otherwise. To treat joint beat and downbeat estimation as a sequence labeling problem, we further generate $\mathbf{Y} \in \{0,1\}^{T\times 3}$ based on $\mathbf{Y}_{db}$ and $\mathbf{Y}_b$, which is a sequence of one-hot vectors indicating the categorical label of each time step. The $\mathbf{Y}$ is used to compute the FL (with $\mathbf{P}$) while the $\mathbf{Y}_b$ and the $\mathbf{Y}_{db}$ are for the DL (with $\mathbf{P}_b$ and $\mathbf{P}_{db}$, respectively), as depicted in Figure 2.

4.2 Experiment

We evaluate the proposed architecture on the four datasets and report the beat and the downbeat estimation performances using the standard F1 measure with a tolerance window of ±70 ms. The hyperparameters of the architecture are set as in Table 1. The model of [15] without DBNs (i.e., the top one in Figure 1) is employed as our baseline model. The numbers of learnable parameters are around 110K and 63K for the proposed model and the baseline,

Input	
Number of frequency bins	$J = 81$ for Audio $J = 88$ for MIDI
Feature extraction	
Kernel size	$w^{(1)}_{ex,1} = 5 \times 41$
Kernel size	$w^{(1)}_{ex,2} = 5 \times 61$
Kernel size	$w^{(2)}_{ex,1} = 15 \times 1$
Kernel size	$w^{(2)}_{ex,2} = 21 \times 1$
Feature dimension	$D = 20$
Sequence modeling	
Kernel size	$w_{seq,1} = 301$
Kernel size	$w_{seq,2} = 401$
Scale factor	$\mathbf{s} = \{1, 2, 3, 4\}$
Number of scales	$S = 4$
Number of layers	$L = 4$
Estimation	
Kernel size	$w_{est} = 7$
Label embedding	
Number of beat phase classes	$K_b = 150$
Number of downbeat phase classes	$K_{db} = 500$
Kernel size	$w_e = 7$

Table 1: Hyperparameters of the proposed architecture.

respectively. Evidently, we can employ separable convolutions to enlarge the receptive field without a catastrophic increase of model capacity. To investigate the effectiveness of the proposed methods, we further perform an ablation study by removing one of the reformulations: feature extraction (`abl_ex`), sequence modeling (`abl_seq`), loss function (`abl_loss`), and label embedding (`abl_lab`).

In line with [15], the Ballroom and the Hainsworth are both split for 8-fold cross-validations. [4] Note that the two datasets are used separately rather than merged as a single cross-validation set. The GTZAN is divided into 10 parts according to the built-in genre labels, with which a 10-fold cross-validation is performed to inspect the performance variance with respect to genre. [5] For the ASAP, we first create a subset by selecting audio recordings which have a paired MIDI file (519 pairs in total). Afterwards, a test set is built from the subset with musical pieces by the four composers: Glinka, Mozart, Schubert, and Rachmaninoff; the remaining data of the subset are used for training. The paired MIDI files are used as the audio counterparts to examine the impact of input modality on the performance.

All the training data are augmented in two ways: 1) by shifting the pitch of an audio signal *before* the STFT is applied, and 2) by changing the hop size of the STFT window. [6] For the ASAP, we only apply the pitch augmentation as its total duration is significantly longer than the other three datasets. By the pitch augmentation, we can easily increase the data amount without extra annotation

[3] `https://github.com/Tsung-Ping/Joint-beat-and-downbeat-estimation`

[4] The details of the data splitting can be found at `https://github.com/superbock/ISMIR2020`.

[5] `jazz.00003`, `jazz.00009`, `jazz.00010`, `jazz.00014`, `jazz.00018`, `jazz.00020` are excluded for they have no downbeat annotations; `reggae.00086` is damaged and also excluded.

[6] We use pitch shifts ∈ {-5 ∼ +6} (semitones) and hop sizes ∈ {18.9, 20.3, 21.8, 23.2, 26.1, 29.0, 31.9} (ms) for the data augmentation.

Task	Model	Ballroom	Hainsworth	GTZAN										ASAP	
				blues	classical	country	disco	hiphop	jazz	metal	pop	reggae	rock	Audio	MIDI
Beat	baseline	96.60	84.18	83.20	51.62	**96.65**	**97.76**	94.61	68.40	82.46	93.84	92.76	89.90	**71.43**	72.45
	proposed	**96.81**	**86.28**	**86.63**	**63.23**	94.82	97.63	**95.58**	**79.80**	**86.48**	**94.81**	**93.05**	**93.01**	71.40	**75.70**

	proposed	**94.21**	**69.11**	**60.98**	**30.17**	**83.91**	**86.28**	**79.10**	**50.66**	**67.21**	83.86	**56.87**	**76.55**	**63.92**	**67.43**

Table 2: Evaluation results in terms of F1 score (%). For the Ballroom and the Hainsworth, the scores are the averaged performances over a 8-fold cross-validation. For the GTZAN, the score on each genre is obtained in a 10-fold cross-validation manner. For the ASAP, the performances on the audio data and on the MIDI data are separately shown.

Task	Model	Ballroom	Hainsworth
Beat	abl_ex	96.08 (-0.73)	85.49 (-0.79)
	abl_seq	96.98 (+0.17)	85.96 (-0.32)
	abl_loss	95.27 (-1.54)	86.52 (+0.24)
	abl_lab	96.54 (-0.27)	86.83 (+0.55)
Downbeat	abl_ex	92.16 (-2.05)	62.27 (-6.84)
	abl_seq	94.16 (-0.05)	69.73 (+0.62)
	abl_loss	91.99 (-2.22)	66.79 (-2.32)
	abl_lab	93.61 (-0.60)	69.58 (+0.47)

Table 3: Ablation study on the Ballroom and the Hainsworth. Performance in terms of F1 score (%) and relative improvement against the proposed model (in parentheses) are provided.

cost; moreover, the model can explicitly learn rhythmic features independent of absolute pitch. By the hop-size augmentation, we can obtain more training data of different tempi with a slight adjustment of the annotations.

4.3 Result

The evaluation results are summarized in Table 2, showing the performance on each dataset in terms of beat estimation and downbeat estimation. When evaluated on the Ballroom and the Hainsworth, the proposed model outperforms the baseline in both beat and downbeat estimations. Moreover, it is surprising that the evaluation results on the Ballroom are even better than [15] (beat: 96.20; downbeat: 91.6) and [14] (beat: 96.20; downbeat: 93.7) considering that we didn't use a combination of datasets for training and DBNs for post-processing; in addition, our model is smaller in capacity than the best model of [14] which has around 4.7M learnable parameters. On the other hand, the results on the Hainsworth indicate that more efforts should be put in dealing with music data of diverse styles. For instance, the choruses collected in the Hainsworth are extremely flexible in tempo at the beginning and particularly at the end of each phrase, and therefore a phrase segmentation technique might be incorporated in the tasks.

For the GTZAN, the proposed model demonstrates its superiority over the baseline in almost all the cases. The average beat estimation performances are 85.12% and 88.50% for the baseline and the proposed model, respectively, while the average downbeat estimation performances are 61.96% and 67.56%. According to the evaluation results, the rhythmic characteristics of `classical` and `jazz` are quite distinct from the other genres. Nevertheless, our model still surpasses the baseline by around 15.5 and 17.2 percentage points in estimating the downbeats of `classical` and `jazz`, respectively. These improvements are notable and indicate the capability of our model in both tasks, especially in downbeat estimation.

For the audio data of the ASAP, the proposed model performs comparably to the baseline on the beat estimation while remarkably outperforms the baseline on the downbeat estimation. For the MIDI data of the ASAP, our model achieves greater results both on estimating the beats and the downbeats. It is worth noting that in all cases, the estimation result is better on the MIDI data than on the audio counterpart. Given that automatic music transcription (AMT) [49–51] is an active research topic in the field of MIR, it could be promising to incorporate AMT techniques into the beat and the downbeat estimations.

Finally, as shown in Table 3, the ablation study indicates that our reformulations of the feature extraction and the loss function have notable positive effect especially on estimating downbeats, while the improvements by the other components are inconsistent over the tasks and datasets. We also observed that for the Hainsworth, the model without the label embedding (`abl_lab`) performs slightly better. This might result from the limited expressiveness of $\mathbf{H}$ due to the regularization on it. A more extensive study is required to justify the proposed reformulations.

5. CONCLUSION

We have addressed the joint beat and downbeat estimation task based on a state-of-the-art approach. By inspecting the potential issues in this approach, we proposed several reformulations to further the performance of deep neural networks. We experimentally showed that the proposed architecture is capable of outperforming the state-of-the-art approach without the aid of a post-processing network. In the scenario of deep learning-based beat and downbeat estimations, as well as in many sequence labeling frameworks, it is common to involve a post-processing stage in addition to the deep neural networks since the outputs by the networks are usually coarse when a simple thresholding method is applied. While involving a post-processing stage often leads to an improvement over the preceding deep learning models, it hinders the formulation of end-to-end training and indicates a necessity to reconsider the employed neural networks. Hopefully, we are able to build a model tailored to the task of interest with a deeper look at the network architecture from the perspective of data.

MUSIC TRANSLATION: GENERATING PIANO ARRANGEMENTS IN DIFFERENT PLAYING LEVELS

oded@hellosimply.com

ABSTRACT

We present a novel task of "playing level conversion": generating a music arrangement in a target difficulty level, given another arrangement of the same musical piece in a different level. For this task, we create a parallel dataset of piano arrangements in two strictly well-defined playing levels, annotated at individual phrase resolution, taken from the song catalog of a piano learning app. In a series of experiments, we train models that successfully modify the playing level while preserving the musical 'essence'. We further show, via an ablation study, the contributions of specific data representation and augmentation techniques to the model's performance.

In order to evaluate the performance of our models, we conduct a human evaluation study with expert musicians. The evaluation shows that our best model creates arrangements that are almost as good as ground truth examples. Additionally, we propose MuTE, an automated evaluation metric for music translation tasks, and show that it correlates with human ratings. Demos are available online. [1]

1. INTRODUCTION

In this paper we tackle the task of generating piano arrangements for specific playing difficulty levels, conditioned on piano arrangements of the same music in a different playing level. The purpose driving this work is to significantly accelerate our rate of content creation for our piano learning app, Simply Piano. [2] In Simply Piano, we have a library of songs for beginner piano learners to practice. Our library contains arrangements in various playing levels, to match the skills acquired by our learners over their piano journey. Arrangements are prepared by expert musicians based on a pre-defined set of piano pedagogy guidelines. These guidelines are strict and are designed to maintain a uniform playing method and skill level in order to help learners familiarize themselves with the piano in a systematic way. Our aim is to be able to automatically generate multiple arrangements, spanning our range of playing levels, from a single human-generated arrangement at a given level.

Our contributions are two-fold. First, we introduce the task of playing level conversion. We share our dataset preparation method and discuss various experiments regarding choice of music representation and data augmentation methods. Second, we develop and share an automated evaluation metric that can be used for music translation or generation tasks where a reference is available. This automated evaluation metric provides a fast, low-effort estimation of human ratings.

2. RELATED WORK

The symbolic music generation field has advanced considerably in recent years. Specifically, the community has been fast in adopting and adapting capable sequence-to-sequence models, such as Transformer [1], which were originally developed for natural language processing tasks such as machine translation.

Some works focus on unconditional music generation, that is, generating music from scratch [2–4]. Many recent ones are based on Transformer and its variants [2, 4–10]. Other works tackle music generation conditioned on specific inputs: emotions [11], structure [12], theme [13], or musical attributes such as note density [14]. In [2, 15], an accompaniment is generated conditioned on a melody or chord progression.

While most papers work in the performance domain (training on MIDI performances), some work in the score domain as we do. Some use custom tokenized score representations [16, 17] while others operate on text-based notation formats like ABC [18, 19].

Works that are most closely related to this paper are those concerning symbolic music style transfer: generating a musical piece in a target style given the same piece in another style. Musical 'style' can refer to various attributes [20]: symbolic abstractions (score), expressive timing and dynamics (performance), and acoustic details (sound). Of relevance to us is only the first of the three.

Due to the lack of datasets with parallel examples in different domains, most works use unsupervised methods for learning style features. In [9], a Transformer with an encoder bottleneck is used to learn a global style representation. This style representation is then combined with melody representations and fed into a decoder to generate the same melody in a different style. [21] also learns a style

representation in an unsupervised manner using an autoencoder bottleneck together with a style classifier. [22] uses inductive biases in the encoder to disentangle chord and texture factors. In [23, 24], CycleGAN is used to transfer music between genres. Difficulty level classifiers such as [25–27] could also be used for generating weakly-labeled non-parallel training data for level translation.

In [28], style translation is performed with supervised learning using synthetic parallel data. To our knowledge, our work is the first to perform supervised domain transfer for symbolic music with real-world parallel data.

3. DATA PREPARATION AND REPRESENTATION

Our proprietary dataset of piano arrangements is taken from the song library of Simply Piano. For each song in the library, expert musicians have created arrangements in up to three levels: Essentials (easy), Intermediate, and Pre-Advanced (more difficult but still aimed at learners). Strict arrangement guidelines have been developed by our musicians to create an approachable and engaging learning path for users. We use a pedagogy system based on hand positions, where the aim is to initially minimize the player's need to shift their hands, and then gradually introduce new hand positions and musical concepts as users progress.

Figure 1 illustrates the different difficulty levels. In this paper, we focus on two levels only: Essentials and Intermediate. Specifically, we tackle the task of translating from Intermediate to Essentials. The main difference between the two levels are in hand positions, rhythmic complexity, and harmonic complexity (amount of simultaneous notes). In Essentials, we only allow a small number of positions and keep position shifts to a minimum. We keep the number of chords small and emphasize the melody. We also limit the range of allowed pitches and rhythms: in Essentials we generally do not use tied notes or sixteenth notes. In both Essentials and Intermediate, we do not use tuplets and multiple indepdendent voices on the same staff.

When approaching the task of song level translation, initial experiments showed that translating entire songs at once is a difficult task: models we trained did not learn a meaningful mapping between levels. The reason is probably that song structure can vary greatly between levels in our dataset. That is, some levels of the same song omit certain phrases, while other levels include extra phrases, or change the phrase order. It seems that for full-song mapping, a larger (or cleaner) dataset is needed.

For this reason, we focus our work on translating individual musical phrases. Fortunately, we could make use of existing annotations for this purpose. Each of our arrangements is divided by musicians into phrases, based on the song structure. For example, a song could have the following phrases: Intro, Verse 1, Verse 2, Chorus, Verse 1, Ending. Phrase names stay consistent between different levels of the same song, allowing for minor variations such as 'Phrase 1' $\Leftrightarrow$ 'Phrase 1a'.

We use the phrase boundary annotations to derive a dataset of parallel phrases from our library of arrangements. This is illustrated in Figure 2. We start from two

Figure 1. Comparison of three difficulty levels. From bottom to top: *Pre-Advanced* is fully harmonized with rhythmic bass in the left hand and chords in the right hand. *Intermediate* is transposed to the easier key of C major and contains a simplified accompaniment. The right hand chords are omitted, and the melody is split differently between the hands to accomodate for less hand shifts. In *Essentials*, the accompaniment is reduced to a minimum, and a tied note in the melody is removed to simplify the rhythm.

parallel arrangements of the same song in the source and target levels. We discard arrangements where the target and source have different time signatures. We then transpose the source arrangement to the same key as the target arrangement (see details below).

Following that, we match phrases from the source and target levels using heuristics that take into account phrase order, names, and durations. These heuristics were crucial for obtaining a dataset of sufficient size. To account for added or removed phrases, we compute a diff between the source and target phrase names. Phrases with exact name (and order) matches are then considered to be parallel if their duration difference is 2 measures or less. For phrases with no exact name matches, we diff the phrase durations instead, and consider phrases as parallel if their durations match and their names are sufficiently similar.

In some songs, different levels were written in different keys (e.g., Essentials in C major and Intermediate in D major), to fit the arrangement to the desired playing level. For our task, it was important that source and target phrases maintain the same key, so that the model could learn a consistent mapping. Since we didn't have key annotations for the dataset, we implemented a heuristic method for transposition estimation.

We initially tried existing methods for key estimation [29] for each of the phrases, however these weren't accurate enough. Since we only need to estimate the transposition (and not the actual key), we came up with a dedicated heuristic: convert each of the arrangements (source s and target t) into a "pitch-class piano-roll", a boolean matrix (P_s and P_t) with time and pitch-class dimensions, in which 1 signifies the given pitch-class is active at the given time.

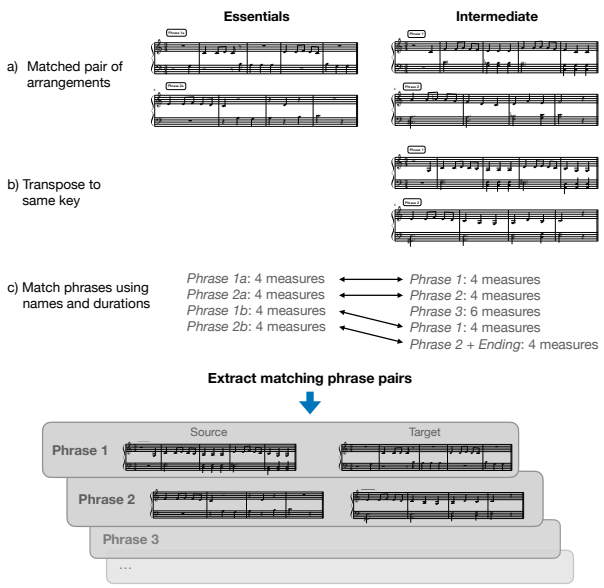

Figure 2. Data preparation: we start with two arrangements of the same song in different levels, transpose them to the same key, and extract matching phrase pairs.

We then compute the pitch-class overlap ($\sum P_s \cap P_t$) between the piano-rolls for each possible transposition (out of 12 possibilities) and take the one that gives the maximum overlap. We use this value to transpose the source level's phrases to match the target level's key.

While the transposition might slightly affect the source phrases' difficulty, the target's difficulty is kept intact. We found that including these examples improves the generated results, since it allows us to increase the dataset size considerably.

3.1 Music Representations

Sequence-to-sequence models such as Transformer operate on a stream of tokens. In order to use these models we must represent music as a sequence, even if it is polyphonic or consists of multiple tracks. Since symbolic music is multi-dimensional in nature, various ways to turn music into a token sequence have been proposed. MidiTok [30] gives a good summary of various representations.

It is crucial to choose a representation that fits the given task. We experimented with three representations for piano music: MIDI-like, Notes, and Notes+Hands. The MIDI-like representation uses note on and note off tokens, along with time shift tokens to signify the passing of time [2, 31]. MIDI-like representations are commonly used, perhaps because it is easy to derive them directly from MIDI files. For our use case, the MIDI-like representation has two limitations: it forces the model to meticulously track active notes in order to later output corresponding note off tokens (potentially leading to syntax errors), and it does not encode the metrical structure of music, potentially leading to compound alignment errors if a single time-shift is wrong.

To counter these problems we employ the Notes representation, which uses three tokens for each note: offset, pitch, and duration. The offset token signifies the note's time offset from the beginning of the measure. A 'bar' token is output at the beginning of each measure. This is similar to REMI [6] (but without velocity tokens), in that it (partially) encodes the metrical structure of music.

Since our output is sheet music, we must output two separate staves for the right and left hands. Since the MIDI-like and Notes representations do not encode track information, we use a heuristic by which all notes on or above middle C are assigned to the right hand, and any note lower than middle C is given to the left hand. Chords (notes with identical onset and offset times) are always grouped to one hand. This heuristic generally matches our dataset's specific characteristics, but is quite coarse and leads to hand assignment errors.

To solve this, we test an additional representation, Notes+Hands, which is identical to the Notes representation but adds a 'hand' token to each note. As stated in [15], such a representation emphasizes the harmonic ('vertical') aspect of music. In the case of piano music, sorting notes by time (and only then by track) emphasizes the overall coherence of the two piano hands over the melodic coherence of each hand separately.

3.2 Data Augmentation

Since our dataset is small, even small models quickly overfit it, limiting our ability to scale model size, consequently limiting the amount of information the model can learn. Previous work has shown that data augmentation can turn an overfitting problem into an underfitting problem, allowing us to iteratively increase model size [32]. We followed this protocol by gradually adding data augmentation methods and increasing model size to improve the final results.

To match our translation task, we needed augmentations that meaningfully alter both source and target phrases, without corrupting the relationship between them. We implemented the following augmentation methods: adding empty measures at random locations; randomly cutting the beginning or end of phrases; removing some measures randomly; and rhythm augmentation (doubling the duration of each note) in some measures.

We purposefully do not include transposition in the list of augmentations, even though it is commonly used in other works. As described above, the arrangement style in our dataset is not transposition-invariant: many features depend on absolute pitch such as hand positions, fingering, key signatures, range limits and hand allocation.

We release our data augmentation code, [3] built on top of the muspy library [33]. We believe that these augmentation methods could be useful for other symbolic music generation tasks, especially when working with small datasets.

4. MODEL

We use a classic Transformer model [1], specifically the BART [34] encoder-decoder implementation from the hug-

[3] https://github.com/matangover/muspy-augment

gingface `transformers` library [35]. The specifics of this implementation (compared to classic Transformer) are that it uses learned position embeddings (we saw slightly better results with these compared to sinusoidal embeddings) and GeLU rather than ReLU as the activation function (this did not seem to make a difference in our experiments). As in the original Transformer, we use a shared weight matrix for the encoder, decoder, and output embedding layers.

We experimented with various model configurations: model dimension, number of layers, number of attention heads. We found that larger models ($d_{\text{model}} > 64$) quickly overfit our training dataset and do not achieve good performance on the validation dataset. The optimal model dimension was found to be 32–64 (with the feed-forward layer dimension always set to $4 \cdot d_{\text{model}}$ as in the original Transformer). The optimal number of layers was 3 to 5, depending on the amount of data augmentation. As discussed in Section 3.2, use of more data augmentation enables us to increase model size without overfitting the data.

We trained using the Adam optimizer [36] with $\beta_1 = 0.9$, $\beta_2 = 0.999$, $\epsilon = 10^{-8}$, a learning rate of 0.003 and 1,000 warmup steps.

Our dataset contains a total of 5,543 phrase pairs taken from 1,191 songs. We split the data into train (5,241 phrases), validation (244 phrases), and test (58 phrases) splits. We split phrases by song (never including phrases from the same song in different splits) to avoid data leakage between splits. The validation set was used to stop model training after validation loss stopped decreasing. The test set was used for final evaluation (see Section 7).

During prediction, the model outputs a probability distribution for the next output token given all the input tokens and the previous output tokens. However, if at each decoding step we simply pick the most likely output (greedy decoding), we might end up with a non-optimal sequence [37]. We experimented with two decoding methods: beam search and sampling. We found that sampling produces more diverse results (due to its random nature) but beam search produces overall superior results for our task.

5. INTERFACE FOR INTERACTIVE USE

While our model can be used unattended to create arrangements in the target level, in practice we found that it is beneficial to keep musicians "in the loop" by allowing them to use the model interactively rather than in a 'fire and forget' fashion. We created an interface in which a musician can load a source arrangement, translate it phrase-by-phrase to the target level, and review the results side by side.

Furthermore, the auto-regressive nature of the model enables interesting use cases: a musician could manually modify some notes and ask the model to re-generate the subsequent music accordingly. Additionally, if we use random sampling decoding (see Section 4) we could generate multiple alternatives for each measure using different random seeds and offer the musician a choice. We could also offer knobs that control sampling parameters such as temperature (for controlling the output diversity vs. quality trade-off) or top-k/top-p thresholds (ways of eliminating unlikely outputs to increase the probability of choosing more likely predictions).

In this way, our model becomes part of the creative process, rather than replacing it. It becomes a tool that assists musicians in their job.

6. EVALUATION METRIC

Evaluation is often difficult for music generation due to the absence of pre-defined criteria and because output quality is subjective [38]. Standard practices are reporting perplexity (the likelihood of the ground truth test data given the trained model) and conducting human evaluation studies [2, 4, 9, 15, 31]. Some works also calculate scores based on distributions of certain musical features, either comparing generated data to ground truth distributions [9, 15, 39] or using self-similarity in the generated data itself [3].

In machine translation (of text), evaluation metrics such as the popular BLEU metric [40] have been developed to measure the correspondence between generated translations and ground truth references. BLEU has been shown to correlate with human ratings. We are not aware of a similar metric for music generation tasks. To this end, we propose MuTE (Music Translation Evaluation), an automated evaluation metric for symbolic music translation or generation tasks where a reference is available.

MuTE is a score between 0 and 1. Like BLEU and similar metrics, it is designed to reflect the correspondence between a machine-generated example and a human-generated reference. BLEU measures word n-gram precision (the portion of correct predictions out of all predictions) and deliberately omits recall because of the desire to allow for multiple reference translations of the same phrase. In our case, we only have a single reference for each phrase, hence we can easily use both precision and recall, and combine them using the harmonic mean to give the commonly used F1 score [41].

MuTE works by treating the model as a multi-label classifier that predicts at every time step what pitches are active. To compute the MuTE score, we convert the reference and target music to piano-rolls (where the time unit is set to a certain small metrical unit – in our case, a sixteenth note), and calculate the F1 score over pitches. We do not compute a global score for the entire piece, since that would mean disregarding note order and timing. Instead, we treat each time-slice of the piano-rolls as an individual sample, compute an F1 score for each time-slice, and average those scores. For time-slices where both the reference and target are silent (and hence precision and recall calculation would result in division by zero), we set the score to 1.

We also need to account for cases in which the target differs from the reference in its duration – if, for example, the model 'skips' some measures of the input. We design a procedure that is intended to match the way a human would judge such cases, by detecting skipped or added measures and adjusting the comparison accordingly.

For this, we precede the scoring step with a measure-level alignment procedure. We perform the alignment us-

ing dynamic time warping [42]. The feature vectors for the alignment are each measure's pitch-class piano-roll (see Section 3). We found that using pitch-class piano-rolls gives a more robust alignment compared to regular piano-rolls. The distance between each two feature vectors is computed using the Hamming distance (the proportion of elements that disagree between the two vectors). We use the computed alignment path to align the reference and target's (regular) piano-rolls. The aligned piano-rolls are used to compute the F1 score, while masking out the misaligned segments to assign them a score of 0, thus penalizing the model for any alignment errors.

One additional element of MuTE that pertains to our use case is the desire to reflect the separation between the two hands: we would like to penalize wrong hand allocation of notes. For this reason, we use 'track-specific' MuTE: we calculate a separate MuTE score for each hand and average them to get the final score. We found the mean-of-hands metric to correlate better with human ratings than the vanilla MuTE score calculated over both tracks combined.

We note that the measure-based alignment method is specifically suitable for our use case because we use a measure-based representation for our models, and we noticed that models sometimes omit or repeat some measures. For other use cases, the alignment could be computed over individual time steps or beats, or skipped altogether.

Figure 3 illustrates the calculation of the MuTE score. In Section 7 below, we show that the MuTE score correlates with human ratings. While simple and effective, the MuTE score has caveats. First, it does not differentiate between sustained and repeated notes. For example, a half note is considered identical to two consecutive quarter notes of the same pitch. Second, it does not allow for minor variations that might be acceptable to a human rater, such as octave changes and rhythmic variations. Third, the hand-specific version does not account for notes that are missing in one hand but present in the other hand. We plan to address these shortcomings in a future version.

We release a Python library for computing the MuTE score [4] and we welcome researchers to adopt it or adapt it for their use cases as needed.

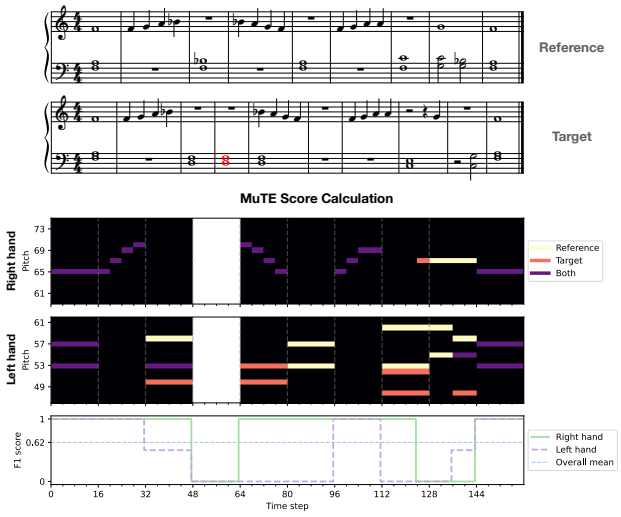

Figure 3. Illustration of the MuTE score calculation. The target score has an added measure (marked in red) with regard to the reference. The misaligned region is masked (in white) on the piano-rolls. The per-hand sample-wise pitch F1 score is calculated from the aligned piano-rolls, and scores are averaged to get the final MuTE score.

Figure 4. Scores for each model version, as rated by human experts. Our best model (Augment) achieves ratings almost as high as human generated examples (Human).

7. RESULTS

We report the results of our experiments on converting Intermediate level arrangements to Essentials, and compare our models' outputs to matching reference arrangements created by expert musicians. For evaluation we conduct a human evaluation study, calculate MuTE scores (see Section 6) and report the correlation between human ratings and MuTE scores. Furthermore, we run several ablation studies to study the effect of our data augmentation techniques and the choice of music representation.

7.1 Human Evaluation Study

For this study we selected 11 songs from the test set (none of these songs' phrases appeared at training). From each song we extracted a single phrase and translated it from Intermediate level to Essentials, using 4 variants of the model that differ in representation and augmentation. We also extracted the matching phrases from the ground truth Essentials arrangement for comparison.

The first 3 model variants differ only in the music representation they use: MIDI-like, Notes, and Notes+Hands (see details in Section 3.1). The fourth model variant uses the Notes+Hands representation and adds data augmentation (see Section 3.2) with randomly varying parameters to about half of the training examples.

This resulted in 55 examples, which were then rated by 6 expert musicians who are familiar with the Essentials level guidelines. The examples were randomly ordered and all identifiers of model version and ground truth were removed. Musicians were told all 5 examples are different model versions and were not aware of the details of the ver-

[4] https://github.com/matangover/mute

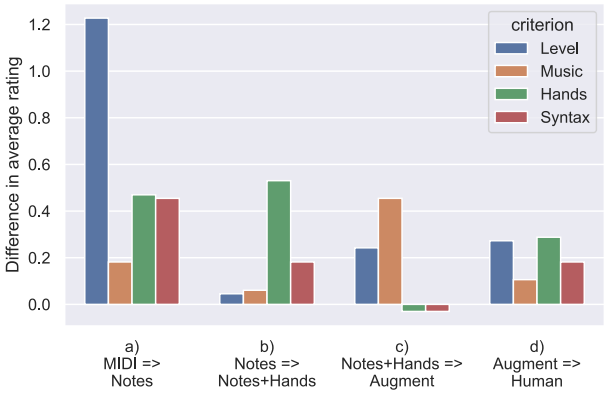

Figure 5. Difference in average rating, per criterion, between model variants. a) Moving from MIDI to Notes improved across all criteria, mostly Level. b) Adding hand information improved hand assignment. c) Augmentation improved preserving musical content. d) No particular criterion stands out in the difference from our best model to the human-generated ground truth.

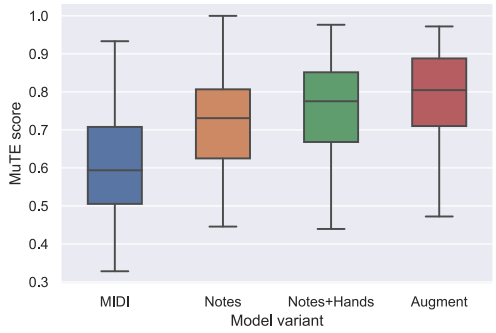

Figure 6. Evaluation of our model variants on the test set using the MuTE score.

sions or of the presence of human-generated ground truth. Ratings between 1–5 were collected in 5 criteria:

1. Meeting Essentials level guidelines (Level)
2. Preserving musical content (Music)
3. Correctly assigning hands according to allowed hand positions (Hands)
4. Avoiding syntactic style errors such as crossover voices (Syntax)
5. Maintaining structure: avoiding missing or extra bars (Alignment)

The maximum possible total score is 25. Figure 4 shows the distributions of scores for each model variant and for the ground truth. These results show that the changes between model variants improved overall output quality. The best model (Augment) achieves ratings almost as high as the ground truth (Human).

In Figure 5 we show the gains in each criterion from the changes in each model variant. Some differences are easily explainable, for example, adding hand information improved the correct assignment of hands. Interestingly,

Figure 7. A scatter-plot showing the relationship between human ratings and MuTE scores. The black line shows a linear regression model fit and the shaded area shows the 95% confidence interval for the regression estimate.

the difference between our best model to the ground truth cannot be attributed to any specific criterion. We left out the Alignment criterion from the figure, as ratings under 5 were very rare. The few ratings below 5 were given almost only to the MIDI model variant, which is more prone to alignment errors due to the lack of *bar* tokens.

7.2 Automated evaluation

We calculate MuTE scores (see Section 6) for the entire test set (58 phrases from 12 songs). The results are shown in Figure 6, and confirm the human evaluation results. Additionally, for the 55 examples rated by human musicians, we compare the MuTE scores to the human ratings (the MuTE score of the ground truth compared to itself is always 1). As shown in Figure 7, we find that MuTE scores are correlated with human ratings with a Pearson correlation coefficient of 0.56 ($p = 4 \cdot 10^{-29}$). While the correlation is not perfect, it shows that MuTE can be used as an estimator for human ratings. Furthermore, MuTE correlates better with the total human rating than with any of the individual criteria's ratings: the correlation coefficients with the indvidiual criteria are 0.27 (Alignment), 0.37 (Hands), 0.47 (Level), 0.37 (Music), and 0.29 (Syntax). The similarity of figures 6 and 4 further shows that MuTE scores can be used to rank models with similar results to human rankings, while being cheaper and faster to compute.

8. CONCLUSION

We presented the task of playing level conversion: converting piano arrangements from one difficulty level to another. We ran several experiments focused on simplifying arrangements to an easier level, and showed the importance of data representation and augmentation. Our best model creates arrangements that achieve human ratings almost as high as reference arrangements composed by expert musicians. We designed the MuTE evaluation metric and showed that it correlates with human ratings. For the benefit of the community, we share our data augmentation and evaluation code.

9. ACKNOWLEDGEMENTS

Thanks to the musicians at Simply for creating the arrangements used to train our models, and for helping perform the evaluation. Thanks to Eran Aharonson for valuable discussions and feedback.

ABSTRACT

Automatic Music Transcription (AMT), in particular the problem of automatically extracting notes from audio, has seen much recent progress via the training of neural network models on musical audio recordings paired with aligned ground-truth note labels. However, progress is currently limited by the difficulty of obtaining such note labels for natural audio recordings at scale. In this paper, we take advantage of the fact that for monophonic music, the transcription problem is much easier and largely solved via modern pitch-tracking methods. Specifically, we show that we are able to combine recordings of real monophonic music (and their transcriptions) into artificial and musically-incoherent mixtures, greatly increasing the scale of labeled training data. By pretraining on these mixtures, we can use a larger neural network model and significantly improve upon the state of the art in multi-instrument polyphonic transcription. We demonstrate this improvement across a variety of datasets and in a "zero-shot" setting where the model has not been trained on any data from the evaluation domain.

1. INTRODUCTION

The variety of sounds that can appear in a musical recording is effectively infinite. Numerous instruments, articulation styles, dynamics, recording conditions, synthesizer parameters, processing effects, and more can all interact to produce the enormous space of sounds that can be heard in recorded music. This diversity of sound is a challenge for Automatic Music Transcription (AMT), the task of extracting a symbolic representation from a musical recording. In this paper we focus on the specific task of automatically extracting a symbolic representation consisting of musical *notes*. For each note we would like to infer its pitch, absolute timing of its onset and offset in seconds, and the instrument that played the note. We do not attempt to infer a musical *score* with time signatures, key signatures, etc., merely a sequence of notes with absolute timestamps that can be represented as MIDI [1].

Most recent progress in AMT has been driven by neural networks trained on musical recordings paired with their note transcriptions. However, this progress is currently bottlenecked by the limited number of existing ground truth transcriptions, which is in turn bottlenecked by the difficulty of creating note transcriptions that are precisely aligned with audio. Creating ground truth transcriptions manually is possible only for trained musicians, and is a notoriously tedious process. Furthermore, trained musicians rarely annotate the timing of note events to the precision needed for training AMT systems.

Besides being limited in number, existing transcribed recordings are also limited in *character*, as only a few methods are able to produce such aligned data efficiently:

Capture a musical performance using an instrument equipped with sensors, e.g. a Disklavier [2] or guitar equipped with hexaphonic pickup [3]. This yields highly accurate ground-truth transcriptions but is difficult to scale across many instruments due to the difficulty of needing to equip each instrument with specialized sensors. In addition, data created in this way is likely to be limited to a small number of recording environments, as it is easier to invite multiple performers to record in a single location than to create many sensor-equipped instruments, distribute them to performers, and ask the performers to share recordings with captured transcriptions.

Synthesize a sequence of notes using a software synthesizer [4, 5]. While this technique produces high-quality audio-label alignment, the space of sounds that can be generated by a synthesizer only partially covers the space of instrument sounds an AMT system is expected to transcribe. In particular, for instruments such as violin and saxophone where the sound of each note and transition is mediated by a large number of control parameters (typically "provided" by a human performer via body positioning), we do not yet have good methods for generating music that matches the realism and diversity of human performances.

Align an audio recording and its corresponding symbolic score using dynamic time warping [6]. This technique

Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

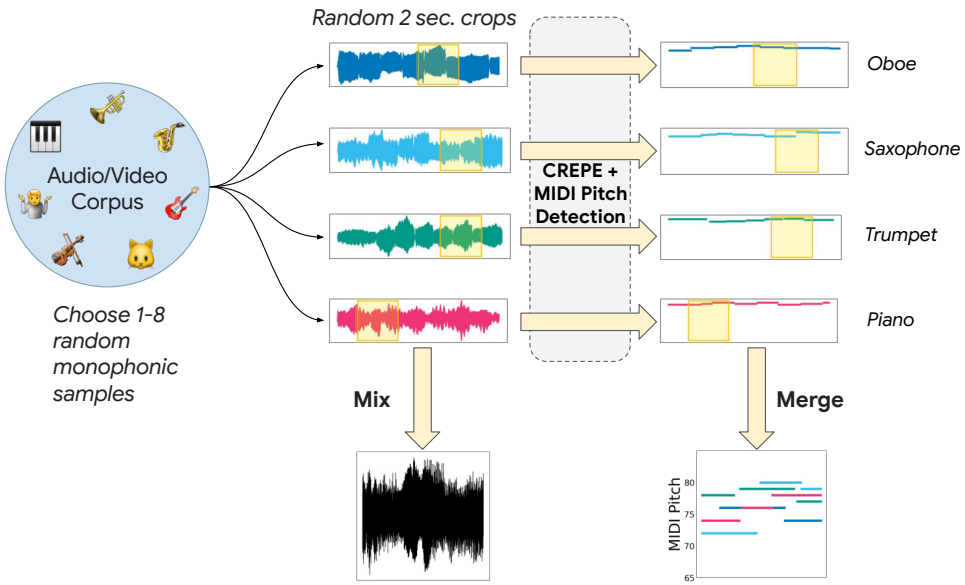

Figure 1. Overview of our dataset generation pipeline. Monophonic recordings are gathered from an audio/video corpus. Each training example selects 1-8 20 second clips, and then takes random ∼2 second crops from each clip for MIDI pitch detection. The resulting audio clips are mixed and MIDI clips are merged to form a polyphonic mixture for training.

has the advantage of being applicable to pre-existing audio recordings where a score is available. However, the resulting labels often end up poorly aligned due to dynamic time warping errors or when the recording does not exactly match the provided score.

In this paper, we demonstrate a new technique for creating training data for AMT models: transcribing in-the-wild monophonic (i.e. one note playing at a time) recordings and mixing the audio and transcriptions together as training data for a neural network. Monophonic recordings are much easier to transcribe due to the existence of highly accurate pitch trackers such as CREPE [7]. This technique does not suffer from any of the limitations described above; it can be applied to any monophonic audio clip, and the audio and note labels are accurately aligned.

By generating a large number of polyphonic mixes of transcribed monophonic recordings, we are able to greatly increase both the *quantity* and *diversity* of data used to train multi-instrument polyphonic transcription models. An important part of scaling our transcription data is that we mix recordings without regard to whether or not they "go together"; the mixtures are rhythmically and harmonically incoherent. Nonetheless, using these recordings allows us to train larger and better models that surpass the existing state of the art in multi-instrument AMT.

2. RELATED WORK

2.1 Automatic Music Transcription

The field of automatic music transcription (AMT) has a rich history in MIR, but has been advancing rapidly in recent years as AMT models begin to take advantage of deep learning models and large-scale datasets. For example, the Onsets & Frames model by Hawthorne et al. [2] uses a deep convolutional and recurrent neural network to jointly predict note onsets and frames (subsequently treated as an adversarial task by Kim & Bello [8]); Kelz et al. [9] use a convolutional network to model ADSR envelopes in piano transcription; Manilow et al. [10] perform simultaneous transcription and source separation with a multiheaded network; Cheuk et al. [11] use semi-supervised learning to improve transcription on low-resource datasets and later explore the effect of adding a spectrogram reconstruction loss [12], and recently Maman & Bermano [13] demonstrate the use of synthetic data and iterative alignment to enable training on weakly-aligned scores.

The unsupervised pretraining of large neural sequence architectures has been critical to scaling performance in natural language processing (NLP) [14], computer vision [15], and automatic speech recognition (ASR) [16], but the dynamics of pretraining are only beginning to be empirically well-understood [17–19]. Recently some AMT systems have adopted the same sequence architectures used in NLP (e.g. MT3 [20]), but using *pretraining* in combination with these architectures for AMT is a relatively unexplored area. While in this paper we only examine the effects of large scale pretraining on MT3, the data strategies presented are orthogonal to these improvements in model architectures and can ideally work in concert to create better overall AMT systems.

2.2 Dataset Mixing and Labeling Heuristics

Heuristically-labeled and randomly-mixed data have been used to improve large deep learning models in other tasks and domains. For example, data augmentation strategies that combine existing labeled examples are common in computer vision [21–23]; such strategies have been shown to reduce memorization of corrupt labels [21],

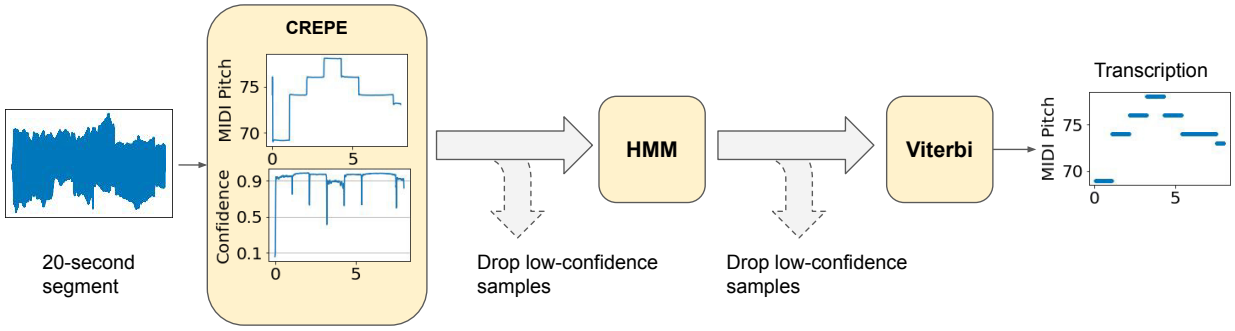

Figure 2. Overview of pitch tracking pipeline. HMM parameters are described in Section 3.3.

improve prediction and robustness on out-of-distribution data [21, 24], stabilize training of generative models [21], and reduce supervised models' overconfidence on samples outside the training distribution [25]. In the domain of AMT, Callender et al. [26] use data mixing to recombine random crops of drum audio samples and find that it improves a drum transcription model.

Heuristic techniques have also been used for labeling data and training MIR models. For example, Salamon et al. [27] use an analysis-synthesis framework for f_0 annotation where the model predictions are synthesized and mixed back into the input audio, and show that this produces results that are statistically indistinguishable from models trained on the manually-annotated mixes. Maman and Bermano [13] use dynamic time warping to generate music transcription labels from synthesized audio. In ASR, Fonseca et al. [28] show that unsupervised representation learning (via contrastive learning) can rival state-of-the-art models without expensive human-labeled datasets for audio scene separation. Furthermore, training with incoherently mixed single-instrument recordings, as we do here, is a widespread technique used for training music source separation systems [5, 29–32]. However, we are unaware of any systems that use heuristically-labeled *and* randomly-mixed data to scale AMT systems.

3. MODEL AND TRAINING PROCESS

3.1 Model Architecture

For all experiments, we use an encoder-decoder Transformer [33] architecture. Our model and training process is almost identical to that of Gardner et al. [20], with two main exceptions. First, while we use the T5.1.1 [1] [14] "Small" architecture used in [20] for some experiments, for others we use the larger T5.1.1 "Base" model.

Second, we pretrain our model on a large dataset consisting of mixes of automatically-transcribed monophonic recordings drawn from an Internet-scale pool of videos; this is the main contribution of the current work. In our experiments, we vary the number of pretraining and fine-tuning steps for the model as shown in Table 1. We share our code publicly at `https://github.com/magenta/mt3`, along with a checkpoint pretrained on our dataset of monophonic mixes.

[1] `https://github.com/google-research/text-to-text-transfer-transformer/blob/main/released_checkpoints.md#t511`

3.2 Data Representation

We use the exact input and output representation of Gardner et al. [20]: log-Mel spectrograms as input and a MIDI-like output vocabulary containing time, pitch, note on/off, instrument, "tie" section token, and drum tokens. This output vocabulary is capable of representing arbitrary multi-instrument polyphonic MIDI. As in Gardner et al. [20], we ignore note *velocities* as they are not present in most ground-truth transcriptions.

Again following Gardner et al., we split the input audio (and target labels at training time) into segments of 2.048 seconds (256 spectrogram frames at a hop size of 8 ms) [34]. At inference time, we transcribe each segment independently and concatenate their transcriptions. We also use the "tie" representation of Gardner et al. which requires the model to declare all notes that are active at the beginning of each segment. At inference time, if the model fails to declare a note that was active in the previous segment, we turn off the note.

3.3 Monophonic Detection and Transcription

We process a dataset of music recordings obtained in the wild to (a) detect clips that are likely to be monophonic, and (b) transcribe those clips into sequences of notes. While our heuristic process is far from the ideal approach to monophonic transcription, its main benefit is that it is simple and easy to apply to an Internet-scale data corpus.

Our process of creating a set of transcription labels from unlabeled audio data is illustrated in Figure 2, and proceeds as follows. First, we split each recording into non-overlapping 20-second segments. Then, we use the CREPE [7] pitch tracker to extract f_0 and confidence values from each segment at a frame rate of 100 Hz. If any of the four 5-second sub-segments has fewer than 20% of its confidence values above 0.95, we discard the entire segment. We do not run Viterbi smoothing on the f_0 values.

We then model the sequence of f_0 and confidence values with a hidden Markov model, where the hidden state

Model Size	# Pretrain Steps	# Finetune Steps	MAESTRO	Cerberus4	GuitarSet	MusicNet	Slakh	URMP
small (MT3)	0	1M	.82	.76	.78	.34	.55	.50
base (MT3)	0	1M	.85	.78	.78	.26	.61	.51
small (ours)	1M	100k	.84	.81	**.82**	.35	.59	.73
base (ours)	500k	100k	**.87**	**.83**	**.82**	**.38**	**.66**	**.78**
base (ours) vs. small (MT3)		($\Delta\%$ Rel.)	+6.0%	+9.2%	+5.1%	+12%	+20%	+56%

Table 1. Onset+Offset+Program F1 scores on different datasets, taking into account pitch, instrument, onset time, and offset time. Numbers in the first row are taken directly from Gardner et al. [20] and represent the previous state of the art. Numbers in the second row are from using the existing MT3 training procedure and data with a larger capacity model. The next two lines show the effect of our pretraining procedure. Pretraining on monophonic mixes yields some benefit even for the "Small" model, but does even better when model size is increased to "Base". Using a "Base" model without pretraining does considerably worse than with pretraining.

Model	MAESTRO	Cerberus4	GuitarSet	MusicNet	Slakh2100	URMP
			Frame F1			
small (MT3)	.86	.87	.89	.68	.79	.83

base (ours)	**.97**	**.95**	**.91**	**.56**	**.83**	**.90**
			Onset+Offset+Program F1			
small (MT3)	.82	.76	.78	.34	.55	.50
base (ours)	**.87**	**.83**	**.82**	**.38**	**.66**	**.78**

Table 2. Transcription improvement over MT3 for Frame, Onset, and Onset+Offset+Program F1.

is a MIDI pitch value (0-127) or rest. (Note that we do not model onsets separately.) The transition distribution models the probability of a state change, set to expect two state changes per second or probability 0.04 of changing at any frame. The f_0 observations are modeled as a Gaussian distribution centered at the corresponding MIDI note frequency, with a standard deviation of 0.2 semitones. We use a mixture of 3 Gaussians to model octave errors, with probability 0.025 of an octave error occurring in either direction, respectively. We model $P(\mathrm{r}|\mathrm{c})$ independently of f_0, where r is the rest state and c is the CREPE confidence value. We treat c^v as the probability a frame is not a rest, where we empirically determine $v = 7.5$.

We use the forward algorithm to compute $P(f_0, \mathrm{c})$ and discard the audio segment if the log-likelihood per frame is less than 0.3. This is useful for filtering out vocal recordings or other monophonic audio that is not well modeled by a sequence of discrete notes using the equal-tempered Western scale. Then, we use the Viterbi algorithm to infer the maximum-likelihood sequence of notes.

The above process and parameters were determined empirically on a small amount of unlabeled audio from our in-the-wild dataset. We believe that this process could be replaced by a more rigorous monophonic transcription model such as the one in Wu et al. [35]; however, we find that our process provides sufficiently strong results in practice to benefit AMT training. We plan to release our source code publicly, including our monophonic detection and transcription code. While we are unable to share our dataset, we believe that our results can likely be replicated on any large corpus of in-the-wild musical audio.

4. EXPERIMENTS

Our experiments measure how our pretraining method affects the accuracy of a Transformer-based transcription model. This section describes our experimental process, from data gathering to model training and evaluation.

4.1 Gathering Monophonic Recordings

We downloaded 10M audio recordings from an online audio/video sharing site, filtering based on metadata in an attempt to restrict ourselves to solo non-vocal musical performances on pitched instruments (i.e. not drums). We then split each recording into non-overlapping 20-second chunks and apply the monophonic detection and transcription process described in Section 3.3. Only about 1% of the chunks are detected as monophonic; we believe this is because most of the solo recordings are of performances on polyphonic instruments such as piano or guitar. Still, we choose not to exclude these instruments entirely as they are occasionally performed monophonically.

We also attempt to use the associated metadata to identify the instrument in each recording, which we use as instrument labels in the training examples. Table 3 shows the number of training clips identified as each instrument; we use the instrument vocabulary of Gardner et al. [20], originating in Manilow et al. [5]. In early experiments,

Instrument	# Clips	Instrument	# Clips
Violin	327,914	Oboe	3,234
Flute/Piccolo	96,507	Bass Guitar	2,264
Tenor Sax	71,737	Electric Piano	2,059
Acoustic Guitar	59,231	Tuba	1,526
Electric Guitar	58,037	Harp	1,233
Clarinet	53,513	Bassoon	1,114
Trumpet	52,695	Xylophone	897
Cello	23,856	Double Bass	751
Viola	22,027	Baritone Sax	317
Sopr./Alto Sax	18,784	Synth	288
Piano	18,626	Voice	123
Trombone	14,969	Organ	99
French Horn	7,135		

Table 3. Number of labeled segments for each instrument in our dataset after filtering as shown in Figure 2.

we found that these metadata-based instrument labels only led to a minor improvement in the model's performance, so even in the case where metadata is unavailable we still expect our overall approach to work.

After the entire data gathering process, we are left with ~5,000 hours of automatically-transcribed monophonic music recordings. This is 3 times more than all of our fine-tuning and evaluation datasets combined, 20 times more if we exclude synthetic audio, and over 100 times more if we exclude synthetic audio and piano. Furthermore, by mixing together random segments of monophonic audio at training time, we increase the effective dataset size so substantially that the model is unlikely to ever see the same combination of source recordings twice during training.

4.2 Pretraining

We pretrain an encoder-decoder Transformer [33] model as described in Section 3.1 on mixes of up to 8 monophonic recordings and their corresponding note labels. The process that generates each training example is as follows:

1. Choose the number of tracks k for the mix uniformly at random from 1-8.
2. Take the next k 20-second clips.
3. From each clip, choose a 2.048-second segment uniformly at random.
4. Mix the audio from the k clips together by summation, then peak normalize.
5. Combine the note labels from the k transcriptions into a single stream. If each transcription has already been serialized, we can perform a merge to ensure the note labels end up in the correct temporal order.

The much larger training datasets generated by our heuristic labeling enables us to scale the model size that we use, allowing us to potentially leverage the scaling benefits of large Transformer models [17]. To that end, we test two different sizes of model from T5 [14]: the T5.1.1 "Small" model used in MT3, and the relatively larger "Base" model. When using the smaller "Small" T5.1.1 model, we train for 1M steps. While pretraining the "Small" model continues to improve up to 1M steps, we found that 500k pretraining steps works best for the "Base" model; this is in line with prior research which has suggested that larger pretrained models are more susceptible to diverging or overfitting [17].

Our first experiment is modeled after the one proposed in Gardner et al. [20], where we train on a combination of multiple datasets and then evaluate on a held-out portion of each dataset. Our goal with this experiment is to measure the effect of pretraining on a collection of standard transcription datasets, using standard transcription metrics. Following Gardner et al., we evaluate on 6 datasets:

MAESTRO [2]: a dataset of 1276 classical piano performances with MIDI captured via Disklavier.

Slakh [5]: a dataset of 2100 synthesized songs from the Lakh MIDI Dataset [36]. We train on 10 random subsets of tracks from each song, and evaluate on full mixes.

Cerberus4 [10]: a subset of the instruments in Slakh, where mixes consist of exactly 4 tracks: guitar, piano, bass, and drums.

GuitarSet [3]: a dataset of 360 guitar recordings, transcribed using a hexaphonic pickup.

MusicNet [6]: a dataset of 330 classical music recordings, with MIDI files aligned by dynamic time warping.

URMP [37]: a dataset of 44 classical music recordings with instruments independently recorded and transcribed.

We measure transcription performance using the F1 metric over notes (Onset+Offset+Program), where in order for two notes to "match" they must have the same pitch and instrument and be close enough in onset time and offset time. We use the default tolerances in the `mir_eval` [38] library: onset times must be within 50 ms to match, and offset times must be within the larger of 50 ms or 20% of the note's true duration.

Our results are shown in Table 1. When using a "Small" model, pretraining provides a small increase in F1 score across all datasets. A further advantage of pretraining is that it lets us scale up to a "Base" model, which provides a more significant boost. Note that using a "Base" model without pretraining does not provide the same performance improvement, likely because the existing datasets are simply too small for the model to take advantage of its increased capacity. Table 2 compares our best model to MT3 across all F1 metrics and shows that pretraining on monophonic mixtures leads to substantial improvements in the state-of-the-art. It's worth noting that MusicNet is now known to have many misalignements, that are likely the cause of the lower scores [13].

Model Size	# Pretrain Steps	# Finetune Steps	MAESTRO	Cerberus4	GuitarSet	MusicNet	Slakh	URMP
small (ours)	1M	0	.04	.00	.13	.03	.00	.19
base (ours)	500k	0	.03	.00	.12	.03	.00	.22
small (MT3)	0	525k	.28	.07	.19	.14	.02	.17
base (ours)	500k	1000	**.39**	**.11**	**.29**	**.17**	**.06**	**.33**

Table 4. Onset+Offset+Program F1 scores (considering pitch, instrument, and onset/offset times) using the LODO methodology, where each dataset in turn is held out from training and used only for evaluation. The first two rows use no finetuning, the third row is taken directly from Gardner et al. [20], and the fourth row uses a model pretrained on monophonic mixes and finetuned for only 1000 steps. LODO scores are lower for all datasets, but pretraining provides a considerable boost. This evaluation is somewhat unfair to Slakh as it contains instruments that do not appear in the other datasets.

Model	MAESTRO	Cerberus4	GuitarSet	MusicNet	Slakh2100	URMP
			Frame F1			
small (MT3)	.60	.55	.58	.53	.55	.76
base (ours)	**.65**	**.57**	**.69**	**.62**	**.64**	**.82**
			Onset F1			
small (MT3)	.28	.21	**.78**	.18	.14	.23
base (ours)	**.83**	**.54**	.71	**.48**	**.45**	**.54**
			Onset+Offset+Program F1			
small (MT3)	.28	.07	.19	.14	.02	.17
base (ours)	**.39**	**.11**	**.29**	**.17**	**.06**	**.33**

Table 5. Zero-shot transcription improvement over MT3 for Frame, Onset, and Onset+Offset+Program F1.

4.3 Zero-Shot Experiments

While standard in AMT, the methodology of the previous experiment is unsatisfactory in that for most real applications, we want to be able to automatically transcribe recordings from musical domains that were not present in our training data; splitting a homogeneously-constructed dataset into "training" and "test" partitions is not sufficient. This "out-of-domain" or "zero-shot" transfer is considered an extremely challenging task in AMT [13, 20]. We simulate the zero-shot condition with a leave-one-dataset-out (LODO) methodology, similar to the experiment described in the appendix of Gardner et al. [20].

For each of the five evaluation datasets or "folds" (since Slakh and Cerberus overlap we combine them into a single fold), we train a model on four of the folds and test on the other fold. This ensures that the model has not seen any data from the test domain during training, a much more difficult task as the model must be robust to a wider range of instrument timbres and recording conditions. Under LODO evaluation, Gardner et al. report an Onset+Offset+Program F1 score of less than 0.3 for all datasets, and less than 0.2 for all non-MAESTRO datasets.

Our results for the LODO evaluation are shown in Tables 4 and 5. Although our LODO F1 scores are lower than in the supervised case due to the difficulty of the task, pretraining on monophonic mixes increases the F1 score for all datasets. This is unsurprising, as our pretraining data exposes the model to a much wider range of instrument sounds and recording conditions. Possibly more surprising is that the pretrained model does very poorly without further finetuning on existing datasets (first two rows of Table 4); we have no satisfying explanation for this phenomenon and leave it to future work.

5. CONCLUSION

We have shown that we can take advantage of the relative ease of monophonic music transcription to improve upon the state of the art in multi-instrumental polyphonic music transcription by obtaining a large number of monophonic recordings, heuristically transcribing them, and mixing several of them together at a time as pretraining examples for a neural network model. This yields improvements across many datasets, in both standard and zero-shot multi-task settings. Notably, this pretraining boosts performance of downstream transcription models despite the fact that the pretraining audio is musically "incoherent", consisting of randomly-mixed monophonic audio tracks without regard to key, tempo, style, composition, or instrumentation.

Our work provides the first evidence that Internet-scale pretraining can be used to improve Transformer-based AMT models, and we do so with a simple set of heuristics that is straightforward to implement and fast to execute. While the benefits of large-scale pretraining for large Transformer models are well-known, the benefits of pretraining have yet to arrive to the AMT community, despite the wide availability of unlabeled audio data relative to the amount of audio with transcription-quality labels. We hope that the methods presented here, along with the accompanying open-source checkpoints and code, enable further advances in using large-scale audio data for scaling AMT models beyond the scope of existing supervised datasets.

ABSTRACT

An ideal audio retrieval system efficiently and robustly recognizes a short query snippet from an extensive database. However, the performance of well-known audio fingerprinting systems falls short at high signal distortion levels. This paper presents an audio retrieval system that generates noise and reverberation robust audio fingerprints using the contrastive learning framework. Using these fingerprints, the method performs a comprehensive search to identify the query audio and precisely estimate its timestamp in the reference audio. Our framework involves training a CNN to maximize the similarity between pairs of embeddings extracted from clean audio and its corresponding distorted and time-shifted version. We employ a channel-wise spectral-temporal attention mechanism to better discriminate the audio by giving more weight to the salient spectral-temporal patches in the signal. Experimental results indicate that our system is efficient in computation and memory usage while being more accurate, particularly at higher distortion levels, than competing state-of-the-art systems and scalable to a larger database.

1. INTRODUCTION

Audio fingerprinting is the principal component of an audio identification task. Finding perceptually similar audio in a massive audio corpus is computationally and memory expensive. Audio fingerprinting is a technique that derives a content-based audio summary and links it with similar audio fragments in the database. It allows for an efficient and quick search against other audio fragments. There are several possibilities for fingerprinting applications on digital devices, such as smartphones and TVs, that are becoming ubiquitous. Music identification on mobile devices, based on query-by-example, is a common use case in which a user hears a song in a public area and wants additional information about it [1, 2]. The second-screen service is another interesting fingerprinting application gaining attention [3]. It provides meta information of the broadcast content a user is watching/listening to on their devices. In addition, the broadcast sponsors also get benefits from informing viewers and listeners of their products and services. With the ease of music sharing across digital platforms, there is an increasing need to identify copyrighted content, a task which can also be accomplished by audio fingerprinting.

An audio fingerprinting system faces certain challenges for reliable audio identification in a real-world context. First, it should identify the query audio snippets corrupted with distortions such as background noise and reverberation. Secondly, the system must recognize audio using a few seconds of the audio snippet, which is crucial for fingerprinting systems embedded in digital devices to provide users with an interactive experience. Lastly, the system should generate fingerprints and search in a database in a computationally and memory-efficient manner.

In the past several decades, many audio fingerprinting systems have been developed for audio retrieval tasks. The fingerprinting method proposed by Wang *et al.* [4] (Shazam) is widely used. It captures a set of salient peaks in the audio spectrogram, assuming they remain unaffected under audio distortions. Further, these peaks are transformed into hashes to enable a fast search. Philips fingerprinting system [5] is another widely known approach that generates binary fingerprints based on energy changes across spectral-temporal space. However, this approach is computationally intensive. Another approach, named Waveprint, has been introduced in [6]. Waveprint computes the binary fingerprints using top-k wavelets and subsequently processes them using the Min-Hash technique to obtain the compact representations. This system deploys a fast indexing algorithm known as LSH (locality-sensitive hashing) for an efficient audio search. The system proposed in [7] utilizes pseudo-sinusoidal components to derive fingerprints robust against noise and reverberation. These systems, however, rely on handcrafted features that make it difficult to accurately identify the query audio when it is distorted with severe background noise and reverberation. Moreover, these systems require long (>5s) audio queries to deliver accurate results.

Deep learning, particularly unsupervised learning, has recently been introduced in the audio fingerprinting domain. [8] proposed SAMAF which utilizes a sequence-to-sequence autoencoder consisting of LSTM layers. Google's music recognizer system [9] trains a CNN based on the triplet loss function to generate compact audio fin-

gerprints. Another approach proposed in [10] trains a similar encoder as [9] using the contrastive learning framework and performs a maximum inner product search within a minibatch during training.

Typically, the audio is rich in content and contains irrelevant and redundant information that needs to be suppressed or eliminated to generate discriminative audio embeddings. This fact gives rise to the question of how to enable a CNN to capture the salient information in the signal and suppress the irrelevant ones. In this work, we seek to address this problem using the attention mechanism, inspired by their success in the audio domain [11, 12]. To this end, we propose to augment the resnet-like architecture with a channel-wise spectral-temporal attention mechanism. The temporal attention mechanism [13] has been widely employed in the recurrent neural networks to reweigh the recurrent output at different time indices and combine them to produce a meaningful feature vector at a particular time index. However, the spatial attention mechanism, i.e. attention on feature dimensions, has not been investigated earlier in the context of robust audio representations. Therefore, with the proposed approach, we aim to learn a multidimensional attention mask applied to the CNN features that assign more weight to the salient spatial patches and vice versa. As a result, we expect that the CNN will generate robust audio embeddings. In addition, our work focuses on performing a comprehensive search for our system to be applicable in audio synchronization tasks.

2. PROPOSED METHOD

Our work aims to generate embeddings for each audio segment of length L, extracted with a hop size of H from an audio track.

Our method builds on simCLR [14], a simple contrastive framework for learning visual representations. It maximizes the similarity between latent representations corresponding to an image under different augmented views using the contrastive loss function.

We employed this framework in the audio domain by mapping pairs of spectrograms corresponding to clean audio and the distorted one closer to one other in the latent space. In our work, the clean audio was distorted with signal distortions such as background noise and reverberation. Furthermore, a time offset was added to the distorted audio.

2.1 Audio Preprocessing

We randomly select a segment x_{clean} of length L from an audio track and resample it to a sampling rate of F_s for training the neural network model. Note that randomly chosen segments may be mostly silent and may thus not contribute to the training of the model. Moreover, such segments introduce errors in the retrieval process. Therefore, the segments with energy levels lower than a threshold t were discarded.

2.2 Data Augmentation pipeline

We generate a positive sample x_{pos} corresponding to each x_{clean} by stochastically applying a sequence of augmentations to x_{clean}. The following augmentations are considered:

- **Time offset**: A temporal shift of up to 40% of H is added to deal with the potential temporal inconsistencies in the real world situation.
- **Noise mixing:** A randomly selected background noise is added in the range of 0-25dB SNR.
- **Reverberation:** The audio segment is filtered with a randomly selected room impulse response to simulate the room acoustic environments.
- **SpecAugment:** Two randomly chosen time and frequency maskings are applied in the spectrogram. The width of the mask is set to 0.1% of their respective axis dimension. Moreover, this augmentation serves as a regularizer to prevent overfitting.

Layer	Input size	Output size
Encoder:		
CNN layer	1×64×96	32×64×96
ResBlock1	32×64×96	32×64×96
ResBlock2	32×64×96	64×32×48
...		
ResBlock6	512×4×6	1024×2×3
Flatten		6144
Projection Head:	$d * i$	$d * o$
Conv1D + ELU	128×48	128×32
Conv1D	128×32	128×1

Table 1. The proposed model employs a resnet-like architecture as the encoder and a projection head that maps the encoder output to a low-dimensional latent space. The projection head consists of 2 linear layers, each split into d branches with input size i and output size o. The model takes a log Mel spectrogram as the input.

2.3 Architecture

2.3.1 CNN encoder with Spatial-Temporal Attention

Residual networks [15] are characterized by skip connections that circumvent some intermediate layers and merge their input and output. The main advantage of such architectures is to prevent the vanishing gradient problem, which hinders training deep network architectures. Therefore, we propose a resnet-like architecture enhanced by the spatial-temporal attention mechanism that enables the CNN to learn discriminative audio representations.

Our proposed architecture contains a front-end that consists of a CNN layer and a resnet block with a kernel stride of 1x1 to retain the full temporal information since we want the discriminative embeddings to also be able to distinguish between fragments that have a similar timbre but different temporal evolution, for example adjacent audio

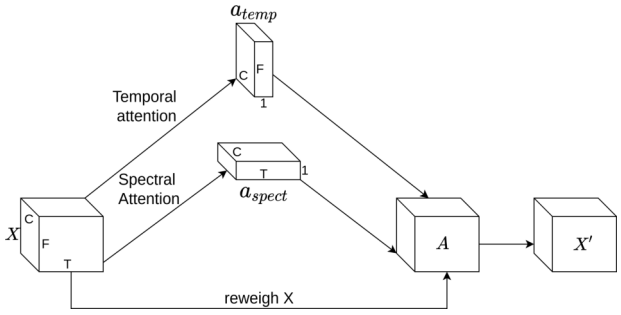

Figure 1. The illustration of spectral-temporal attention mechanism on input feature.

segments. Furthermore, the back-end consists of subsequent resnet blocks containing 2 convolutional layers. The spatial dimensions of each block are downsampled using a stride of 2x2, while the depth of each block is designed to be double of the preceding layer. Note that every convolution layer uses kernels of size 3x3, and a ReLU activation and batch normalization follows each convolution layer. The overall structure of the architecture is presented in Table 1.

CNNs have demonstrated their ability to extract complex features from low-level features, such as the log Mel spectrogram. However, the CNN features are translation-invariant, which implies that the spatial regions are treated equally in the feature map, which may not be useful in the audio context. Therefore, using the attention mechanism, we aim to enhance the interesting spatial patches by assigning more weight to time indices and frequency bands containing salient information and vice versa.

In order to apply the spectral-temporal attention mechanism, a channel-wise mask is computed and applied to the CNN features X of dimension $C \times F \times T$. We use two different attention weights, denoted by $a^{temp} \in \mathbb{R}^{C\times F\times 1}$ for temporal attention and $a^{spect} \in \mathbb{R}^{C\times 1\times T}$ for spectral attention that are modeled as:

$$\boldsymbol{a^{temp}} = \mathrm{softmax}(\boldsymbol{X^T W_{temp}}), \tag{1}$$

$$\boldsymbol{a^{spect}} = \mathrm{softmax}(\boldsymbol{X^T W_{spect}}), \tag{2}$$

where $\boldsymbol{W_{temp}}$ and $\boldsymbol{W_{spect}}$ are learnable weights. Furthermore, the spectral-temporal attention mask $\boldsymbol{A} \in \mathbb{R}^{C\times F\times T}$ is computed using the outer product between attention weights:

$$\boldsymbol{A} = \boldsymbol{a^{spect}} \otimes \boldsymbol{a^{temp}} \times S \tag{3}$$

where, S is a scaling factor to rescale the attention mask to enable easy gradient flow during model training. Finally, the CNN feature map is reweighted using the mask $\boldsymbol{A}$ as:

$$\boldsymbol{X'} = \boldsymbol{A} * \boldsymbol{X} \tag{4}$$

2.3.2 Projection Head

The final output of the CNN encoder is projected into a lower-dimensional latent space via a projection head. The fully connected layers in the projection head result in a large number of model weights. Therefore, as used in previous studies [9, 16], we utilize the split head to split the encoder output into d branches. Each branch is then passed through the corresponding linear layers and their final outputs are finally concatenated to generate a d-dimensional embedding, followed by L^2 normalization.

2.4 Contrastive Learning framework

We employ a contrastive learning approach [14] for training the model to map the similar audio samples closer together and pull away different audio samples. As discussed in Section 2.2, pairs of clean segments and their corresponding distorted versions are generated for training the model. These pairs are equivalent to the anchor and positive sample pairs as denoted in the simCLR framework. For each sample in a mini-batch of size N (N/2 pairs), there are N-2 negative samples since we also allow a positive sample to be an anchor sample in the batch. We train the proposed model using these pairs that are mapped into the latent space where the contrastive loss is formulated. We use the normalized temperature-scaled cross-entropy loss as devised in [14]:

$$\mathcal{L}_{\mathrm{i,j}} = -\log \frac{\exp(\mathrm{sim}(\mathrm{e_i}, \mathrm{e_j})/\tau)}{\sum_{\mathrm{k}=1}^{\mathrm{N}-1} 1_{[\mathrm{k}\neq\mathrm{i}]} \exp(\mathrm{sim}(\mathrm{e_i}, \mathrm{e_k})/\tau)}, \tag{5}$$

where, τ is a temperature hyperparameter that allows learning from hard negatives. The cosine similarity is used to calculate pairwise similarity.

2.5 Database-creation and Indexing

The trained model is used as a fingerprinter to extract fingerprints from the audio tracks. The fingerprint for a given audio track is generated as follows: First, we extract segments of length L with a hop size of H. These segments are pre-processed as mentioned in Section 2.1. Then, the audio segments are transformed into log Mel spectrograms and fed to the model to generate encoded embeddings. We term these embeddings as subfingerprints, which form a fingerprint of the entire audio track when stacked in the time–ordering sequence. Finally, we extract the subfingerprints of every audio segment in the database and link them with their corresponding timestamps and the audio identifier to create a reference database.

Finding the nearest neighbors for a sample in a d-dimensional space is not a trivial task (when *d>50*) [6]. Also, the brute-force search strategy in a massive database is computationally expensive. Therefore, we employ the Locality Sensitive Hashing (LSH) [17] to index the subfingerprints database. It allows for efficient retrieval by only comparing a fraction of the dataset to retrieve the exact match. Moreover, it adds the noise-robustness property to the retrieval process.

2.6 Retrieval process

This section describes the process of finding the closest matching audio snippet from an indexed database, given a

query audio snippet. For a given query audio, we follow the same procedure to generate subfingerprints as mentioned in the previous subsection. Suppose the query $Q = (q_m)_{m=1}^{M}$ is composed of M subfingerprints. We use LSH to retrieve the nearest match for each subfingerprint q_m, denoted as I_m (the index). To identify the closest matching audio track, we retain counts of the audio identifiers corresponding to the retrieved matches. The query audio is finally identified with the audio identifier with the maximum counts.

We also locate the precise timestamp of the query audio in the identified audio track. To accomplish this, we first eliminate the retrieved matches that do not belong to the identified audio track. Next, we generate the set of candidate sequences S_i of length M with their starting indices as $I_i = I_m - m$. Finally, we select candidate sequence S_i, which have at least 50% intersecting retrieved indices. The timestamp corresponding to I_i is chosen as the matching timestamp of query audio in the retrieved audio track.

3. EXPERIMENTAL SETUP

3.1 Dataset

- **Free Music Archival (FMA)** [18]: is an open, large-scale, and easily accessible dataset commonly used for various music information retrieval tasks. We used the *fma_large* and *fma_medium* versions of the dataset for model training and testing, respectively. There are 106k and 25k 30s audio clips in the *fma_large* and *fma_medium*, respectively. Note that we excluded the shared clips between both datasets for training the model.
- **Noises:** We used a range of real-world background noises for training and testing. We extracted the noise signals from database [1], which includes a wide range of sounds from the MUSAN corpus [19], for training the model. For testing the system, we used the ETSI database [2], from which we chose seven distinct background noises: Babble, Living Room, Cafeteria, Car, Workplace, Traffic, and Train Station.
- **Room Impulse Responses (RIRs):** We used real RIRs [1] corresponding to different acoustic environments, ranging from a small room to a large hall, for training the model. We selected six RIRs from Aachen Impulse Response Database [20] with t60 values ranging from 0.1s to 0.8s for testing the system.

3.2 Implementation details

We compared our approach with a baseline system [10] that generates fingerprints using an encoder similar to Now-Playing's [9] architecture and does a comprehensive search. To the best of our knowledge, it is the only method that employs a neural network model to generate robust audio fingerprints and performs better than conventional approaches. We chose the log Mel spectrograms as input to our model and the baseline method. Table 2 lists the experiments configurations used for developing our audio fingerprinting system.

Parameter	Value
Sampling rate (F_s)	16 kHz
Audio segment length (L)	960 ms
Energy threshold (t)	0 dB
log Mel spectrogram dimensions (F $\times$ T)	64 $\times$ 96
Subfingerprint hop length (H)	100 ms
Subfingerprint dimensions (d)	128
Batch size (N)	512
Scaling factor (S)	100
LSH configuration:	
Tables	50
Hash bits	18
Number of probes	200

Table 2. Experiments configurations

We trained the models with the Adam [21] optimizer for 150 epochs using the cyclic learning rate. The initial learning rate was 5e-4 and reached a maximum of 5e-2 in 40 epochs. We also tweaked the temperature hyperparameter in the [0.01-0.1] range and found no significant benefits. The model was trained on a single NVIDIA Tesla V100 GPU for about 40 hours.

We built a reference database of $\sim$7.3M fingerprints using the *fma_medium* dataset. We used LSH implementation [3] to index the generated audio subfingerprints. Furthermore, the retrieval performance was equivalent to the brute force search after fine-tuning the LSH, with less than a 0.1% drop in retrieval accuracy at various distortion levels.

3.3 Evaluation metric

We used the following metric for system evaluation at audio/segment level retrieval:

$$accuracy = \frac{n\ hits\ @\ top\text{-}1}{n\ hits\ @\ top\text{-}1 + n\ miss\ @\ top\text{-}1} \times 100 \quad (6)$$

Note that a match is declared correct for the segment level search if the located timestamp of the query in the correct retrieved audio is within $\pm$ 50 ms.

3.4 Search query

We used the *fma_medium* dataset to generate 10,000 search queries, which were randomly extracted from different audio tracks. To assess system performance at different distortion levels, we distorted queries with noise, reverberation, and a combination of both. To generate a noisy reverberant audio query, we first convolved both the audio and the noise signal with the RIR corresponding to a t60 level

[1] https://www.openslr.org/28/
[2] https://docbox.etsi.org/
[3] https://github.com/FALCONN-LIB/FALCONN

of 0.5s and then added both signals at SNR levels ranging from 0dB to 25dB. In addition, we created queries of lengths: 1s, 2s 3s, and 5s to test our system efficiency for varying lengths.

4. RESULTS AND DISCUSSION

In the following, we present the performance of our system under different distortion conditions. We compare our system with the baseline system as mentioned in the previous section and the Audfprint system.

4.1 VS. Baseline system

- **Noise:** Table 3 presents the performance of the systems in noisy conditions. It can be seen that our system performs better than the baseline system by a reasonable margin, particularly at the 0dB and 5dB SNR levels. Moreover, our system can precisely locate the timestamp with reasonable accuracy, given enough query length (>2s) in very high noise conditions too. The performance gap narrows with the increase in SNR level and becomes smaller from 20dB onwards. We noted that the performance gap between systems was less than 2% at SNR levels of 20dB and more, irrespective of the query lengths.

- **Reverb:** As can be seen in Table 4, the retrieval accuracy of the systems drops with an increase in t60 levels, i.e., high reverberant environments. Furthermore, we discovered that the reverberation causes embeddings correspondings to adjacent audio segments to be very similar, which is most likely the reason that the correct match was not found at the top-1 rank in many cases, which resulted in low retrieval performance of the system. Nevertheless, the presented results indicate that our system performs effectively even in high reverberation environments for short query snippets. The baseline system is quite effective in a low reverberation environment with more than 80% retrieval accuracy. However, its performance falls short at higher reverberations, even with long query snippets.

- **Noise and Reverb:** The systems were tested in a more challenging situation by considering a noisy and reverberant environment. As shown in Table 5, the performance of both systems degrades with the addition of reverberation compared to their performance under noisy conditions. Due to added reverberation, the retrieval accuracy of our system drops by around 15% at 0dB SNR, but it improves on the less noisy conditions. On the contrary, the baseline system performs poorly, particularly at 0dB SNR. Furthermore, the accuracy gap remains over 15% compared to its performance in noisy conditions, even at higher SNR levels. It indicates that our system is more resilient against noisy and reverberant environments than the baseline system.

Method	Query length (s)	0dB	5dB	10dB	15dB
Ours	0.96	**76.8**	**84.8**	**87.4**	**88.5**
Baseline		62.7	79.4	85.5	87.6
Ours	2	**82.7**	**90.8**	**93.2**	**94.1**
Baseline		71.1	86.5	90.4	92.0
Ours	3	**83.9**	**92.9**	**94.6**	**95.5**
Baseline		76.8	88.5	91.4	93.8
Ours	5	**85.8**	**93.9**	**94.7**	**96.8**
Baseline		79.8	89.4	91.5	94.2

Table 3. Top-1 hit rate (%) performance in the segment-level search for varying query lengths in noisy conditions.

Method	Query length (s)	0.2s	0.4s	0.5s	0.7s	0.8s
Ours	0.96	**85.1**	**84.1**	**78.8**	**83.3**	**74.4**
Baseline		78.4	75.5	67.5	75.1	62.2
Ours	2	**89.1**	**87.3**	**80.6**	**85.4**	**75.0**

Ours	3	**90.1**	**87.9**	**81.0**	**86.8**	**76.3**
Baseline		87.2	83.3	73.9	80.8	66.9
Ours	5	**91.2**	**89.6**	**82.6**	**88.4**	**77.4**
Baseline		87.8	84.3	75.1	81.9	67.6

Table 4. Top-1 hit rate (%) performance in the segment-level search for varying query lengths in reverberant conditions.

The above-stated results show that our system performs reasonably well with short query snippets in different distortion environments. Furthermore, it indicates that our system does not require long queries to achieve reasonable performance at higher distortion levels. However, the performance of the systems improves with the increase in the query length using our proposed simple yet effective sequence search strategy. Therefore, the system can be fed with longer queries to obtain more reliable results.

Attention mechanism effect: Based on system performance in a noisy reverberant environment, we examine the effectiveness of adding an attention mechanism to the model. Table 6 shows that the attention mechanism improves retrieval accuracy, particularly at low SNR levels, with small benefits at higher SNR levels. Furthermore, we noted similar results hold true in other distortion conditions, i.e., noisy and reverberant environments. These results support that the spatial-temporal attention mechanism enhances the CNN to generate robust audio embeddings.

Embedding dimensions: We examined the effect of the audio embedding dimension on the system performance using the 0.96s queries. We observe that shrinking the dimensions from 128 to 64 has little impact on the system, especially in the reverberant environment. However, in the noisy reverberant and noisy environments, retrieval

Method	Query length(s)	0dB	5dB	10dB	15dB

	0dB	5dB	10dB	15dB	20dB
Attention	60.3	76.6	81.3	82.8	84.6
No attention	52.4	68.1	75.7	79.9	82.3

Table 6. The effect of added attention mechanism on Top1-hit rate performance of the system in noisy reverberant environments for 0.96s long queries.

accuracy declines by 5.6% and 3.8% at 0dB SNR, respectively, whereas accuracy losses are minimal at other SNR levels. Furthermore, increasing the number of dimensions from 128 to 256 does not provide significant improvements. This investigation allows reducing dimensions further without a significant performance drop to resolve the space constraints problem.

Computational and Memory load: We further investigated the efficiency of our system based on its computational and memory requirements. The final size of the sub-fingerprints database is roughly 1.25GB, with 128 32-bit floating numbers representing each audio subfingerprint. We use the *Intel Xeon Platinum 8268* CPU to do an in-memory search due to the small database size. We report that the LSH takes about 0.01s to retrieve top-5 matches for a query subfingerprint. Moreover, our system takes about 0.25s to process a 3s long query and locate its timestamp in the identified reference audio. It is also worth noting that the retrieval process can be sped up by employing a parallel search method. Furthermore, there is scope for investigating the computation load reduction by storing subfingerprints in low-bit floating numbers without a significant drop in the retrieval accuracy.

4.2 VS. Audfprint

We also compare our system with the Audfprint [4] based on the Shazam method. We notice that Audfprint performs poorly in the segment level search, particularly at high distortion levels. Therefore, we only compare its performance with ours for the audio identification task. Moreover, its performance deteriorates with short query lengths; hence we present the retrieval results with 5s audio query snippets in Table 7.

It can be seen that our system delivers excellent retrieval accuracy, with over 95% accuracy under high distortion conditions. On the contrary, the Audfprint method performance degrades severely at high distortion levels, which indicates that our system also outperforms the conventional approach for the audio identification task. It should be noted that the Audfprint system uses a hash table to index the database, resulting in reduced fingerprint database size. Furthermore, the size of the database generated by Audfprint is around 400 MB, which is roughly three times less than ours.

Distortion	Method	0dB	5dB	10dB	15dB
Noise	Ours	**95.0**	**98.7**	**98.9**	**99.2**
	Audfprint	72.1	82.7	89.4	91.2
Noise+ Reverb	Ours	**84.3**	**96.8**	**98.5**	**98.9**
	Audfprint	64.8	79.4	87.2	92.3
		0.2s	0.4s	0.5s	0.7s	0.8s
Reverb	Ours	**99.2**	**99.5**	**98.9**	**99.6**	**98.7**
	Audfprint	96.1	94.6	81.8	89.6	40.2

Table 7. Top-1 hit rate (%) performance in the audio-level search in different distortion conditions.

5. CONCLUSION

This paper presents an audio fingerprinting system robust against high noise and reverberation conditions. Our work focuses on generating robust audio embeddings by employing a contrastive learning framework. Moreover, we propose to enhance CNN with the channel-wise spectral-temporal attention mechanism to reweigh the CNN features. This enables CNN to assign more weight to salient patches in the CNN features, resulting in discriminative audio embeddings. Furthermore, our system performs a comprehensive search to precisely estimate the timestamp of the query in the identified reference audio using a simple sequence search strategy, which makes our system applicable to audio synchronization tasks. Our system performs well compared to the baseline [10] and Audfprint [4] methods. Also, our system is computationally and memory-efficient due to the compact embeddings that make our system deployable on an extensive database. The future direction of this work is to obtain discrete audio embeddings to speed up the audio retrieval process.

6. ACKNOWLEGMENT

This work has been supported by the research grant(PB/EE/2021128-B) from Prasar Bharati. We would also like to extend our gratitude to IITK Paramsanganak for their GPU computing resources.

SIATEC-C: COMPUTATIONALLY EFFICIENT REPEATED PATTERN DISCOVERY IN POLYPHONIC MUSIC

Otso Björklund
University of Helsinki

ABSTRACT

The use of point-set representations of music enable repeated pattern discovery to be performed on polyphonic music. The discovery of patterns containing polyphony is also enabled by the use of point-set representations. The SIA and SIATEC algorithms discover repeated patterns in point-sets by computing maximal translatable patterns and their translational equivalence classes. While the algorithms are relatively efficient, their application to larger pieces of music is not viable due to quadratic space complexity. This paper introcudes a novel algorithm, SIATEC-C, for repeated pattern discovery in point-set representations of music. The algorithm discovers repeated patterns and finds all of their occurrences, while running with subquadratic space complexity. The algorithm can also provide significant running time improvements over the comparable SIATEC algorithm. The computational performance of the algorithm is compared with SIATEC. The accuracy of the algorithm is also evaluated on the JKU-PDD data set.

1. INTRODUCTION

This paper presents a novel algorithm for computationally efficient repeated pattern discovery in symbolically represented polyphonic music. The main contribution of the algorithm is efficient production of candidate patterns for a post-processing phase where the patterns can be refined, and musically unimportant patterns can be filtered out.

The goal of repeated *pattern discovery* is to find musically important patterns and their occurrences in a piece of music (*intra-opus*) or in a corpus (*inter-opus*). In repeated pattern discovery no query is given by the user unlike in *pattern matching*, where the goal is to find occurrences of a query pattern [1]. Decomposing a piece of music into its constituent elements is a fundamental part of music analysis [2]. Repeated pattern discovery can thus be applied to multiple problems in computational music analysis, such as motivic analysis [3, 4], tune classification [5], segmentation [6], and style analysis [7]. A compressed representation of a piece formed by its repeated patterns can even be considered an analysis of the piece [8, 9].

Björklund, "SIATEC-C: Computationally efficient repeated pattern discovery in polyphonic music", in *Proc. of the 23rd Int. Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

Repeated pattern discovery is a challenging problem due to certain characteristics of music. Repetition is prevalent in music causing algorithms that focus just on finding repetitions to output large numbers of patterns even for short pieces of music [4, 10]. Often most of the repeated patterns discovered by an algorithm do not correspond to patterns that have musical significance [11]. Instead of relying on repetition alone for discovering musically significant pattern, methods for identifying which patterns are musically important are needed.

The SIATEC-C algorithm presented in this paper improves upon the running time and space complexity of previous point-set algorithms by avoiding the computation of patterns with large temporal gaps and small patterns that are already included in a larger pattern.

2. RELATED WORK

String representations of music have been employed for both pattern matching and discovery in monophonic music. Monophonic music can be represented as a string for pattern matching [12] or a set of strings for pattern discovery [13]. String representations have been often used for mining *closed* patterns, that is, patterns that cannot be extended without reducing the number of occurrences [4, 10]. Monophonic music can also be represented as a pitch signal which enables the use of signal processing methods. Wavelet analysis is used by [14] for repeated pattern discovery in monophonic music.

Polyphonic music can be split into monophonic voices in order to use monophonic pattern discovery methods (e.g., in [13, 15]. Voice separation can be challenging if the voice information is not included, and using monophonic pattern discovery on separate voices cannot be directly used to discover polyphonic patterns or patterns that move from one voice to another, such as *call-and-response* patterns in jazz.

Point-set representations of music enable pattern matching [16] and discovery in polyphonic music [11] with patterns that can be polyphonic. Time-shifts and transpositions of a pattern can be performed by translating the points of the pattern by a vector. The SIA-family of algorithms (see [17] for an overview) discover repeated patterns in music by computing *maximal translatable patterns* (MTP) and finding their occurrences by computing the *translational equivalence classes* (TEC) for the patterns ([11]). The definitions of MTPs and TECs are covered in section 3.

The SIA algorithm by [11] computes all MTPs in a k-dimensional point-set of n points in $O(kn^2 \log n)$ worst-case time and $O(kn^2)$ space, and the SIATEC algorithm computes the TECs of all MTPs in $O(kn^3)$ worst-case time and $O(kn^2)$ space. The worst-case space complexity of computing all MTPs has been improved upon by [18] to $O(kn)$. Another variant of SIA is the SIAR algorithm by [19], which aims to improve the computational performance of MTP computation by restricting the number of difference vectors by a sliding window.

A musical pattern may be *time-warped* and *time-scaled*. [20] present an algorithm that can discover transposed and time-warped repeating patterns in a two-dimensional point-set of n points in $O(n^2 \log n)$ time. The algorithm by [21] can discover transposed and time-scaled repeated patterns in a two-dimensional point-set in $O(n^4 \log n)$ time.

The number of patterns discovered by computing MTPs can often be very large even for small point-sets [11]. Various approaches based on the use of *compression ratio*, *compactness*, and other heuristics have been developed for selecting the musically most important patterns from the set of discovered MTPs. The COSIATEC and SIATEC-Compress algorithms [9, 22] compute a compressed representation of a point-set. The algorithm by [23] similarly aims to compute a representation formed by musically important patterns. [24] further develops the idea of computing a highly compressed representation of a point-set by recursively splitting the input point-set and refining the TECs by removing redundant translation vectors.

MTPs can contain large temporal gaps, such that, the MTP may consist of a musically important pattern and additional points called *isolated members* [19, 25]. [19] proposes a solution to the problem of isolated membership by using an additional processing stage called *compactness trawling* to split MTPs into smaller patterns without isolated members. Post-processing MTPs with compactness trawling in SIA has been found to improve precision and recall [26] over plain SIA. Compactness trawling combined with the symbolic fingerprinting method presented in [27] have been employed in the SIARCT-CFP algorithm to discover inexact occurrences of repeated patterns with high precision and recall [28].

3. BACKGROUND AND DEFINITIONS

In a point-set representation of music, note events are represented as points and a piece of music is represented as a point-set $D \subset \mathbb{R}^k$, where k is the dimensionality of the points. Often $k = 2$, where the first dimension represents the onset time of a note event, and the second dimension represents the pitch of the note event. The rest of this paper assumes that the points are two-dimensional, and $p.x$ denotes the onset time and $p.y$ the pitch of a point p. The number of points in a point-set D is denoted by $|D|$ or n. By using only the onset time of the note events, patterns can be matched based on the *inter-onset-intervals* (IOI) of the adjacent notes. This allows for variations in the durations of the notes. The IOI between consecutive note events p_1 and p_2 is defined as the difference $p_2.x - p_1.x$.

A point-set can be sorted by using a *lexicographical ordering* [11]. A two-dimensional point p_1 is considered to be less than a point p_2, if and only if, $p_1.x < p_2.x$ or $p_1.x = p_2.x$ and $p_1.y < p_2.y$. Lexicographical ordering can be extended to points of any dimensionality. A lexicographically sorted point-set is denoted D_s.

A pattern $P \subset \mathbb{R}^k$ is also a point-set, and P is said to occur in D if $P \subseteq D$. Shifting a pattern P in time and transposing it can be expressed as translation by a vector t, where $t.x$ is the time shift and $t.y$ is the transposition. Translating a pattern P by a vector t is denoted $P + t$ [11]. The points in patterns are assumed to be in ascending lexicographical order in this paper.

The maximal translatable pattern, ***MTP***, of a vector t in a point-set D is defined by [11] as

$$MTP(t, D) = \{d \mid d \in D \wedge d + t \in D\}. \quad (1)$$

The MTP of t in D is formed by the set of all points ind D that can be translated by t so that the translated points are also included in D. Negating the translation t produces the same MTP, that is, $MTP(t, D) = MTP(-t, D)$ [11], therefore only MTPs for translations that are greater than the zero vector are considered. All difference vectors between points in a point-set referred to in this paper are also assumed to be greater than the zero vector. All MTPs in a point-set can be computed with the SIA algorithm [11].

There are at most $n(n-1)/2$ MTPs in a point-set with n points. This occurs when differences between any pair of points are distinct. Conversely, there are at least $n - 1$ MTPs in a point-set. The minimum number of MTPs occurs in a point-set where all points are placed on a line with a constant distance between adjacent points. These extreme cases are unlikely to occur in point-sets representing music, however, they are useful for analysis of algorithms that compute MTPs. A point-set with a minimum number of MTPs is denoted by D_{min} and a point-set with a maximum number of MTPs is denoted by D_{max}.

A pattern P may have multiple occurrences in a point-set D. The set of all occurrences of P in D is represented by the *translational equivalence class* (TEC) [11] of the pattern. Two patterns A and B are considered translationally equivalent if, and only if, there exists a translation t such that $A = B + t$. Translational equivalence of A and B is denoted by $A \equiv_{\mathrm{T}} B$. The translational equivalence of patterns can be compared using their *vectorized representations* [11]:

$$VEC(P) = \langle p_2 - p_1, p_3 - p_2, \ldots, p_l - p_{l-1} \rangle, \quad (2)$$

where p_i denotes the ith point of a lexicographically sorted pattern P of length l. Two patterns are translationally equivalent if and only if their vectorized representations are equal [11]. The TEC of a pattern P in a point-set is the set of all subsets that are translationally equivalent to P:

$$TEC(P, D) = \{Q \mid Q \equiv_{\mathrm{T}} P \wedge Q \subseteq D\}. \quad (3)$$

The SIATEC algorithm can be used to compute the TECs of all MTPs in a point-set [11]. The TEC of a pattern P

can be represented by storing one occurrence of the pattern and the translation vectors required to produce all other occurrences of P [11].

4. THE SIATEC-C ALGORITHM

The SIATEC-C algorithm computes TECs of patterns in a point-set D, such that, the IOI between adjacent points in a pattern is at most a given threshold δ. SIATEC-C also avoids producing small patterns when the points covered by the pattern are already covered by a larger discovered pattern. SIATEC-C thus avoids producing patterns with isolated members while reducing the running time and memory footprint. This approach aims at similar results as compactness trawling in [19]. Cutting patterns at large IOI gaps has also been suggested in [29].

The outline of SIATEC-C is described in algorithm 1. The pseudocode aims at a concise presentation of the algorithm. A more thorough pseudocode description and a reference implementation of the algorithm that covers all details is also made available [1]. The algorithm takes as its inputs a point-set D and the IOI thershold δ. The first components of the points are assumed to represent to onset times of note events. The algorithm outputs the discovered patterns and all of their occurrences represented as TECs.

The algorithm begins by sorting the input point-set in ascending lexicographical order to produce the point-set D_s. The variables T and W are used for tracking a sliding window for each point in D_s in the onset dimension. The sliding windows are used in computing MTPs in order to restrict the number of MTPs that need to be kept in memory simultaneously. The array T keeps track of the index from where to continue computation on each iteration, and the array W keeps track of the upper bounds of the windows. The indexing in the pseudocode starts at 1 and array access is denoted by brackets. For T the value at index i stores the index in D_s for where the next sliding window starts. The value at index i of W stores the upper bound of the sliding window for the ith point of D_s. The indices in T are initialized to the range from 1 to n (line 4) and on line 5 the upper bounds are initialized for each point $p \in D_s$ to be $p.x + \delta$. The values in the array C keep track of the size of the largest pattern occurrence that covers the corresponding point in D_s.

The *difference index* structure I is computed by the COMPUTEDIFFINDEX function. Difference vectors between all pairs of points, p_i and p_j, for which the IOI between the points does not exceed the theshold δ, are computed. The differences along with the index-pairs $\langle i, j \rangle$ are stored in the intermediate array I'. The array is sorted in ascending lexicographical order by the difference vectors and indices. The sorted array is partitioned by the difference vectors, so that an array of entries of the form $\langle v, [\langle s_1, t_1 \rangle, \ldots, \langle s_i, t_i \rangle] \rangle$ is created. Each entry contains a difference vector v and the corresponding *source* and *target* indices. The source indices s_i are the indices of points in D_s that can be translated by v within D_s, and the corresponding target indices are of the points that are produced by translating the point at the source index by v. The index structure I is sorted in ascending order of difference vectors and all source and target indices for an entry are also in ascending order.

Algorithm 1 SIATEC-C Algorithm

```
1:  function SIATEC-C(D, δ)
2:      D_s ← SORT_Lex(D)
3:      n ← |D_s|
4:      T ← [1, 2, ..., n]
5:      W ← INITWINDOWBOUNDS(D_s, δ)
6:      C ← [0, 0, ... 0] of n zeros
7:      I ← COMPUTEDIFFINDEX(D_s, δ)
8:      while T[1] ≤ n do
9:          M ← COMPUTEMTPS(D_s, T, W)
10:         M' ← CUTANDSORT(M, δ)
11:         for P ∈ M' do
12:             if IMPROVESCOVER(P, C) then
13:                 FINDTRANSLATORS(P, I, D_s, C)
14:                 OUTPUTTEC
```

In the main loop of the SIATEC-C algorithm (lines 8–14 of 1), MTPs are computed for translation vectors within the sliding windows by the COMPUTEMTPS function. The MTPs are computed by first computing all translations between pairs of points where the target point is within the sliding window of the source point. The indices of the source points are stored in pairs with the translations. The array thus produced is sorted in ascending lexicographical order and partitioned by the translation vectors. The function is otherwise equal to the SIA algorithm [11], except that the difference vectors are limited by the sliding windows defined by the arrays T and W, and the indices of the MTP and its translated occurrence are also stored. The sliding windows are used to avoid keeping all $O(n^2)$ differences in memory at the same time. On each iteration the indices in T are updated to the point just outside the current window and then the sliding window upper bounds in W are incremented by δ.

The produced MTPs can have gaps in them that exceed the threshold δ. Thus the MTPs are cut on line 10 to produce the set of patterns M', where the IOI between no adjacent patterns points exceeds δ. The patterns are also sorted in descending order of size to ensure that larger patterns are handled first. The function IMPROVESCOVER checks if the pattern, or its translated version, is larger than any of the patterns that cover the same points. A pattern is considered to improve the cover only if it improves the cover value of at least one point. This step reduces the number of small and duplicate patterns that would be otherwise output by the algorithm. Small patterns may be output by the algorithm even if a larger pattern covering the same points is discovered. This occurs in the case that the small pattern is found on an earlier iteration of the main loop (lines 8–14).

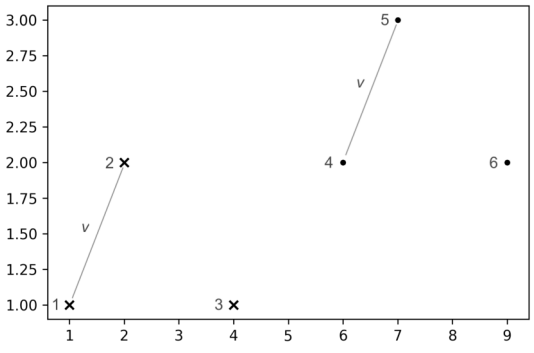
4.1 Finding translators

Finding the translators of a pattern P is achieved by traversing the index-pairs stored in I using the vectors of the vectorized representation $VEC(P)$. This is equivalent to finding translationally equivalent prefixes of P and extending the prefixes until they are equal in length to P.

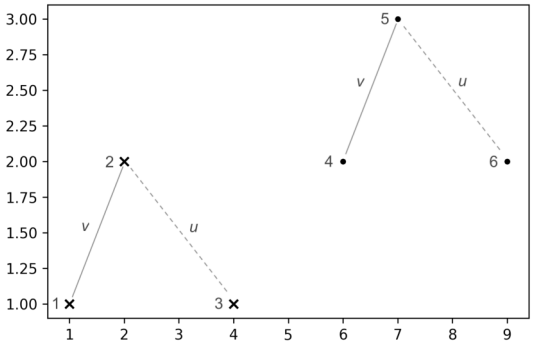
Algorithm 2 SIATEC-C: Find translators and update cover

```
1:  function FindTranslators(P, I, D_s, C)
2:      V ← VEC(P)
3:      v ← V[1]
4:      A ← { t | ⟨s, t⟩ ∈ FindIndices(v, I) }
5:      for i ∈ [2, ..., |V|] do
6:          v ← V[i]
7:          A′ ← FindIndices(v, I)
8:          A ← { t | ⟨s, t⟩ ∈ A′ ∧ s ∈ A }
9:      l ← P[|P|]
10:     τ ← { D_s[i] − l | i ∈ A }
11:     C ← UpdateCover(P, A, C, I)
12:     return τ
```

Figure 1 illustrates the process of finding the translators of a pattern P, $VEC(P) = [v, u]$ with a very minimal point-set example. The crosses and points form two three-point patterns that are translationally equivalent. First binary search is used to find the index pairs for v from I, returning the index pairs $[\langle 1, 2\rangle, \langle 4, 5\rangle]$. The second elements of these pairs are the indices of points that can be translated with u to continue translationally equivalent prefixes of P. On the next iteration the index-pairs associated with u are retrieved producing the index-pairs $[\langle 2, 3\rangle, \langle 5, 6\rangle]$. The target indices 2 and 5 of the vector v are matched with the source indices of u to find that the translationally equivalent prefixes can be extended with the points at indices 3 and 6 to find the last points of translationally equivalent occurrences of P. The translators can be computed simply as the difference between the last points of the found occurrenc es and the last point of P.



(a) Step 1: Prefix of length 2



(b) Step 2: Prefix of length 3

Figure 1: FindTranslators example

4.2 Time and space complexity

The following theorems present the worst case time and space complexity of SIATEC-C.

Theorem 4.1. *Let D be a 2-dimensional point-set with n points. Let m be the largest number of points in any span of length δ in the onset dimension and let h be the number of points in the largest MTP in D. Then the worst case time complexity of* SIATEC-C *is $O(hn^2 \log nm)$.*

Proof. Computing the difference index I requires computing $O(nm)$ difference vectors, sorting them, and partitioning. Thus ComputeDiffIndex runs in $O(nm \log nm)$ time.

The number of iterations the main loop on lines 8–14 of algorithm 1 executes is approximately $\frac{n}{\delta} = O(n)$. Computing the MTPs requires also computing $O(nm)$ difference vectors, sorting and partitioning them into MTPs, and then sorting the MTPs by size, thus running in $O(nm \log nm)$ time. However, the total amount of computation required to compute MTPs in the loop performs the same number of difference vector computations and comparisons as computing all MTPs and sorting them by size, thus the total amount of work needed for MTP computation during the execution of the algorithm is $O(n^2 \log n)$ just as in SIA [11].

For a pattern P, the size of its vectorized represenation is $|P| - 1$. The FindTranslators function is thus run on $O(n^2)$ difference vectors in total. For each difference vector, the loop finds the index pairs from I in $O(\log nm)$ time using binary search and computes the intersection of A with the source indices in A'. The number of index pairs that can be found for a difference vector v in I is equal to the size of the largest MTP in D, denoted by h. Thus computing the intersection of sorted arrays is linear in h, resulting in time complexity of $O(h \log nm)$ for a single difference vector in P. Overall, finding all translators for all produced patterns has a worst case time complexity of $O(hn^2 \log nm)$.

The overall worst case time complexity of the algorithm is thus dominated by computing the translators, resulting in a worst case time complexity of $O(hn^2 \log nm)$.

□

Theorem 4.2. *Let D be a 2-dimensional point-set with n points, and let m be the largest number of points in any span of length δ in the onset dimension. Then the worst case space complexity of* SIATEC-C *is* $O(nm)$.

Proof. Computing the difference index I requires storing $O(nm)$ difference vectors and corresponding index pairs, and after partitioning the number of difference vectors and index pairs does not increase. Therefore I takes $O(nm)$ space.

On each iteration of the main loop on lines 8–14 of algorithm 1 the MTP computation requires keeping $O(nm)$ difference vectors in memory.

In the FINDTRANSLATORS function the number of index pairs contained in A or A' is at most the equal to the size of the largest MTP in D. Therefore the space complexity of FINDTRANSLATORS is $O(n)$.

The space complexity of SIATEC-C is dominated by I and the MTP computation, therefore the worst case space complexity is $O(nm)$. □

5. RESULTS

This section contains the computational performance results of the SIATEC-C algorithm and its evaluation on the JKU-PDD dataset.

5.1 Computational Performance

The running time and memory usage of the SIA, SIAR ($r = 1$), SIATEC, and SIATEC-C algorithms was measured on two types of point-sets: D_{min} and random patterns. The point-set sizes ranged from 1000 to 10000 in increments of 1000. The D_{min} dataset was chosen as it produces the worst-case running time of SIATEC-C and can thus provide an estimate of the upper bound of running time and memory usage. Random patterns were used instead of concatenating short pieces of music together to control the sizes of MTPs in the benchmark data.

The algorithms were implemented using the Rust [2] programming language. The measurements were performed on a machine running Ubuntu 20.04 with an Intel i7-processor and 16GB of memory. The IOI threshold parameter δ of SIATEC-C was set to a 50.0 for the artificial point-sets, for music point-sets $\delta = 4$ was used throughout, corresponding to one measure in $\frac{4}{4}$ time.

The measurements for running times are plotted in figure 2 and the maximum heap usage measurements are plotted in figure 3. Log-scale is used on the y-axis as the measurements vary greatly in the range of values. The most significant running time improvements SIATEC-C can provide compared to SIATEC can be seen in the plot for the running time on the random pattern point-sets. Even with the largest point-sets, the running time of SIATEC-C is $22.2s$, while the running time of SIATEC exceeds $2500s$. On random pattern point-sets SIAR is the fastest algorithm.

In the case of the D_{min} point-sets the running time of SIATEC and SIATEC-C behaves relatively similarly. With SIAR the D_{min} produces worst-case performance leading the performance of SIAR to be comparable to that of SIA. This is explained by the worst-case time complexity of SIAR, which on a k-dimensional point-set of size n is $O(kn^3)$ [30].

The memory usage was measured using the Heaptrack software [3] that only measures heap memory. With the largest random patterns point-set SIATEC-C uses only $26.08MB$ and with the largest D_{min} point-set $78.20MB$.

On the random patterns point-sets SIAR runs with the smallest memory footprint. However, the D_{min} point-sets illustrates the quadratic space complexity of SIAR [30], with the memory footprint of SIAR exceeding that of SIATEC-C. Thus replacing SIA with SIAR in SIATEC will not guarantee a smaller memory footprint than can be obtained with SIATEC-C.

SIAR can be a very performant algorithm on many point-sets, however, its performance varies greatly depending on the size of the largest MTPs in the input point-set. In order to investigate the impact of the worst-case time and space complexities between SIATEC-C and SIAR, both algorithms were run on a point-set representation [4] of Beethoven's 9th symphony ($n = 107,355$). SIATEC-C ($\delta = 4$) ran in approximately 28 minutes with peak heap usage of $1.97GB$ while SIAR ($r = 1$) ran in approximately 1 hour 7 minutes with peak heap usage $5.64GB$. While SIAR can be the most performant algorithm on small point-sets, due to its worst-case time and space complexity there is no guarantee that it will be the most performant on large point-sets.

5.2 Evalution on JKU-PDD

The accuracy of the SIATEC-C algorithm was evaluated on the JKU-PDD data set [31]. A version of SIATEC-C without any post-processing was evaluated to investigate whether it is capable of achieving establishment precision and recall comparable to other point-set algorithms that have been shown to benefit from post-processing, e.g., compactness trawling [26, 28].

The COSIATEC and SIATECCompress compression algorithms [22] produce a compressed representation of the input point-set by selecting TECs produced by SIATEC. The algorithms COSIATEC-C and SIATEC-CCompress are otherwise equal to COSIATEC and SIATECCompress except they use SIATEC-C instead of SIATEC for producing TECs.

Table 1 displays the mean values of the MIREX metrics over the monophonic and polyphonic corpus of JKU-PDD. Compared to SIATEC and SIAR, SIATEC-C produces fewer patterns and achieves slighlty improved establishment precision and recall.

6. DISCUSSION AND CONCLUSION

In this paper we have presented a novel algorithm SIATEC-C for repeated pattern discovery in symbolic polyphonic

music. The algorithm is based on previous research on repeated pattern discovery in polyphonic music using point-set representations of music [11].

The SIATEC-C algorithm can provide significant running time improvements over SIATEC in discovering patterns and their occurrences when the input consists of patterns that vary in size. In terms of worst-case performance, SIATEC-C does not provide improvements over SIATEC in running time. The most significant improvement SIATEC-C can provide in terms of computational efficiency is its small memory footprint, in which SIATEC-C can outperform SIAR. By keeping the memory usage small, repeated pattern discovery based on point-set representations can be applied to much longer pieces of music than previously.

The simple heuristic of cutting patterns at large IOI gaps in SIATEC-C was found to perform at least as well as the MTP-TEC computation performed by SIATEC in terms of precision and recall. Using SIATEC-C as the TEC algorithm for the compression algorithms COSIATEC and SIATECCompress did not improve their precision or recall. A different approach to filtering and refining the patterns produced by SIATEC-C is thus needed.

The version of SIATEC-C presented in this paper uses the size of patterns as a means of prefiltering. The cover array approach can also be used with other measures that can be computed for a point-set pattern, such as compactness [11, 22]. Evaluating the musical importance of a pattern is a challenging problem. As SIATEC-C also finds all occurrences of the patterns it discovers, the algorithm can be extended with various pattern filtering methods.

7. ACKNOWLEDGEMENTS

ABSTRACT

Self-supervised learning has steadily been gaining traction in recent years. In music information retrieval (MIR), one promising recent application of self-supervised learning is the CLMR framework (contrastive learning of musical representations). CLMR has shown good performance, achieving results on par with state-of-the-art end-to-end classification models, but it is strictly an encoding framework. It suffers the characteristic limitation of any encoder that it cannot explicitly combine multi-timescale information, whereas a characteristic feature of human audio perception is that we tend to perceive all frequencies simultaneously. To this end, we propose a generalization of CLMR that learns to extract and explicitly combine representations across different frequency resolutions, which we coin the tailed U-Net (TUNe). TUNe architectures combine multi-timescale information during a decoding phase, similar to U-Net architectures used in computer vision and source separation, but have a tail added to reduce sample-level information to a smaller pre-defined number of representation dimensions. The size of the decoding phase is a hyperparameter, and in the case of a zero-layer decoding phase, TUNe reduces to CLMR. The best TUNe architectures, however, require less training time to match CLMR performance, have superior transfer learning performance, and are competitive with state-of-the-art models even at dramatically reduced dimensionalities.

1. INTRODUCTION

Representation learning is a fast-moving sub-field of machine learning that seeks to distill information encoded in different types of input signals into less noisy abstract representations that are suitable for various downstream tasks. Such representations, which are learned without explicit supervision, have been successfully applied to a broad variety of musical and non-musical task domains [1], including audio tagging [2, 3] and speech recognition [4]. After self-supervised training, the learned representations are then evaluated by *probing*, a term originating from natural language processing [5–7]. In MIR, probing is also known as shallow network training or transfer learning [2, 8–13]. When probed, these self-supervised learning methods perform comparably to end-to-end trained models [3, 14, 15].

One of the more common learning architectures used for MIR tasks is the convolutional neural network (CNN) [16–19]. CNNs typically consist of either only an encoder path or an encoder and decoder path. One distinctive CNN with both an encoder *and* a decoder path model is the U-Net, consisting of variants of the encoder and decoder paths called contractive and expansive paths. Our work focuses specifically on adapting the U-Net architecture [20] to representation learning. To the best of our knowledge, there is little to no published research in computer vision, MIR, or signal processing that has considered the potential of U-Nets for representation learning.

U-Nets originated from the field of biomedical image segmentation, where they were introduced with the goal of being more data-efficient and less time-consuming to train for segmentation tasks, while also being able to perform well with relatively few data points and in the presence of class imbalance [20, 21]. U-Net architectures have shown top performance in segmentation, winning the ISBI cell tracking contest by a large margin in 2015 [20]. One of the arguments for how well U-Net architectures perform is the way the contractive and expansive paths allow the network to incorporate features across multiple resolutions.

U-Nets have also been shown to perform well within the audio domain. Their application to source separation in the time-frequency domain yielded state-of-the-art results [22], after which the U-Net established itself for source separation in the raw audio domain as well [23]. In raw audio and speech generation, U-Nets perform on par with Wavenet [24], with fewer parameters and faster inference [25]. We are also motivated to explore U-Net-like architectures for representation learning because of their intuitive relation to the *slow feature hypothesis* [26], which states that much of the meaningful information contained in signals changes gradually, over larger timescales. Without requiring a formal transformation to the frequency domain, U-Net architectures can extract these slow features alongside fine-grained high-frequency information by encoding and combining features across multiple timescales [25].

Given the scarcity of publicly available labelled data in MIR, we focus further on U-Nets for *self-supervised* learning. Specifically, we adapt the contrastive semi-supervised learning method from CLMR [3], since this has shown great promise on label training efficiency and generalisability of learned representations to out-of-domain MIR datasets. Specifically, we generalise the SampleCNN [27] en-

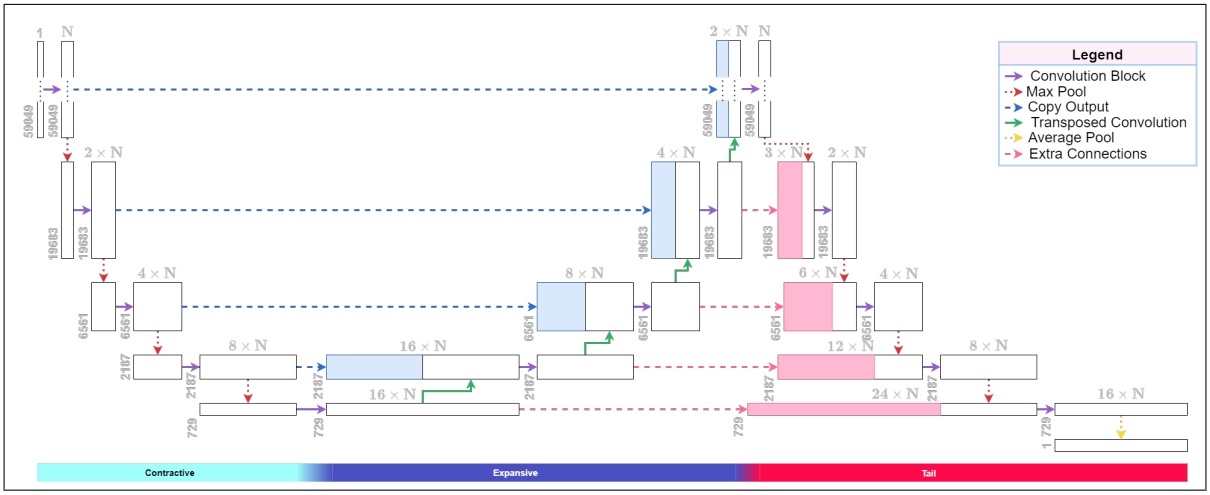

Figure 1: The TUNe architecture extracts features containing information obtained at multiple timescales. To this end, it consists of three main components: (1) the *contractive path* iteratively extracts features at a given timescales and reduces the signal resolution; (2) the *expansive path* upsamples the extracted features at lower resolutions and concatenates them into higher-resolution features than those obtained from the contractive path; and finally, (3) the *tail* combines the features extracted at multiple timescales and reduces their spatial resolution, ultimately yielding a single, low-dimensional, multi-timescale representation for an input signal.

coder architecture used in CLMR with a new architecture we dub the *tailed U-Net* (TUNe). TUNe architectures are like U-Net architectures, but with an additional contractive path – the tail – extending the original architecture by a mapping from a representation at the input resolution to a reduced latent representation size (see Figure 1). Intuitively, the 'U' shape of the network extracts a representation at the original temporal resolution, encoding a combination of slow feature patterns with higher-frequency components from the input signal, whereas the tail learns temporally reduced patterns from this enriched signal.

Our main contribution is this novel angle for the use of U-Nets for representation learning on signal data. Furthermore, we investigate a number of architectural setups with different model sizes to assess the performance and parameter efficiency of TUNe networks. In order to evaluate the learned representations, we transfer them to a range of benchmark MIR tasks, showing competitive performance with a drastically shortened training regime, parameter count, and representation dimensionality.

2. RELATED WORK

State-of-the art algorithms for audio-based MIR tasks (e.g., chord recognition, key detection, and music audio tagging) are generally built on one of three input forms: (1) time-frequency representations of the audio signal, (2) raw time-domain audio, or (3) a combination of raw audio and time-frequency representations [28]. Among the top-performing raw audio input architectures are musicCNN [2], JukeBox [29], and SampleCNN [27]. SampleCNN was introduced for raw audio classification and later adapted for CLMR's contrastive learning setting. We use CLMR's version of SampleCNN as a reference point for both performance and number of parameters. Moreover, the TUNe convolution blocks introduced in Section 3 are based on the filter–stride–max pooling operation used in SampleCNN, which downshifts the effective frequency range modelled by the convolution kernels applied in subsequent layers. Note that because of this use of pooling operations, much high-frequency information is discarded in the extraction of the encoding from the input. Instead, our proposed approach explicitly combines these subsampled lower-frequency features with high-frequency features obtained at the original temporal resolution.

For a range of benchmark MIR datasets, CLMR is currently the best-performing self-supervised model that does not require industry-scale hardware to train [14]. It is a self-supervised learning framework, and as such, it requires no labelled data for training. Specifically, it is a contrastive learning framework: given two similar inputs to the network (e.g., two segments from the same song), the loss function is designed to ensure that the learned representations of these samples should lie closer to each other than the representations of samples from two different songs. CLMR also includes music-specific data augmentations to ensure a robust representation learning framework for MIR, for example, transposing the pitch of a segments up or down and still instructing the network to predict a closer distance to the original fragment than to the other audio segments in the batch. Because mapping the representations with a projector head instead of directly using the network representation results in a better representations [30], the output layer is replaced with an identity function and a projector head is added to the models trained with CLMR.

3. TAILED U-NET ARCHITECTURES

The architecture for representation learning we explore in this work is based on the traditional U-Net [20]. The U-

Net's success on segmentation tasks has been argued to come from its explicit extraction of features at multiple resolutions, which allows it to respond to fine-grained features as well as long-range dependencies in the input. In representation learning for audio, we are interested in constructing encodings which similarly carry both high- and low-frequency information. Because U-Nets were originally designed for image segmentation, however, variants of the architecture traditionally produce an output at the spatial resolution of the input: $\mathbb{R}^{I \times C}$ where I is the input length and C the number of classes given by the task. Representation learning models, on the other hand, aim to decouple the dimensionality of the representation from the temporal resolution of the original input signal, to accommodate usage in a wide variety of downstream tasks. They typically output a single representation: $\mathbb{R}^{R}$ with R the size of the representation. To address this mismatch, we propose adding a tail module to the U-Net. The tail module serves (1) to combine enriched sequence length representation obtained at multiple resolutions in the contractive and expansive path, and (2) to reduce the resolution of these features to a single compact multi-timescale representation. See Figure 1 for an overview of our architecture.

In addition to the tail module, we introduce another improvement on the TUNe architectures: TUNe+. TUNe+ networks have additional connections between the expansive and tail path (the pink arrows and blocks in Figure 1). This explicit transfer of information at lower resolutions should allow for better multi-timescale feature information flow, further improving the obtained representations.

3.1 Contractive Path

The contractive path of the network is built from a block consisting of a convolution, a batch normalisation layer, and a ReLU activation function, following CLMR's encoding architecture [3]. This block is repeated N_{con} times (default 4). In Figure 1, this block is indicated with purple arrows. The output of this block is saved to combine with the corresponding expansive block later. After each block, max pooling is applied to extract the most prominent patterns at a given resolution, represented by the red arrows in Figure 1. The output of the max pooling is then passed on either to the next layer in the contractive path or, after the N_{con}-th block, to the beginning of the expansive path. Every layer in the encoder path doubles the amount of channels. The convolution operation is performed with a kernel size of 3 and a stride of 1, and the max pooling operation with a kernel size of 3 and stride of 3. Furthermore, the convolution operation is applied on a padded input, such that input and output to the convolution are of equal sequence length.

3.2 Expansive Path

Whereas each layer of the contractive path reduces the signal resolution, the expansive path of the network is made up of blocks that are paired with blocks from the contractive path, each one gradually *increasing* the signal resolution again. The expansive path block, which is repeated N_{exp} times (default 4), consists of a strided transposed convolution, represented by the green arrows in Figure 1, with a kernel size of 3, stride of 3, and 0 padding, to keep the dimensionality the same as the output of the contractive block at the same depth. The output of each strided transposed convolution is concatenated with the output of its pair from the contractive path (see the blue arrows leading into the blue-and-white blocks in Figure 1). Next, a convolution followed by batch normalisation and ReLU activation is used to combine the multi-scale features in the concatenated outputs. The upsampling by strided transposed convolution enables the network to combine lower frequency features with the higher frequency information obtained at higher resolutions in the contractive path. The input–output channel ratio for the strided transposed convolution is 2:1, and for the convolution block is also 2:1, because of the concatenation of the encoder block and strided transposed convolution output.

3.3 Tail

The blocks in the tail of a TUNe model are identical to the blocks of the contractive path, each of the N_{tai} blocks (default 4) doubling the number of channels until the representation size is reached. In a TUNe+ model, the tail blocks differ from the contractive path blocks because TUNe+ tail blocks are paired with blocks from the expansive path. As illustrated by the pink arrows in Figure 1, each TUNe+ tail block combines the output of the previous tail block with the output of the expansive block at the same resolution. The input–output channel ratio in this case is 3:2, because the input gets ⅔ of the input channels from the expansive path and ⅓ from the previous tail block. Depending on the number of downsampling steps in the tail module, any remaining temporal dimensions O are projected to a single representation using average pooling, mapping from $\mathbb{R}^{O \times R}$ to $\mathbb{R}^{R}$ with R the representation size. This operation is indicated by the yellow arrow in Figure 1.

The TUNe network architecture allows for flexible network adjustments. When removing all tail layers the resulting TUNe is equivalent to the original U-Net. If all expansive layers are removed there is no way to distinguish contractive and tail layers, and adding six contractive or tail layers is equivalent to CLMR. Since the output does not have to end with the same dimensionality as the input, one can add and remove contractive, expansive, or tail layers without needing to add or remove layers along the other paths. We leverage this compositionality to conduct experiments with the TUNe architecture that explore representations built up over a differing number of timescales, in order to explore the impact of the structure of each respective module on the capacity of the resulting representation to perform in downstream tasks.

4. EXPERIMENTS

To explore the validity and performance of our proposed setup, we trained multiple TUNe architectures with varying path lengths for 1000 epochs on the MagnaTagATune

Variant	N_{con}	N_{exp}	N_{tai}	Filters	Parameters (M)	MTT_{AUC}	MTT_{AP}
Vanilla TUNe	4	4	4	34	2.4	87.7	33.0
TUNe Contractive+1	5	5	4	18	2.3	88.3	33.9
TUNe Contractive+2	6	6	4	9	2.1	88.6	34.6
TUNe Contractive+3	7	7	4	4	1.7	88.0	33.5
TUNe Expansive-1	4	3	3	34	2.3	87.6	33.0
TUNe Expansive-2	4	2	2	35	2.4	87.7	33.1
TUNe Expansive-3	4	1	1	38	2.3	87.6	33.0
TUNe Tail+1	4	4	5	28	2.3	88.2	34.4
TUNe Tail+2	4	4	6	19	2.3	88.7	35.2
TUNe Tail+3	4	4	7	15	2.3	89.1	36.5
TUNe Tail+4	4	4	8	13	2.3	89.2	36.6
TUNe Tail+5	4	4	9	11	2.1	89.2	36.5
TUNe CLMR-tail	4	4	10*	10*	2.5	89.4	36.7
TUNe+	4	4	9	11	2.2	89.2	36.6
Vanilla TUNe Small	4	4	4	11	0.4	86.8	31.9
TUNe+ Large	4	4	9	34	7.4	89.4	37.1
TUNe+ Smaller Rep	4	4	9	11	1.4	89.2	36.1
musicnn 10 000 [2]	-	-	-	–	11.8**	90.7	38.4
TUNe Tail+5 10 000	**4**	**4**	**9**	**11**	**2.1**	**89.5** (**89.6**)	**37.0** (**36.7**)
TUNe+ 10 000	**4**	**4**	**9**	**11**	**2.2**	**89.3** (**89.8**)	**37.1** (**37.1**)
CLMR 10 000 [3]	10	0	0	–	2.4	88.7 (89.3)	35.6 (36.0)

Table 1: TUNe variant performance on the MagnaTagATune (MTT) tag prediction task with number of parameters and number of initial filters. The performance is measured after 1000 epochs (except where noted otherwise) with the area under the receiver operating characteristic curve MTT_{AUC}, and the average precision, MTT_{AP}. The table is divided into six sections: the Vanilla TUNe model with no layers added; the results of adding contractive layers; the results of removing expansive layers; the results of adding tail layers; the results parameter-efficiency experiments; and the results of the best TUNe models and the CLMR baseline after training for 10 000 epochs. In addition to the shallow probe, we trained a probe with an extra linear layer for the longer trained models and report this score in parentheses. TUNe Tail+5 and TUNe+ at 10 000 epochs are the best-performing models overall, exceeding CLMR's performance at 10 000 epochs and performing only slightly worse than state-of-the-art end-to-end–trained musicnn. Multiple other variants match CLMR performance even though only trained for 1 000 epochs.

* For the CLMR-tail experiment, the number of filters corresponds to the initial number of filters used for the contractive and expansive path. For the tail, we used the same architecture as CLMR's SampleCNN and report the number of blocks.

** Number of parameters is taken from the last reported number of parameters, musicnn [31].

audio dataset. As baseline, we compare to CLMR [3]. We ensure a fair comparison by varying the number of channels in each TUNe architecture to obtain a total parameter count comparable to the CLMR baseline. Next, we trained five variants: (1) a version where the tail was fixed to the published pre-trained CLMR model, in order to test whether the contractive and expansive paths (the 'U') add information; (2) a TUNe+ network, still restricted to have no more parameters than CLMR, to test whether the extra connections between the expansive path and the tail allow for better feature information flow; (3) a filter-restricted model, to test whether the number of filters can be a bottleneck for the deeper models; (4) a large TUNe+ network with an unrestricted number of parameters; and (5) a model with a smaller representation dimension. Finally, we evaluated the out-of-domain dataset generalisability of our two best models on three different datasets for the same probing task. [1]

[1] Pretrained models and source code for all experiments are available to download at `https://github.com/Marcel-Velez/TUNe`

4.1 Hyperparameters and Preprocessing

The hyperparameters we used for pre-training were the same as [3], following their setup with data augmentations. We used an Adam optimiser [32], and He initialisation [33] for all convolutional layers. As input, we sampled audio files at 22 050 Hz for 59 049 samples. We also used the same architecture for the projector head as [3]. This output is then used for the contrastive learning objective. For every experiment, we used a batch size of 96. In order to be able to train with such a batch size, we trained every model data-parallel (DP) on two Titan RTXs, except for Vanilla TUNe and TUNe+ Large. To train these variants with a batch size of 96, we used three Titan RTXs.

4.2 Exploring the TUNe Architecture

Because the number of permutations of how many contractive layers are added, expansive layers are subtracted, tail layers are added grows exponentially, we chose to investigate the influence of each of these paths separately. Every model was trained on the audio of the MagnaTagA-

Tune (MTT) dataset [34]. This dataset consists of 25 863 music clips of 29 seconds of audio from 5223 songs. Each of these clips has one or more tags, making it a multi-class classification task dataset. We use the same train-validation-test split as is common within MIR [35–37]. After training, each model was probed on the MTT tagging task using a single linear-layer probe and evaluated using two metrics. The first metric is the receiver operating characteristic curve (MTT_{AUC}), which is popular but can be positively biased for imbalanced datasets [38], and the average precision (MTT_{AP}). We report results for each model in Table 1.

The only constraint for these variations was to have fewer parameters than CLMR, so as to exclude the model being bigger being a possible reason for performing better. The TUNe architecture follows a fixed input channel–output channel ratio per layer, and thus in order to keep the number of parameters smaller than CLMR, we only had to change the number of output channels of the first block. The remainder of the network changes in proportion. A complete overview of the number of parameters and initial output filters can be found in Table 1.

4.2.1 Contractive Path Depth

When varying the contractive path depth, we also added an equal number of expansive layers, in order to keep the upper resolution of the U and the tail the same; the tail remained unchanged so that the final representation size remained unchanged. Starting from the vanilla default of 4 contractive layers, adding layers increased performance up until $N_{\text{con}} = 6$, suggesting that the extra contractive and expansive layers – a deeper U – do allow for better integration of feature information for the representation dimensionality. Contractive+3 ($N_{\text{con}} = 7$) drops slightly in performance, which initially seems contradictory to the Contractive+1 and +2 results. We believe this can be attributed to the potentially exponential parameter growth of adding layers to the contractive and thus also expansive paths: to prevent the exponential growth and remain within our constraint on the maximum number of parameters, adding layers entails reducing the number of filters. TUNe Contractive+3, for example, has only 4 initial filters, as compared to 34 in Vanilla TUNe, and this may no longer be enough to achieve good performance.

To test this hypothesis, we ran Vanilla TUNe with the number of filters from TUNe+ (labelled Vanilla TUNe Small in Table 1), and conversely ran TUNe+ with the number of filters from Vanilla TUNe (labelled TUNe+ Large in Table 1). Vanilla TUNe performance dropped and TUNe+ Large performance increased under these conditions, suggesting that the number filters could indeed be the bottleneck for Contractive+3.

4.2.2 Expansive Path Height

In order to analyze the effect of expansive path height, we applied a similar procedure. For every expansive layer we removed, we also removed a tail layer to keep the final representation dimensionality unchanged. Because this modification reduced dimensionality, we were able to *add* initial filters in order to come closer to the dimensionality of CLMR. Nonetheless, removing expansive layers seems to have little influence: removing up to three layers of the expansive path and tail leaves performance essentially unchanged. Put differently, the extra initial filters seem to be able to compensate for reduced integration of the higher frequency timescale features due to a shallower U.

To see whether the U shape in fact adds information and increases performance, we trained a TUNe model with a tail path identical to pretrained CLMR. If the U shape does not add information, such a model should perform equally well or worse than baseline CLMR; if it performs better, then there is evidence that the contractive and expansive paths are contributing signal enrichment important for representation learning. Indeed, TUNe with a CLMR tail performs better with a single layer probe than baseline CLMR can even after 10 times as many training epochs and a multi-layer probe. It seems that the contractive–expansive path pair is a powerful performance enhancer for time-domain music representation learning.

4.2.3 Tail Length

The model performance after adding 1 to 5 layers to the tail path shows a steady increase per layer added until Tail+4, after which performance seems to plateau. In general, we should expect longer tails to improve performance, because the model average pools the remaining sequence length at the end of the tail path. With fewer tail layers, we average over a longer sequence, and when averaging, detailed information is replaced with an aggregation, thereby losing possible important information. The parameter constraint could again be responsible for the eventual plateau, as we see that the TUNe+ Large model from before also performs better than either Tail+4 or Tail+5. But it is a plateau, not a decrease: Tail+5 performs equivalently to Tail+4, and it does so with fewer parameters and potentially less loss of precision from averaging than Tail+4. We choose Tail+5 as our best model from this block.

4.2.4 Extra Connections

The model with extra connections, TUNe+, performs comparably to the Tail+5 model, with only .1 higher MTT_{AP}. It still shows similar MTT_{AUC} scores as CLMR 10 000 epochs trained and outperforms CLMR MTT_{AP}-wise. To further explore the influence of the added connections we chose TUNe+ to be one of the two variants used for the probing experiments (Section 4.3).

4.2.5 Smaller Representations

All of these variants showed reasonable performance for the same representation size, with only slightly varying numbers of parameters. To test the parameter efficiency of TUNe architectures, we trained another variant of the TUNe+ with the same number of initial filters, but reducing the representation size from 512 to 256. The results were impressive. Even with 44% fewer parameters and a representation size half that of the other TUNe architectures we tested, TUNe+ Smaller Rep still performs equally

well as CLMR after 10 000 epochs. Compared to the best TUNe architectures, it achieves comparable MTT_{AUC} and only marginally worse MTT_{AP}.

4.2.6 Longer Training

In order to be conservative with computing resources, we first trained all of the aforementioned models for 1000 epochs only and probed with only a single linear layer. As a final comparison, we trained the two best models, TUNe Tail+5 and TUNe+, an additional 9 000 epochs. Because of the random data augmentations and the size of MTT, training for more epochs results in the models 'hearing' an increasing amount of natural variation in the audio, which in turn improves performance. We evaluated these models using the same probing tasks, once with a single linear layer and once with a two-layer probe to see how much introducing nonlinearity could increase performance. In Table 1, we report these additional multi-layer performance figures in brackets. The MTT_{AUC} score does increase with the multilayer probe, but the MTT_{AP}, on the contrary, decreases. Overall, however, these two 10 000-epoch models are the best performing models from our entire series of experiments, achieving slightly lower performance than the musically motivated end-to-end trained musicnn [2] and outperforming CLMR 10 000 epoch results.

4.3 Probing Tasks

In order to compare the TUNe performance to state-of-the-art models, we evaluate TUNe with probing: training a shallow model on downstream tasks [10]. We use the same datasets as [3] for the CLMR training.

When probing a model, we evaluate the pre-trained model representations on a different dataset than the model is pre-trained on. This evaluation on a different dataset is done by training a probe, often a single linear layer or a multi-layer perceptron with one hidden layer. This probe takes the output representation of the main model as input and outputs the desired classes or values for the task in question. Probing is often used to test certain representation characteristics, in our case, to see how well the learned representations from other types of datasets generalise to music tagging.

We ran the probing experiment to see how well our network could generalise representations when trained on three different datasets: the medium Free Music Archive dataset [39], the fault-filtered GTZAN dataset [40,41] containing 930 songs, and the McGill Billboard dataset [42] containing 712 songs. Next, we probed the trained models on the MTT dataset, of which the results are displayed in Table 2. For this probing experiment, we used a learning rate of 3e^{-4}, weight decay of 10^{-6}, and an early stopping mechanism. Early stopping occurred if the probe's validation score did not improve for five epochs.

TUNe architectures allow for excellent out-of-dataset representation generalisability. Even when both TUNe Tail+5 and TUNe+ were trained on the McGill Billboard dataset, which is more than 33 times smaller than MTT, the models still only perform 4% worse on AUC than the models pre-trained on MTT. When they are trained on the GTZAN dataset, which is about the same size as McGill Billboard, both variants outperform CLMR regardless of (non-MTT) training set. With pre-training on the MTT-sized FMA dataset, the TUNe models perform almost as well as they did in the original MTT-only experiments.

Probing Variant	Training Data	MTT_{AUC}	MTT_{AP}
TUNe+	FMA	89.1 (89.4)	36.2 (36.1)
TUNe Tail +5	FMA	88.9 (89.2)	35.3 (35.9)
CLMR	FMA	86.2 (86.6)	30.6 (31.2)
TUNe+	GTZAN	87.2 (87.9)	32.6 (33.9)
TUNe Tail +5	GTZAN	86.9 (87.5)	32.6 (33.0)
CLMR	GTZAN	81.9 (85.4)	26.2 (29.5)
TUNe Tail +5	Billboard	84.7 (85.8)	28.6 (29.9)
TUNe+	Billboard	84.5 (85.9)	28.7 (30.5)
CLMR	Billboard	82.7 (84.2)	26.9 (27.8)

Table 2: TUNe Tail +5, TUNe+ and CLMR out-of-domain probing experiments. The table shows the probing performance on MagnaTagATune of each of the three models, trained on the Free Music Archive medium (FMA), fault-filtered GTZAN, and the McGill Billboard dataset. In addition to the shallow probe, we trained a probe with an extra linear layer and report this score in parentheses. CLMR results are taken from [3].

5. CONCLUSION

In this paper, we introduced TUNe network architectures, a generalisation of a recent representation learning framework called CLMR. TUNe brings the strengths of U-Nets to representation learning. TUNe networks comprise three sections, called the contractive, expansive, and tail paths, which can be flexibly lengthened or shortened. We performed several experiments exploring the contribution of each of these paths and compared them against CLMR. We evaluated TUNe's performance in three ways. First, we trained and evaluated variants of our model with CLMR on MagnaTagATune (MTT), outperforming CLMR marginally after training for a fraction of CLMR's time. Second, we evaluated the best two models with out-of-domain probing tasks. Both TUNe architectures improved upon the already competitive CLMR performance and showed that TUNe architectures allow for an even better generalisation of music representations. In the supplemental material, we include the results of further experiments showing how TUNe architectures can also achieve competitive performance on other downstream tasks, even at small model sizes. TUNe sets a new standard for parameter efficiency and the ability of modern self-supervised networks to extract salient features, and we hope that it will encourage MIR researchers to use self-supervised music representations more widely.

ABSTRACT

A vocoder is a conditional audio generation model that converts acoustic features such as mel-spectrograms into waveforms. Taking inspiration from Differentiable Digital Signal Processing (DDSP), we propose a new vocoder named SawSing for singing voices. SawSing synthesizes the harmonic part of singing voices by filtering a sawtooth source signal with a linear time-variant finite impulse response filter whose coefficients are estimated from the input mel-spectrogram by a neural network. As this approach enforces phase continuity, SawSing can generate singing voices without the phase-discontinuity glitch of many existing vocoders. Moreover, the source-filter assumption provides an inductive bias that allows SawSing to be trained on a small amount of data. Our evaluation shows that SawSing converges much faster and outperforms state-of-the-art generative adversarial network- and diffusion-based vocoders in a resource-limited scenario with only 3 training recordings and a 3-hour training time.*

1. INTRODUCTION

Singing voice synthesis (SVS) aims to generate human-like singing voices from musical scores with lyrics [1–9]. State-of-the-art (SOTA) voice synthesis techniques involve two stages: acoustic feature modeling from musical scores and audio sample reconstruction via a so-called "vocoder." A *neural vocoder* takes an acoustic feature such as mel-spectrogram as input and outputs a waveform using deep learning networks [10–22]. However, phase discontinuities within partials often occur due to the difficulty of reconstructing realistic phase information from a mel-spectrogram. This may lead to a short-duration broadband transient perceived as "glitch" or "voice tremor," which is more audible during long utterances commonly found in singing [18], as exemplified in Figure 1.

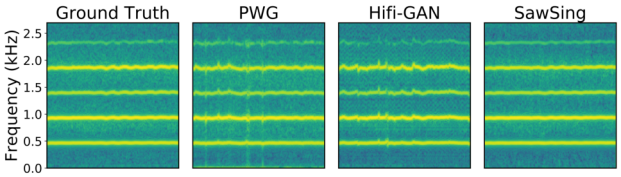

Figure 1: The magnitude spectrograms of a long utterance of an original recording ('ground truth') and those reconstructed by two widely-used neural vocoders, Parallel WaveGAN (PWG) [14] and HiFi-GAN [15], and the proposed SawSing. Each vocoder is trained on 3 hours of recordings from a female singer until convergence. We see glitches in the results of PWG and HiFi-GAN.

Differentiable Digital Signal Processing (DDSP) [23] introduces a new paradigm for neural audio synthesis. It incorporates classical digital signal processing (DSP) synthesizers and effects as differentiable functions within a neural network (NN), and combines the expressiveness of an NN with the interpretability of classical DSP. The use of phase-continuous oscillators is a potential solution to the phase problem from which regular neural vocoders suffer, and the strong inductive bias of this approach may obviate the need of large training data. Furthermore, DDSP has already succeeded in achieving sound synthesis of, and timbre transfer between, monophonic instruments [23–30]. These motivate us to explore whether the DDSP approach can be applied to build a singing vocoder.

This paper proposes SawSing, a DDSP-based singing vocoder which reconstructs a monophonic singing voice from a mel-spectrogram. The architecture of SawSing similarly consists of an NN and classical DSP components; unlike DDSP, its DSP portion is a subtractive harmonic synthesizer which filters a sawtooth waveform containing all possible harmonic partials, plus a subtractive noise synthesizer which filters uniform noise. The sawtooth signal enforces phase continuity *within* partials, thereby avoiding the glitches. Moreover, the partials of a sawtooth signal are guaranteed to be in phase, so it also enforces the phase coherence *between* partials, intrinsic to human voices. The function of the NN, on the other hand, is to infer from the mel-spectrogram the fundamental frequency (f0) of the sawtooth signal and the filter coefficients of the harmonic and noise synthesizers for each time frame.

Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

In our experiments, we use data from two singers (each three hours) of the MPop600 Mandarin singing corpus [31]. We compare the performance of SawSing with the neural source-filter (NSF) model [12], two existing DDSP-based synthesizers, the original additive-based DDSP [23] and the differentiable wavetable synthesizer [27], and a few famous neural vocoders, i.e., two generative adversarial network (GAN)-based models [5, 14] and a diffusion-based model [21]. We consider both a regular scenario where the vocoders are trained for days using the 3-hour dataset, and a resource-limited scenario with constraints on training data and training time. Our experiments show that SawSing converges much faster and outperforms the other vocoders in the resource-limited scenario.

The main contribution of the paper is two-fold. First, we show that despite differences between instrumental sounds and singing voices [32], the classic idea of subtractive synthesis [33, 34] can be applied to singing voices using the DDSP approach.[1] Second, we provide empirical evidences showing that DDSP-based vocoders can compare favorably with sophisticated, SOTA neural vocoders. Furthermore, since DDSP-based vocoders are lightweight and training-efficient, they have the potential to be used in creative and real-time scenarios of singing expression with limited training data of a target singing voice [36, 37].

We open source our code at `https://github.com/YatingMusic/ddsp-singing-vocoders/`. For audio examples, visit our demo webpage `https://ddspvocoder.github.io/ismir-demo/`.

2. BACKGROUND

Neural vocoders often aim to reconstruct a waveform $\mathbf{y} \in \mathbb{R}^{1\times T}$ from an input mel-spectrogram $\mathbf{X} \in \mathbb{R}^{M\times N}$:

$$\mathbf{y} = f_{\text{vocoder}}(\mathbf{X}), \tag{1}$$

where M, N, T denote respectively the number of mel filter banks, spectral frames, and time-domain samples. The conversion from $\mathbf{X}$ to $\mathbf{y}$ can be done, for example, by upsampling $\mathbf{X}$ multiple times through transposed *convolutions* until the length of the output sequence matches the temporal resolution of the raw waveform [13, 15]. As usual reconstruction loss functions such as mean-square errors cannot reflect the perceptual quality of the reconstruction, GAN-based approaches [13–15] learn discriminators to better guide the learning process of the generator (i.e., f_{vocoder}). Newer diffusion-based approaches [20, 21] avoid the use of discriminators and learn to convert white Gaussian noises $\mathbf{z} \in \mathbb{R}^{1\times T}$ (i.e., of the same length as $\mathbf{y}$) into structured waveform $\mathbf{y}$ through a denoising-like Markov chain, using $\mathbf{X}$ as a condition. The mapping process between $\mathbf{X}$ and $\mathbf{y}$ of such neural vocoders appears to be a black box that is hard to interpret. However, given sufficient training data (e.g., recordings amounting to 24 hours [15, 20, 21, 38] or 80 hours [18]) and training time (e.g., days), SOTA neural vocoders can reconstruct the waveforms with high fidelity.

The majority of neural vocoders, however, have been originally developed for speech. When the rate of utterances is fast, as is common in speech, the glitches resulting from the phase discontinuities within partials may be perceptually masked by the natural transients of the voice. However, during singing, where long utterances are common, these discontinuities are more audible.

To improve the performance of GAN-based vocoders for singing voices, the idea of incorporating the f0 information has been explored recently. PeriodNet [16] uses f0 to create sine excitation as input to Parallel WaveGAN (PWG) [14] to model the periodic part of human voices. Guo *et al.* [17] further filter such an f0-driven excitation signal with a linear time-variant finite impulse response (LTV-FIR) filter whose coefficients are estimated from the input mel-spectrogram, and use the resulting "harmonic signal" as input to PWG and MelGAN [13]. SingGAN [18] uses more complicated "adaptive feature learning" layers to incorporate the f0. These models were shown to outperform older GAN-based vocoders such as PWG and MelGAN in listening tests, but no evaluations against the newest GAN-based vocoder HiFi-GAN [15] and diffusion-based vocoders were reported. Moreover, their evaluation did not consider resource-limited scenarios.

We propose in this paper a radically different approach that uses traditional DSP synthesizers (instead of upsampling convolutions) as the backbone for f_{vocoder}. While the ideas in DDSP have flourished and been applied to synthesizing not only instrumental sounds [23–27], but also audio effects [39–43], their application to singing synthesis remains under-explored. The only exception, to our knowledge, is the preliminary work presented by Alonso and Erkut [44], which employed exactly the same additive synthesizer as the original DDSP paper [23]. However, they did not compare the performance of their vocoder with any other vocoders. Our work extends theirs by using a subtractive harmonic synthesizer instead, with comprehensive performance evaluations against SOTA neural vocoders such as HiFi-GAN and FastDiff [21].

We note that, while a DDSP-based vocoder may solve the glitch problems by inducing continuous phase hypothesis using a harmonic synthesizer, this hypothesis may constrain the model learning ability. Experiments reported in this paper are needed to study its performance.

Publicly-available training corpora for singing tend to be much smaller than those for speech [31, 45] (often $\leq$10 hours). Therefore, besides tackling the glitch problem, our premise is that SawSing can learn faster than prevalent neural vocoders without a large training corpus, due to its strong inductive bias. Moreover, the success of SawSing may pave the way for the exploration of other advanced DSP components for singing synthesis in the future.

3. ORIGINAL DDSP-ADD SYNTHESIZER

The idea of DDSP is to use DSP synthesizers to synthesize the target audio, with the parameters of the synthesizers Φ

[1] We note that the use of a sawtooth waveform in DDSP-based models has been attempted for speech synthesis [35] and instrumental synthesizer sound matching [26], but its application to singing vocoder is new.

inferred from the mel-spectrogram with an NN. Namely,

$$\mathbf{y} = f_{\text{DSP}}(\Phi)\,, \quad \Phi = f_{\text{NN}}(\mathbf{X})\,. \tag{2}$$

The original DDSP model [23], referred to as **DDSP-Add** below, adopts the *harmonic-plus-noise* model for synthesis [46] and decomposes a monophonic sound into a periodic (harmonic) component $\mathbf{y}_{\text{h}}$ and a stochastic (noise) component $\mathbf{y}_{\text{n}}$, i.e., $\mathbf{y} = \mathbf{y}_{\text{h}} + \mathbf{y}_{\text{n}}$, and reconstructs them separately with an *additive* harmonic oscillator (thus the name "-Add") and a *subtractive* noise synthesizer. [2] The former computes $\mathbf{y}_{\text{h}}$ as a weighted sum of K sinusoids corresponding to the f0 and its integer multiples up to the Nyquist frequency (for anti-aliasing), for $t \in [1, T]$:

$$\mathbf{y}_{\text{h}}^{\text{DDSP-Add}}(t) = A(t) \sum_{k=1}^{K} c_k(t)\, \sin(\phi_k(t))\,, \tag{3}$$

where $A(t)$ is the global amplitude corresponding to the time step t, $c_k(t)$ is the amplitude of the k-th harmonic satisfying $\sum_{k=1}^{K} c_k(t) = 1, c_k(t) \geq 0$, and the instantaneous phase $\phi_k(t)$ is computed by integrating the instantaneous frequency $kf_0(t)$, i.e., $\phi_k(t) = 2\pi \sum_{\tau=0}^{t} kf_0(\tau) + \phi_{0,k}$, with $\phi_{0,k}$ initial phase, set to zero. The parameters A, c_k, f_0 are estimated by f_{NN} for each frame $i \in [1, N]$ and then upsampled to the time-domain with linear interpolation. On the other hand, $\mathbf{y}_{\text{n}}$ is obtained by convolving a uniform noise signal ζ ranging from -1 to 1 (with the same length as a frame) with an LTV-FIR filter $\psi_{\text{n}}(i) \in \mathbb{R}^{L_{\text{n}}}$ estimated per frame:

$$\bar{\mathbf{y}}_{\text{n}}(i) = \zeta * \psi_{\text{n}}(i)\,. \tag{4}$$

The final $\mathbf{y}_{\text{n}}$ is obtained by overlap-adding sequence of segments $\bar{\mathbf{y}}_{\text{n}}(i)$ for the frames $i = 1 \ldots N$. Jointly, the parameters $\Phi := \{A(i), \{c_k(i)\}_{k=1}^{K}, f_0(i), \psi_{\text{n}}(i)\}_{i=1}^{N}$ are estimated from the mel-spectrogram $\mathbf{X}$ per frame by f_{NN}, which is a small network with few parameters.

Engel *et al.* [23] showed that DDSP-Add can synthesize realistic violin sounds with only 13 minutes of expressive solo violin performances as training data. Alonso and Erkut [44] employed DDSP-Add for singing synthesis, but with limited performance evaluation.

4. PROPOSED SAWSING VOCODER

Under the same harmonic-plus-noise signal model [46], SawSing modifies the the harmonic synthesizer of DDSP-Add [23] with two ideas. First, given the f0 estimated from $\mathbf{X}$, SawSing approximates $\mathbf{y}_{\text{h}}$ by a sawtooth signal, which contains an equal number of even and odd harmonics with decaying magnitudes, dropping the coefficients A and c_k:

$$\widetilde{\mathbf{y}_{\text{h}}}^{\text{SawSing}}(t) = \sum_{k=1}^{K} \frac{1}{k} \sin(\phi_k(t))\,. \tag{5}$$

[2] The terms "additive" and "subtractive" are used to describe how a signal is synthesized. An additive synthesizer generates sounds by combining multiple sources such as oscillators or wavetables, while a subtractive synthesizer creates sounds by using filters to shape a source signal, typically with rich harmonics, such as a square or sawtooth wave [46].

Second, $\widetilde{\mathbf{y}_{\text{h}}}$ is treated as the "excitation signal" and shaped into the desirable $\mathbf{y}_{\text{h}}$ by means of an LTV-FIR filter $\psi_{\text{h}}(i) \in \mathbb{R}^{L_{\text{h}}}$ (that is different from $\psi_{\text{n}}(i)$). To apply the filter, we extract the segment of $\widetilde{\mathbf{y}_{\text{h}}}$ corresponding to the same frame i and multiply its short-time Fourier Transform (STFT) element-wise with the STFT of $\psi_{\text{h}}(i)$ in the frequency domain, before converting it back to the time domain with the inverse STFT and overlap-adding. SawSing uses the same subtractive noise synthesizer as DDSP-Add. Therefore, the parameters to be estimated from $\mathbf{X}$ by f_{NN} are $\Phi^{\text{SawSing}} := \{f_0(i), \psi_{\text{h}}(i), \psi_{\text{n}}(i)\}_{i=1}^{N}$.

We observe that to compute $\mathbf{y}_{\text{h}}$, DDSP-Add learns NN to attenuate each of the k source harmonics *individually* (i.e., with c_k), while SawSing entails a *source-filter* model [12], using the f0-constrained sawtooth signal in Eqn. (5) as the excitation source and a time-varying filter $\psi_{\text{h}}(i)$ decided by the NN for spectral filtering. The filter coefficients correspond to formants produced by the vocal folds and do not correlate with f0.

Besides differences in the harmonic synthesizer, SawSing also uses a different loss function from DDSP-Add. For monophonic instrumental sounds, Engel *et al.* [23] showed it effective to use the multi-resolution STFT (MSSTFT) loss as the reconstruction loss for training. This loss considers the difference between the magnitude spectrograms of the target and synthesized audio, denoted as $\mathbf{S}_j$ and $\widehat{\mathbf{S}_j}$ below, for J different resolutions.

$$l_{\text{MSSTFT}} = \sum_{j=1}^{J} \|\mathbf{S}_j - \widehat{\mathbf{S}_j}\|_1 + \|\log(\mathbf{S}_j) - \log(\widehat{\mathbf{S}_j})\|_1\,. \tag{6}$$

For singing voices, however, we found that MSSTFT loss alone cannot train adequately. We introduce an additional f0-related loss term to facilitate learning:

$$l_{f_0} = \|\log(f_0) - \log(\widehat{f_0})\|_1\,, \tag{7}$$

where the target f0 (f_0) and the estimated one ($\widehat{f_0}$) are both extracted by the WORLD vocoder [47]. Thus, our Sawsing loss function becomes $l_{\text{total}} = l_{\text{MSSTFT}} + l_{f_0}$. Moreover, we found that training is unstable unless the gradients between f_{DSP} and the head of f_{NN} for f0 prediction are detached.

4.1 Implementation Details

First, we resampled the audio recordings to 24 kHz and quantized them to 16 bits. Next we cropped the recordings into 2-second excerpts (i.e., $T = 48$k) and extracted 80-band mel-spectrograms from each ($M = 80$), with a Hann window of 1024 samples for STFT and a hop size of 240 samples (i.e., 10ms). Accordingly, we set $N = 200$.

We used filter length $L_{\text{h}} = 256$ for the harmonic synthesizer for SawSing, and filter length $L_{\text{n}} = 80$ for the subtractive noise synthesizers. We used at most $K = 150$ sinusoids for SawSing. To avoid sound clipping, we applied a global scaling factor of 0.4 to the sawtooth signal in Eqn. (5) to ensure that the range of the summed sinusoids always lies in $[-1, 1]$.

We chose a lite version of the Conformer architecture for f_{NN} [48], for its well-demonstrated effectiveness in

capturing both local and global information in a sequence of acoustic features in speech tasks. It consists of a pre-net (shallow 1D convolution with ReLU activation and group normalization), a self-attention stack (3 layers), a convolution stack (2 layers) with post layer normalization, and a final linear layer whose output dimension is equal to the number of synthesis coefficients. We used the Adam optimizer with 0.002 learning rate.

While the original DDSP-Add paper [23] uses $J = 6$ for MSSTFT, we found setting $J = 4$ to be sufficient in our implementation. Specifically, we used four different FFT sizes (128, 256, 512, 1024) with 75% overlapping among adjacent frames. While it is possible to introduce a scaling factor to control the balance between l_{MSSTFT} and l_{f_0}, we found doing so does not markedly improve the result.

5. EXPERIMENTAL SETUP

5.1 Baselines

Our evaluation considers in total six baselines. The first three explicitly employ f0, while the last three do not.

First, we adopted two existing DDSP-based vocoders, the original additive-based DDSP (**DDSP-Add**) [23, 44] and the differentiable wavetable synthesizer (DWTS) [27]. **DWTS** replaces the fixed sinusoids in the additive harmonic synthesizer of DDSP-Add by K' learnable (rather than pre-defined) one-cycle waveforms ("the wavetables") $\mathbf{w}_k \in \mathbb{R}^B, k \in [1, K']$, to gain flexibility to model a wider variety of sounds (but only tested on instrumental sounds in [27]). Mathematically, $\mathbf{y}_{\text{h}}^{\text{DWTS}}(t) = A(t) \sum_{k=1}^{K'} c_k(t)\sigma(\mathbf{w}_k, \phi_\pi(t))$, where σ is an indexing function that returns a sample of $\mathbf{w}_k$ according to the instantaneous modulo phase $\phi_\pi(t)$ computed from $f_0(t)$. For fair comparison, we used the same Conformer-like architecture for the f_{NN} for DDSP-Add, DWTS, and SawSing, and the same noise synthesizer. Moreover, while the original DDSP-Add used only l_{MSSTFT}, thus we used $l_{\text{total}} = l_{\text{MSSTFT}} + l_{f_0}$ for all three in our implementation. Like SawSing, we set $K = 150$ for DDSP-Add. DWTS only needs small K' as the wavetables are learnable; we set $K' = 20$, with wavetable length being $B = 512$.

We also employed the neural source-filter (**NSF**) waveform model [12], which was proposed before the notion "DDSP" was coined [23]. Unlike SawSing, NSF uses unweighted sinusoids (i.e., $\sum_{k=1}^{K} \sin(\phi_k(t))$) as the source signal, and uses stacked dilated-convolution blocks instead of a simple LTV-FIR filter. We adapted the open-source code from the original authors to implement NSF, as well as the following three baselines.

For GAN-based neural vocoders, we used **PWG** [14] and **HiFi-GAN** [15], both of which were developed for speech, not singing.[3] PWG is a non-autoregressive version of WaveNet [10] that learns to transform a random noise into target audio with 30 layers of dilated residual convolution blocks, conditioning on the mel-spectrogram. For HiFi-GAN, we used the most powerful "V1" configuration [15], which converts a mel-spectrogram into a waveform directly via 12 residual blocks. It uses a sophisticated multi-receptive field fusion module in the generator, and multiple multi-scale and multi-period discriminators [15].

An increasing number of diffusion-based vocoders have been proposed in the past two years for speech [19–22]. We adopt as a baseline the **FastDiff** model [21], which has been shown to beat HiFi-GAN V1 [15] and diffusion-based models WaveGrad [19] and DiffWave [20] in the mean-opinion-score (MOS) of vocoded speech in listening tests. However, while a noise schedule predictor has been devised to reduce the sampling steps of the denoising Markov chain, the inference time of FastDiff is still around 10 times slower than HiFi-GAN, according to [21].

None of these baselines have been trained on MPop600, which is a relatively new dataset. Therefore, we trained all these models from scratch with the MPop600 data.

5.2 Dataset & Scenarios

Our data is from MPop600 [31], a set of accompaniment-free Mandarin singing recordings with manual annotation of word-level audio-lyrics alignment. Each recording covers the first verse and first chorus of a song. We used the data from a female singer (named `f1`) and a male singer (`m1`); each has 150 recordings. For each singer, we reserved 3 recordings (totalling 3.4–3.6 minutes in length) as the *test* set for subjective evaluation, 24 or 21 recordings (around 27–28 minutes) as the *validation* set for objective evaluation, and used the rest (around 3 hours) as the *training* set. We trained vocoders for `m1` and `f1` independently.

To study the training efficiency of different approaches, we considered the following two scenarios. We used the same validation and test sets for both scenarios.

(a) *Regular* [3h data, well-trained]: we used the full training data to train the vocoders for each singer for up to 2.5 days (i.e., when the training loss of most vocoders converged), and picked the epoch that reaches the lowest validation loss for each vocoder independently. We note that the amount of training time in this "regular" scenario is smaller than those seen in speech vocoders [38], posing challenges for all the considered models.

(b) *Resource-limited* [3min data, 3h training]: in a rather extreme case, we randomly picked 3 recordings from the training set (that collectively cover every phoneme at least once) per singer (3.2–3.4 minutes) for training, using always the epoch at 3-hour training time.

For fair comparison, we train the vocoders of different approaches using a dedicated NVIDIA GeForce RTX 3090 GPU each, fixing the batch size to 16 excerpts.

6. OBJECTIVE EVALUATION

For objective evaluation, we reported the MSSTFT and the mean absolute error (MAE) in f0, as well as the Fréchet audio distance (FAD) [49] between the validation data and the reconstructed ones by the vocoders. FAD measures the

[3] While we did not consider SingGAN [18] in the evaluation for lack of open source code, we should have included PeriodNet [16] for it seems easy to implement. Unfortunately we are aware of PeriodNet too late.

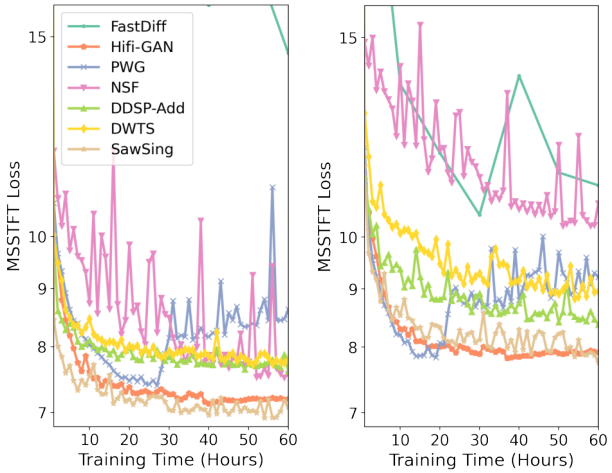
Table 1: Objective evaluation results of three existing neural vocoders (the first three), three existing DDSP-based vocoders (middle) and the proposed SawSing vocoder, trained on either a female or a male singer, in either (a) *regular* scenario [3h data, well-trained] or (b) *resource-limited* scenario [3min data, 3h training]. RTF stands for real-time factor (the inference time in seconds for a one-second excerpt). In each column, we highlight the best result in bold, the second best underlined.



(i) female (ii) male

Figure 2: The MSSTFT loss on the validation set of different vocoders in the 3-hour data & well-trained scenario.

similarity of the real data distribution and generated data distribution in an embedding space computed by a pre-trained VGGish-based audio classifier, and may as such better reflect the perceptual quality of the generated audio.

Figure 2 shows the validation MSSTFT loss as a function of the training time in the regular scenario for the two singers. In Figure 2(i), SawSing converges faster than the other models and reaches the lowest loss (i.e., 6.93), followed by HiFi-GAN and PWG. While DDSP-add and DWTS converge similarly fast as SawSing, they reach at a slightly higher loss (around 7.50). In Figure 2(ii), Sawing, HiFi-GAN and PWG perform comparably in the first 20 hrs. For both singers, PWG overfits when the training time gets too long. Moreover, FastDiff converges the most slowly, followed by NSF. Even with 60-hour training time, the MSSTFT of FastDiff remains to be high (e.g., 14.5 for the female singer), suggesting that our training data might not be big enough for this diffusion-based model.[4]

Table 1 shows the scores in all the three metrics on the validation set for both scenarios, using the epoch (a) at the lowest validation loss or (b) at 3h training. Despite having few trainable parameters, SawSing performs the best in MSSTFT and FAD across both scenarios and both singers, demonstrating its effectiveness as a singing vocoder. For scenario (b), DDSP-Add obtains the second-lowest MSSTFT and FAD across the two singers.

For MAE-f0, SawSing attains scores comparable to the best baseline models. The average MAE-f0 of SawSing is less than a semitone (100 cents). Future work can use a specialized module (e.g., [50]) for the f0 prediction part in f_{NN} of SawSing to further improve the MAE-f0.

Table 1 also shows that the performance gap between scenarios (a) and (b) in all the three metrics tend to be greater for the diffusion- and GAN-based vocodoers than for NSF and the DDSP-based vocoders. Besides, among the evaluated models, the performance gap between (a) and (b) is the smallest in the result of SawSing. In the resource-limited scenario (b), the FAD of HiFi-GAN reaches only 3.50 and 10.5 for the female and male singers, respectively, while the FAD of SawSing can be lower than 1.0. This demonstrates that a strong inductive bias like those employed in NSF and the DDSP-based vocoders is helpful in scenarios with limited training data and training time.

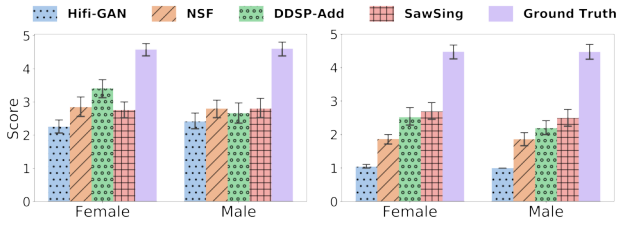
Table 1 also displays the real-time factor (RTF) of the models when being tested on a single NVIDIA 3090 GPU. We see that SawSing and DDSP-Add have the lowest RTF (i.e., run the fastest), followed by HiFi-GAN.

According to Table 1, HiFi-GAN performs the best on average among the first three vocoders across scenarios and singers. NSF and the DDSP-based vocoders obtain comparable scores, but DWTS is notably slower. Hence, we pick HiFi-GAN, NSF, DDSP-Add and SawSing to be further evaluated in the user study below.

7. SUBJECTIVE EVALUATION

We conducted an online study to evaluate the performance of the 4 selected models. We had 2 sets of questionnaires, one for the female and the other for the male singer. For each singer, we prepared 8 clips from the 3 *testing* recordings (i.e., totally unseen at training/validation time), each clip corresponding to the singing of a *full sentence*. We

[4] In the original paper [21], FastDiff was trained on 24 hours of speech data from a female speaker [38], using 4 NVIDIA V100 GPUs. We tried DiffWave [20] but it converged similarly slow on our data.



(a) 3h data, well-trained (b) 3min data, 3h training

Figure 3: MOS with 95% confidence intervals for subjective evaluation of vocoders trained in the two scenarios.

let the vocoders trained in scenario (a) to reconstruct the waveforms from the mel-spectrograms of 4 of the clips, and those of (b) for the other 4 clips. A human subject was requested to use a headset to listen to 5 versions of each of the clip, namely the original 'ground truth' recording and the reconstructed ones by the 4 selected models, with the ordering of the 5 versions randomized, the ordering of the 8 clips randomized, and not knowing the scenario being considered per clip. The loudness of the audio files were all normalized to –12dB LUFS beforehand using `pyloudnorm` [51]. After listening, the subject gave an opinion score from 1 (poor) to 5 (good) in a 5-point Likert scale to rate the audio quality for each audio file.

Figure 3 shows the MOS from 23 anonymized participants for the female and 18 participants for the male singer. In scenario (a), we see that the MOS of the vocoders, including the SOTA HiFi-GAN, mostly reaches 2–3 only, suggesting that training a vocoder on 3-hour data is already challenging. As HiFi-GAN involves a complicated GAN training and much more parameters, its MOS turns out to be significantly lower than those of NSF and the DDSP-based vocoders (p-value$<$0.05 in paired t-test). Interestingly, while there is no statistical difference among the MOS of NSF, DDSP-Add and SawSing for the male singer in scenario (a), DDSP-Add unexpectedly outperforms both NSF and SawSing by a large margin, with statistically significant difference (p-value$<$0.05).

Listening to the result of SawSing reveals that its output contains an audible electronic noise, or "buzzing" artifact, notably when singers emphasize the airflow with breathy sounds and for unvoiced consonants such as `/s/` and `/t/`. DDSP-Add is free of such an artifact. As shown in Figure 4, such artifact appears to due to *redundant* harmonics generated by SawSing that "connect" the harmonics of two adjacent phonemes at its harmonic signal x_{h} for breathing and unvoiced consonants. This may be due to the limited capacity of the LTI-FIR filter of SawSing in distinguishing between the nuances of voiced (V) and unvoiced (NV) components during sound transients, modeling a transient even as a harmonic signal. Unfortunately, it seems that this artifact cannot be reflected in any training loss functions (and objective metrics) we considered, so the network fails to take it into account while updating the parameters. Furthermore, human ears are sensitive to such an artifact, contributing to the lower MOS of SawSing compared to DDSP-Add, despite that SawSing might perform better in

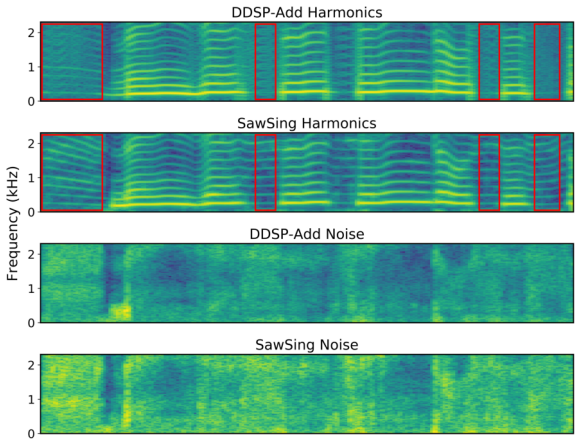


Figure 4: The spectrograms of the harmonic signal x_{h} and noise signal x_{n} generated by DDSP-Add and SawSing for the same clip. The red rectangles highlight the moments the buzzing artifact of SawSing emerges.

other phonemes and long utterances.

Figure 3 also shows that the DDSP-based vocoders do outperform HiFi-GAN greatly in the resource-limited scenario (b) with only 3 training recordings, nicely validating the training efficiency of the DDSP-based vocoders. While the MOS of either DDSP-Add or SawSing is above 2; that of HiFi-GAN is only around 1, i.e., its generation is barely audible. Moreover, SawSing outperforms DDSP-Add in this scenario for both singers, with significant MOS difference for the male singer (p-value$<$0.05), though not for the female singer. This shows that, despite the buzzing artifact, the training efficiency of SawSing can give it an edge over other vocoders in resource-limited applications.

Inspired by [5], we implement a postprocessing method that uses Parselmouth [52] to get V/NV flags and sets the harmonic synthesizer amplitudes to zero for the NV portions. This removes much of the artifact (see the demo page). We share the code on our GitHub repo. Future work can incorporate the V/NV flags at the training phase.

8. CONCLUSION

In this paper, we have presented SawSing, a new DDSP-based vocoder that synthesizes an audio via the summation of a harmonic component obtained from filtered sawtooth waves and a stochastic component modeled by filtered noise. Moreover, we presented objective and subjective evaluations complementing the lack of experiments in the recent work of Alonso and Erkut [44], demonstrating for the first time that both SawSing and DDSP-Add [23, 44] compare favorably with SOTA general-purpose neural vocoders such as HiFi-GAN [15] and FastDiff [21] for singing voices in a regular-resource scenario, and has a great performance margin in a resource-limited scenario.

Future work can improve the harmonic filter of SawSing to resolve the artifact, and use lighter-weight non-causal convolutions [53] for f_{NN} for real-time applications. We can also implement SawSing as a VST audio plugin for usages in creative workflows and music production [54].

9. ACKNOWLEDGEMENT

We are grateful to Rongjie Huang and Yi Ren for sharing with us the code of FastDiff, and Shuhei Imai for helping proofread the paper. We also thank the anonymous reviewers for their constructive feedbacks. Our research is funded by grants NSTC 109-2628-E-001-002-MY2 and NSTC 109-2221-E-007-094-MY3 from the National Science and Technology Council of Taiwan.

EQUIVARIANT SELF-SUPERVISION FOR MUSICAL TEMPO ESTIMATION

Elio Quinton
Universal Music Group

ABSTRACT

Self-supervised methods have emerged as a promising avenue for representation learning in the recent years since they alleviate the need for labeled datasets, which are scarce and expensive to acquire. Contrastive methods are a popular choice for self-supervision in the audio domain, and typically provide a learning signal by forcing the model to be invariant to some transformations of the input. These methods, however, require measures such as negative sampling or some form of regularisation to be taken to prevent the model from collapsing on trivial solutions. In this work, instead of invariance, we propose to use equivariance as a self-supervision signal to learn audio tempo representations from unlabelled data. We derive a simple loss function that prevents the network from collapsing on a trivial solution during training, without requiring any form of regularisation or negative sampling. Our experiments show that it is possible to learn meaningful representations for tempo estimation by solely relying on equivariant self-supervision, achieving performance comparable with supervised methods on several benchmarks. As an added benefit, our method only requires moderate compute resources and therefore remains accessible to a wide research community.

1. INTRODUCTION

Manually annotated data is scarce and expensive to acquire, becoming a bottleneck to the continued progress of supervised learning methods in recent years. This is particularly true in the music domain, where a large proportion of content available is under copyright. Unlabelled data is comparatively abundant and inexpensive. Self-Supervised Learning (SSL) methods, which do not require labeled training data, have shown very promising development by rendering larger unlabelled datasets usable for training and yielding performance comparable or surpassing supervised benchmarks on Natural Language Processing (NLP) [1, 2], computer vision tasks [3], speech processing [4] and music tasks [5]. Self-supervised learning is still only nascent in musical audio, in comparison with other domains. To date it has only been considered with target downstream tasks that are a limited subset of the Music Information Retrieval (MIR) field, e.g. auto-tagging, genre classification or cover song detection [5–7]. With this contribution, we propose to extend the application of a SSL framework to the rhythmic properties of music by applying it to the tempo estimation task, which state of the art is still within the realm of supervised methods [8–11].

Self-supervision is typically realised by creating a pretext task providing a training signal from which it is expected that the model can learn useful representations. The general intuition underpinning this family of approaches is that accurately performing on the pretext task requires the model to learn meaningful representations of the domain at hand. For domains where data is made of discrete tokens, such as text, pretext tasks like masked language modelling or next sentence prediction as have proven to be effective and brought a step change in NLP [2]. Taking inspiration from it, comparable approaches can be devised in the symbolic music domain, which data is also in the form of discrete tokens [12]. In domains where data is dense and continuous, such as images or audio, one option is to apply similar token-based methods to discrete representations of the dense input [13, 14]. Alternatively, Siamese network frameworks [15], where two models process two views of a given input, are a popular choice for handling continuous data directly. In particular, contrastive methods where the pretext task consists in discriminating whether two inputs (or set thereof) should yield a similar, or dissimilar representation have been shown to be effective in computer vision [3] and in the audio domain [16–19], including musical audio [5–7].

In the contrastive learning framework, for every training sample, two views are generated by applying random data augmentations. The training objective then constrains the model to produce representations that are *invariant* to the augmentations applied to the training data and yet discriminative between different samples. The choice of augmentations is a critical design choice that impacts the quality and properties of representation learnt [20]. For example, in [5] the model is trained to be invariant to pitch-shifting. While this is appropriate for fine-tuning on an auto-tagging task, it would not be suitable for downstream tasks such as chord or key estimation. Generally speaking, the invariance constraints explicitly specifies what the representations should *not* be sensitive to. Conversely, *equivariant* constraints can be applied to enforce preferences on what features or concepts may be desirable to capture in the learnt representations [21, 22]. This is particularly at-

tractive in scenarios where it is not clear how invariance constraints can yield a suitable representation, such as F0 estimation [23], or for guaranteeing that the representations capture specific semantically meaningful dimensions such as harmony or rhythm, which may be beneficial for applications such as music search and discovery.

In this work, instead of *invariance*, we propose to use *equivariance* as a self-supervision constraint to learn audio representations that specifically capture musical tempo, from unlabelled data. We propose a Siamese network framework where we produce two views of each training sample by applying a time stretching transformation with random factor and impose an equivariance constraint between the representations. Although the tempo of the training samples is unknown, as a result of the time-stretching transformation, the tempo of each sample is modified in two different, but known, ways. From there we derive a loss function that exploits this information and enforces the equivariant constraint. Because we wish the representations to capture rhythmic properties of music only, we also add audio augmentations to promote robustness against potentially confounding attributes of the audio signal. As is customary with self-supervised pre-training [3, 5], we evaluate the quality of the representations learnt with our method by freezing the model and fine tuning a linear layer on a downstream tempo estimation task.

Our key contributions are the following. 1- To the best of our knowledge, our work is the first to rely solely on an equivariance-based objective to learn musical audio representations. 2- We derive a simple loss function that formally prevents the network from collapsing on a trivial constant solution during training, without requiring any form of regularisation or negative sampling. 3- Our experiments show that it is possible to learn meaningful representations for tempo estimation by solely relying on equivariant self-supervision, and to achieve performance comparable with supervised methods on several benchmarks. 4- Our experiments demonstrate out-of-domain transferability of the representations learnt across multiple datasets. 5- As an added benefit, our method only requires moderate compute resources and therefore remains accessible to a wide research community. In order to further reproducibility we make code and pre-trained models available [1] .

2. BACKGROUND

2.1 Tempo Estimation

In many musical traditions, tempo is one of the fundamental characteristics of music. Tempo estimation was also one of the first tasks to have been explored in the field of MIR [24–28]. Historically, tempo estimation was performed by first extracting an onset detection function [29,30] and then perform tempo estimation via the computation of inter-onset intervals or some form of periodicity function from the onset detection curve [24, 26, 28, 31, 32].

With the introduction of deep learning, like most other MIR tasks, tempo estimation methods have gradually moved towards end-to-end learning where the deep neural network would jointly perform the feature extraction (e.g. onset detection curve) and tempo estimation [8–10]. This evolution brought a boost in performance so that the tempo estimation state of the art benchmark have been based on supervised deep learning for some years [8–10]. In line with this observation, we also adopt a deep neural network model described in detail in Section 3.1.

2.2 Siamese networks and trivial solutions

Most of the methods that have been shown to be successful at self-supervised representation learning for domains where data is dense and continuous, such as image and audio [3, 5, 33–35], are variations of the Siamese networks architecture [15]. Another trait these methods have in common is that they aim to maximise the similarity between the representations obtained from different transformations of a training sample. This problem, however, admits trivial solutions. For example, if the model produces a constant output irrespective of input, the representations of the two views would always be identical. Providing a mitigation strategy to prevent the model to collapse to a trivial solution is a major challenge in this family of methods.

A variety of strategies have been proposed to guard against the trivial solution collapse issue in the literature. SimCLR relies on negative sampling, where for each training sample all other samples in the mini-batch are considered as negatives [3]. This class of methods tend to benefit from large batch sizes. The Barlow twins approach prevents collapse by introducing an additional redundancy term to the training loss [36]. The authors also note that the method require smaller batch size than SimCLR. Deep cluster [37] and SwAV [33] prevents collapse by incorporating a clustering mechanism so that image features are not compared directly. Departing from the contrastive approach, BYOL relies only on positive pairs and prevents collapse by introducing asymmetry in the training scheme by updating the model parameters using only one transformed view of the input while the other view is used as a target [34]. In a similar line of work, the SimSiam authors note that the 'stop-gradient' operation introduces some asymmetry that is critical in preventing the collapse to trivial solutions [38]. Also relying on asymmetry, MoCo mitigates the trivial solution collapse by including momentum encoder [39].

The methods described above introduce trivial solution collapse mitigation strategies of varying degree of complexity that are found to work in practice even though their formulation still formally accepts trivial constant solutions. In Section 3.2 we propose a simple framework that formally does not admit a trivial constant solution, does not require negative samples [3, 5], large batches [3, 5], asymmetry [34, 35, 38, 39], non-differentiable operators [33] or stop gradients [38].

2.3 Equivariant objective

A representation $q(w)$ is invariant if it remains unchanged for a certain transformation k of the input w:

[1] https://github.com/Quint-e/equivariant-self-supervision-tempo

$$q(k \cdot w) = q(w) \quad (1)$$

In the case of equivariance, the representation reflects the transformation applied to the input:

$$q(k \cdot w) = k \cdot q(w) \quad (2)$$

Although the bulk of self-supervised methods developed so far rely on the notion of invariance to transformations of the training samples, we argue here that equivariance can provide a useful learning signal for forcing representations to capture meaningful properties of the input data. Recent works in the computer vision domain show that employing an equivariant objective in addition to more common invariant objective is beneficial [21, 22]. In this scenario, the equivariance is enforced against transformations such as rotation or scale. Similarly, equivariance is starting to be explored as an additional training objective in the video domain [40].

In the musical audio domain, SPICE relies on a composite training objective with an equivariance constraint to learn pitch representations from unlabelled data at its core [23]. SPICE generates two views of each training sample by applying pitch-shifting and aims to learn representations that are equivariant to the pitch of musical audio. SPICE requires strong regularisation to train effectively, which is achieved by adding an extra decoder network (discarded at inference time) and corresponding audio input reconstruction term to the loss.

In contrast with previous works, the method we propose here solely relies on a simple equivariance loss term. It does not include an invariance-based objective [21, 22] or any extra regularisation loss term [23].

3. METHODS

3.1 Model

Our model pipeline is a close adaptation of the Temporal Convolutional Network (TCN) architecture architecture introduced first in [41] for beat tracking and later extended to joint beat tracking and tempo estimation in [42]. From the audio downmixed to mono, we compute a magnitude spectrogram with a window and FFT size of 2048 samples and a hop size of 441 samples (i.e. 100 frames per second for audio sampled at 44100Hz). The FFT magnitude spectrogram is then mapped to a Mel Spectrogram with 81 bins ranging from 30 to 17,000Hz, and finally logarithmic compression is applied.

The Log Mel Spectrogram is then fed to a neural network constituted of two main building blocks and which architecture is depicted in Figure 1. The input is first fed through a batch normalisation layer followed by 3 convolutional blocks. It is then processed through 8 TCN layers with 16 filters each and geometrically increasing dilation rates from 2^0 to 2^7. Because we focus on learning tempo representations in this work, we drop the beat tracking branch and adapt the tempo branch architecture so that our network outputs a 16-d vector representation $\mathbf{h}$. All other design parameters are identical to [42]. We chose this TCN architecture because it is specifically designed to model temporal characteristics of music and has been shown to provide very competitive performance despite using very little parameters (33k).

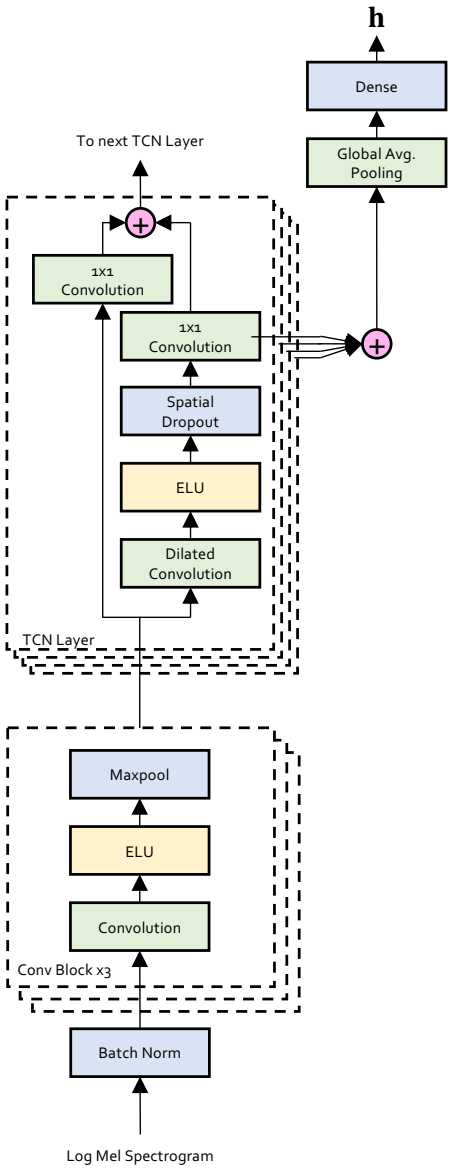

Figure 1. Temporal convolutional neural network (TCN) architecture. The Log Mel spectrogram is first processed through 3 convolution blocks and then through 8 TCN layers with 16 filters and geometrically increasing dilation rates from 2^0 to 2^7. The network outputs a 16-d vector embedding $\mathbf{h}$.

3.2 Training strategy

The objective of the training strategy described below is to learn representations that capture tempo information without having access to tempo annotations at training time. Starting from the observation that the time-stretching modifies the tempo of a music piece, we propose to use equivariance to time-stretching as a self-supervision objective to

learn tempo representations.

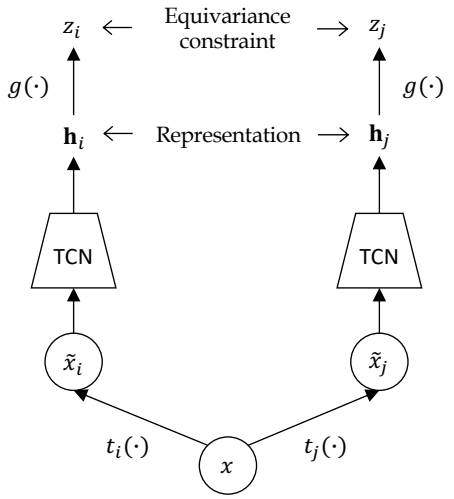

Figure 2. Equivariant self-supervision framework. Two distinct time-stretching transformations (t_i and t_j) are applied to a training sample x to obtain to correlated views ($\tilde{x}_i$ and $\tilde{x}_j$). The TCN network and projection head $g(\cdot)$ are trained to produce a pseudo-tempo scalar z that is equivariant to the time stretching transformation of the input. The projection head is discarded after training.

For a recording taken from the training set, let x be an excerpt of length l_x selected at random in the recording, with unknown tempo $y \in \mathbb{R}$. For each sample x, two views $(\tilde{x}_i, y_i)$ and $(\tilde{x}_j, y_j)$ are produced by applying time stretching transformations noted t_i and t_j respectively using Sox [2]. For each view, the time stretching rate α is drawn uniformly at random from $[1-r, 1+r]$ where r is a hyper-parameter to the training procedure. As a result, we obtain:

$$\tilde{x}_i = t_i(x), \qquad y_i = \alpha_i \cdot y \tag{3}$$

$$\tilde{x}_j = t_j(x), \qquad y_j = \alpha_j \cdot y \tag{4}$$

where the right hand side of eq. (3) and eq. (4) materialises the transformation of the tempo of each view.

In order to allow efficient batch processing at training time, we force the augmented views $\tilde{x}_i$ and $\tilde{x}_j$ to all have the same length l_x by cropping if they are longer and padding with zeros if shorter. In all our experiments we set l_x to be 600,000 audio samples (13.6s at 44.1 kHz).

Because the true tempo y is unknown, we propose to use a pseudo-tempo representation $z \in \mathbb{R}$ as the output of model at training time. Let $f(\cdot)$ be the transformation applied by the TCN and $g(\cdot)$ be a linear projection head, so that $g(f(x)) = z$. The objective is then to constrain the TCN and projection head stack to be equivariant to the time-stretching transformation of the input, so that:

$$g\left(f\left(t(x)\right)\right) = \alpha \cdot z \tag{5}$$

[2] http://sox.sourceforge.net

Since the two views are derived from the same training sample, it is trivial to show that the equivariance formulation expressed in eq. (5) yields:

$$\alpha_i \cdot z_j = \alpha_j \cdot z_i \tag{6}$$

In other words, the equivariance objective is met if eq. (6) is true. Based on this, we can derive the following training loss that is minimised when the equivariance objective is met:

$$\mathcal{L} = \left| \frac{z_i}{z_j} - \frac{\alpha_i}{\alpha_j} \right| \tag{7}$$

Note how this formulation does not allow the model to collapse on a trivial constant solution to minimise the loss. Producing a constant z value for any input does not yield a minimal loss because α values are drawn at random for every training sample, which means that the ratio $\frac{\alpha_i}{\alpha_j}$ varies for every pair of training sample views.

Other formulations of the loss function that are minimised when eq. (6) is true can be derived, but may allow trivial solutions. For example loss functions such as $\mathcal{L}' = |\alpha_i \cdot z_j - \alpha_j \cdot z_i|$ or $\mathcal{L}'' = \left| z_i - \frac{\alpha_i \cdot z_j}{\alpha_j} \right|$ admit a trivial optimal solution for $z_i = z_j = 0$.

3.3 Training parameters

In all our experiments we use a batch size of 16 samples, the Adam optimiser [43] with initial learning rate of 0.001. We pre-train the model for 20 epochs and fine-tune for 100 epochs.

With the aim to promote robustness against non tempo-related attributes of audio signals, we add the following optional random audio augmentations during pre-training: gain, polarity inversion, gaussian noise and SpecAugment frequency masking [44]. Note that our loss function remains unchanged whether or not we apply these augmentations.

3.4 Datasets

For self-supervised training we use the MagnaTagaTune dataset (MTT) [45]. It contains around 25k audio tracks but no tempo annotations.

For fine-tuning and evaluation we use datasets commonly used in the tempo estimation litterature that do contain tempo annotations. Namely we use the following datasets: GTZAN [46], Hainsworth [47] , Giantsteps [48, 49] and ACM Mirum [50].

3.5 Evaluation

After pre-training, we wish to evaluate the representations learnt by the TCN. The projection head $g(\cdot)$ is discarded and all the network weights frozen. We then attach a linear classification head with 300 units and softmax layer to represent the range [0,300] BPM, apply a smoothing window to the ground truth label similar to [42] and fine-tune using the cross-entropy loss.

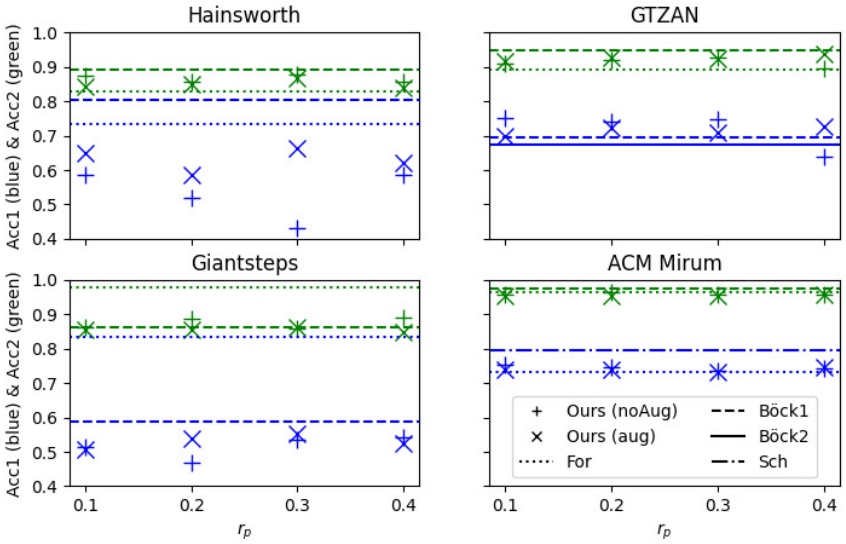

Figure 3. Performance metrics for our proposed method, compared against supervised benchmarks. We report both Accuracy 1 (in blue) and Accuracy 2 (in green). We report results for 8 pre-training conditions, which are combinations of using augmentations ("aug") or not ("noAug") and of $r_p \in \{0.1, 0.2, 0.3, 0.4\}$. In all cases the model is fine-tuned with a time-stretching of strength $r_f = 0.2$. Horizontal lines represent the supervised benchmarks "Böck1" [8], "Böck2" [42], "For" [51], "Sch" [9]. In the interest of legibility, for every dataset and every metric we only display the highest and lowest performing baselines.

In order to evaluate generalisation capability of our model, we perform cross-dataset evaluation. This means that the metrics we report are always computed on a dataset that has never been seen by the model during the pre-training or fine-tuning stages.

In order for our results to be comparable with existing literature, we report tempo performance metrics *Accuracy 1* and *Accuracy 2* scores with a $\pm 4\%$ tolerance [28]. *Accuracy 1* measures the accuracy of the model's prediction of the exact ground truth tempo, while *Accuracy 2* also allows for "octave errors" with factor $\{2, 3, \frac{1}{2}, \frac{1}{3}\}$. We leave further evaluation considerations for future work [52].

4. EXPERIMENTS

4.1 Robustness against trivial solutions

In a preliminary experiment, we ran the pre-training with alternative losses $\mathcal{L}'$ and $\mathcal{L}''$, as defined in Section 3.2. It systematically collapsed to a trivial solution $z \approx 0$. Conversely, we use the loss function $\mathcal{L}$ described in Eq. 7 in all the experiments reported in this paper and did not observe collapse, which confirms its robustness against trivial constant solutions.

4.2 Influence of pre-training augmentation parameters

Figure 3 shows the performance metrics on evaluation datasets for supervised baselines and our method after pre-training on the MTT dataset and cross-dataset fine-tuning and evaluation. We report results for 8 pre-training conditions, which are combinations of using audio augmentations ("aug") or not ("noAug"), and of the strength of time-stretching during pre-training $r_p \in \{0.1, 0.2, 0.3, 0.4\}$. In all cases the model is fine-tuned with a time-stretching of strength $r_f = 0.2$ (see section 4.3).

It appears that adding augmentations yields no notable performance benefit except on Acc1 on the Hainsworth dataset. We hypothesise this is because the TCN architecture already has a strong inductive bias towards temporal and rhythmic structures, which makes it robust against potentially confounding attributes of the audio signal.

The choice and strength of input transformations has been shown to have an impact on the performance of contrastive learning [20]. Intuitively, one expects that very gentle augmentations may not allow to learn robust representations, on the other hand too strong an augmentation may lose semantic content and therefore not allow to learn at all. In our experiments, we observe that the performance tends to dip slightly at the extreme ends of the range of values for r_p. However, it is interesting to note that we do not observe a dramatic degradation of performance even though the transformations applied then (e.g. $r_p = 0.4$) are musically extreme.

Overall these results suggest that the pre-training phase is fairly robust to the choice of time-stretching parameters and to the absence of audio augmentation.

4.3 Influence of fine-tuning augmentation parameters

At the fine-tuning stage, tempo estimation is formulated as a multiclass classification problem, where each class corresponds to a tempo value. Because it is likely that the datasets used for fine-tuning may not contain training sam-

Böck 2 [42]	-	-	-	0.673	0.938	0.764	0.958	0.749	0.974

Table 1. Influence of time stretching parameters during Fine-tuning, and comparison to supervised baselines. In all cases, our model is pre-trained on MTT with $r_p = 0.2$ and no audio augmentations. Highest performance for each metric and dataset shown in bold. Metrics where our model outperforms at least one of the baselines in italics.

ples for each tempo in the full BPM range considered, we also apply a time-stretching augmentation to increase the range of tempi seen during fine tuning.

Table 1 summarises the results using a model pre-trained with $r_p = 0.2$ and no invariant augmentations, for a range of fine-tuning time-streching augmentation strength r_f. As expected, it appears that applying some time-stretching ($r_f > 0$) generally improves performance over not applying any ($r_f = 0$). We also note that the optimal value varies from one dataset to the next. For example results seem to be optimal for relatively large augmentation strength on the GTZAN dataset while they would be optimal for smaller values on ACM Mirum.

4.4 Comparison to supervised benchmarks

Figure 3 shows supervised benchmarks as horizontal lines. Our proposed method's Accuracy 2 performance is comparable with supervised benchmarks on all datasets. Accuracy 1 performance is more inconsistent. It lags behind supervised methods on Hainsworth and Giantsteps datasets, while it is comparable with supervised benchmarks on ACM Mirum. Notably, our method outperforms all supervised baselines in Accuracy 1 on GTZAN. Similar conclusions can be drawn from the results shown in Table 1, under different fine-tuning configurations.

Note that we evaluate our models on datasets that have never been seen during pre-training or fine-tuning and still observe performance generally competitive with supervised benchmarks. Also taking into account that we only fine-tune a linear layer, this result indicates a promising degree of robustness of the representation learnt during pre-training against domain shift.

5. CLOSING WORDS

In this work, we introduced an approach to use equivariance as a self-supervision signal to learn audio tempo representations from unlabelled data. We derive a simple loss function that prevents the network from collapsing on a trivial solution during training, without requiring any form of regularisation or negative sampling. Our experiments show not only that it is possible to learn meaningful representations for tempo estimation by solely relying on equivariant self-supervision, but also demonstrate that we can achieve performance comparable with supervised methods on most benchmarks. We also show that the representations learnt exhibit promising robustness against pre-training and fine-tuning hyper-parameters as well as against domain shift. As an added benefit, our method only requires moderate compute resources by making use of a small model and not requiring large batch sizes, therefore keeping it accessible to a wide research community.

We believe these results open a number of interesting avenues for future work. This paper is focused on tempo estimation but there is potential to extend our investigation to other MIR tasks revolving around rhythmic properties such as beat tracking, metrical structure estimation or rhythm pattern identification. In addition, because no annotated data is required for pre-training, there is potential for investigating applications to low resource musical genres or genres underserved by traditional and current supervised methods. Since our loss function is very simple, it could also be added as an extra objective in SSL frameworks for learning general music representations, at a moderate cost of increased complexity. Last but not least, while invariance typically used in contrastive learning is naturally connected with classification problems, equivariant self-supervision is well suited to tasks that can be formulated as regression problems. We therefore believe there is potential to explore many more applications of equivariant SSL in the music domain and beyond.

ABSTRACT

Tools and methodologies for distinguishing computer-generated melodies from human-composed melodies have a broad range of applications from detecting copyright infringement through the evaluation of generative music systems to facilitating transparent and explainable AI. This paper reviews a data challenge on distinguishing computer-generated melodies from human-composed melodies held in association with the Conference on Sound and Music Technology (CSMT) in 2020. An investigation of the submitted systems and the results are presented first. Besides the structure of the proposed models, the paper investigates two important factors that were identified as contributors to good model performance: the specific music features and the music representation used. Through an analysis of the submissions, important melody-related music features have been identified. Encoding or representation of the music in the context of neural network modes are found noticeably impacting system performance through an experiment where the top-ranked system was re-implemented with different input representations for comparison purposes. Besides demonstrating the feasibility of developing an objective music composition evaluation system, the investigation presented in this paper also reveals some important limitations of current music composition systems opening opportunities for future work in the community.

1. INTRODUCTION

With the rapid development of AI, automatic music composition systems are considered to approach the quality of human-composed melodies in their output under certain conditions. The Conference on Sound and Music Technology (CSMT) organised a data challenge in 2020 to investigate how to tell apart human-composed melodies from computer-generated melodies, where participants were required to develop an algorithm (or a system) that can distinguish computer-generated melodies from human-composed ones. The submitted algorithms can potentially be used to prevent computer systems from being accused of music copyright infringement, and to objectively measure the performance of different algorithmic composition systems.

The primary task in this data challenge was to develop a system to identify human-composed melodies in a dataset where they are mixed with computer-generated melodies. The generated melodies come from several state-of-the-art music generation frameworks [1], including Variational Auto-Encoder (VAE) [2], Transformer [3] and Generative Adversarial Network (GAN) [4]. A training set with only generated melodies was released first, followed by an evaluation set with human-composed melodies mixed in. Two datasets were used for training the music generation systems separately: Bach Chorales [1] in Music21 [5] and HookTheory [2]. The generated and composed melodies thus followed two styles associated with Bach and more generally the pop genre.

The rankings of the participants were determined by the AUC score in ROC tests, based on the task of identifying human-composed melodies. 7 teams participated in the data challenge with a total of 14 submitted systems, covering various types of algorithms. For instance, rule-based system [6], LSTM (Long short-term memory) [7–9], AE (auto-encoder) [10] and more conventional SVM (support vector machine) [11]. The top-ranked submission by Li *et. al* [7] obtained an AUC score of 0.88, which demonstrated the feasibility of using a computer to identify the music source, at least in a specific context of the two styles by distinguishing human compositions from generated melodies.

The results of the data challenge are further investigated in three ways: style, pitch feature and music representation. The sub-rankings regarding the two music styles are also compared, though little difference was observed. However, the system performance shows significant differences in terms of different pitch features in melodies and music representation methods. Moreover, the paper also presents a revised version of the top-ranked system with

[1] https://web.mit.edu/music21/doc/moduleReference/moduleCorpusChorales.html
[2] https://www.hooktheory.com/

different input representations to discuss how music representation affects the identification of melodies.

The identification of computer-generated melodies could be used to ensure that no copyright is claimed for fully-automated computer-generated melodies. [12]. Moreover, measuring similarity between human and computer-generated melodies could become a component of Generative Adversarial Networks (GAN) and similar frameworks for automatic and assistive composition, as well as reduce the subjective bias in the evaluation of music generation systems.

The remainder of the paper is organised as follows: we first review the CSMT 2020 data challenge including submissions and results. The performance differences between submissions regarding different musical features are then investigated. Two experiments on the impacts of music representations are presented followed by a brief conclusion.

2. DATA CHALLENGE

2.1 Task Definition and Organisation

The proposed task for the data challenge was to distinguish human-composed melodies from computer-generated melodies, all in the form of 8-bar single-track MIDI files. A training dataset was released first, containing only computer-generated melodies. The evaluation dataset, with equal numbers of human-composed melodies and generated melodies, was released without the associated labels one month before the final submission deadline. The final results were ranked using the AUC score in ROC test, which identifies human-composed melodies from computer-generated ones.

Time	Event
July 15th, 2020	Release of the development dataset
August 15th, 2020	Release of the evaluation dataset
September 15th, 2020	Deadline of submission (prediction, model and report)
October 20th, 2020	Submission review finished
November 4th, 2020	Result announcement

Table 1: Timeline of the CSMT 2020 Data Challenge

2.2 Dataset

A detailed specification of the dataset, especially the training dataset, can be found in [1]. The components of evaluation set are shown in Table 2 to provide a clearer context of the results presented in this paper. Notice that according to [1], 95% of the human-composed melodies in the evaluation dataset are randomly sampled from those that were used to train the three types of generative models.

2.3 Baseline System

An Auto-Encoder (AE) neural network was used as the baseline system of the challenge, whose source code is available on the official website. Figure 1 plots the model architecture. The model uses a bottleneck structure with the cross entropy loss.

	MTrans	MVAE	MNet	Human	Total
Bach	600	200	200	1000	2000
Pop	600	200	200	1000	2000
Total	1200	400	400	2000	4000

Table 2: The evaluation dataset used in the challenge. "MTrans", "MVAE", "MNet" are short for Music Transformer [13], MusicVAE [2] and MidiNet [4], respectively. Music styles "Bach" and "Pop" are listed separately.

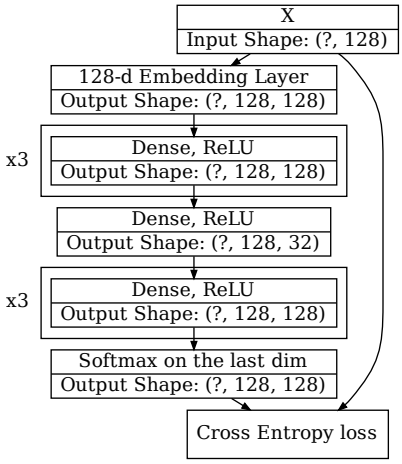

Figure 1: Baseline Auto-Encoder Network Architecture

The baseline model was trained with only real melodies from the Nottingham Folk Tunes dataset [3], consisting of 1,200 American and British songs. The chord information provided in the dataset was not used. The baseline system characterises features of human-composed melodies with an auto-encoder, where computer-generated melodies will result in a high reconstruction loss.

2.4 Overview of the Submitted Systems

For each submitted system, participants were allowed to provide multiple predictions based on different settings or parameters of a model. The challenge received 14 sets of predictions submitted by 7 participants. To simplify references to the submitted systems, aliases are introduced in Table 3 to represent the 8 models. In the table, the presented AUC score is the highest among all predictions of each submitted system.

Around half of the submitted systems outperformed the baseline, these are listed in Table 3. Most participants adopted Deep Neural Networks (DNN), but conventional ML algorithms and rule-based methods were also observed.

There are three main types of methodologies among the submissions: outlier detection, binary classification and heuristics. The outlier detection systems [10] and [14] only learn the feature distribution of the samples of one class

[3] https://github.com/jukedeck/nottingham-dataset

and considers the other class as outliers. Binary classifiers [7–9, 11] use both positive and negative samples for training. The rule-based system [6] uses a set of heuristic rules to test the input melody.

The outlier detection method adopts the idea of Task 2 from the DCASE data challenge 2020. With this configuration, an auto-encoder system is trained in an unsupervised manner for either computer-generated melodies or human compositions. The samples from the outlier class are expected to result in a high reconstruction loss. Besides the baseline system, Ding & Ma [10] and Yu *et al.* [14] used this idea and were ranked 4th and 8th respectively.

The best-performing system [7], Guo *et al.* [8], Xia *et al.* [9], and Wang *et al.* [11] adopted the idea of binary classification. External data, such as Wikifonia, Nottingham and Midi Man [4] . was used to train the classifiers with both positive and negative samples.

The only rule-based system [6] has ranked 2nd as a team, and 3rd as a system, outperforming quite a few ML and DNN systems. In summary, this system takes an 8-bar melody as input and finds the most possible key centers for each bar. The unusual key changes are then counted for every 2 consecutive bars. The key center of a bar is determined by finding out a natural major or harmonic minor scale among all possible scales such that this scale contains most of the notes in this bar. Unusual key changes are defined as any modulations to a distant key, which means the tonic of the new key is 3 fifths or more apart from the original tonic. The success of the system points out that there is still a long way to go for computer music generation systems in learning particular music theories.

3. IMPACT OF STYLE

The evaluation dataset contains equal number of Bach-style and Pop-style melodies. The model performances in each of these two subsets are listed as AUC scores in the column *Bach* and *Pop* of Table 3. Compared with the overall AUC scores, there is no strong difference shown in the model performances given the different style subsets. An exception is that the top-ranked and the second-ranked systems by Li *et. al* are clearly better at evaluating Bach-style melodies than Pop-style ones with differences in the AUC score more than 0.1.

4. IMPACT OF PITCH FEATURES

4.1 Pitch Features

Pitch features are commonly used for the evaluation of generative music systems [15], specifically on melodies. Three pitch features of melodies are proposed for investigating how pitch features impact the performance of the submitted systems: Interval Mean (IM), Interval Standard Deviation (ISD) and Major-scale-rate Standard Deviation (MSD).

Suppose $\mathbf{X}$ is a melody denoted by a MIDI pitch sequence without duration information $[p_1, p_2, \ldots, p_n], 0 \leq p \leq 127$, the first-order forward difference of the pitch sequence $\mathbf{X}$ can be represented as $\Delta\mathbf{X} = [p_2 - p_1, p_3 - p_2, \ldots, p_n - p_{n-1}]$, each of which is an signed integer.

IM and ISD are defined as

$$\mathrm{IM}(\mathbf{X}) := \mathbb{E}[\Delta\mathbf{X}] \tag{1}$$

$$\mathrm{ISD}(\mathbf{X}) := \mathrm{Std}\left(\Delta\mathbf{X}\right) \tag{2}$$

where "Std" is the standard deviation.

Major Scale Rate $\mathrm{MSR}(\mathbf{X})$ is defined as a function that maps a melody $\mathbf{X}$ to a 12-dimensional vector $[c_0, c_1, \ldots, c_{11}]$, where c_i is the number of notes in $\mathbf{X}$ that belong to the natural major scale with pitch class i as the tonic (namely, C major, C♯ major, ..., B major). The vector is normalised by dividing all components by their sum so that $\sum_i \mathrm{MSR}(\mathbf{X})_i = 1$. Major-scale-rate Standard Deviation (MSD) is obtained by

$$\mathrm{MSD}(\mathbf{X}) := \mathrm{Std}\left(\mathrm{MSR}(\mathbf{X})\right). \tag{3}$$

IM approximates the overall tendency of a pitch sequence. For example, if $\mathrm{IM}(\mathbf{X}) > 0$, the melody $\mathbf{X}$ must end at a pitch higher than the starting pitch [5] . ISD measures the unevenness of a melody. A melody with a higher ISD usually sounds more stochastic and chaotic. MSD measures the extent to which a melody is concentrated on a specific (natural major) scale.

4.2 Impact of Pitch Features on Model Performance

For each proposed feature, the following procedure is used to compare the performance of the submitted models given melodies with different IM, ISD and MSD.

For each pitch feature, the feature values are calculated for all melodies in the evaluation dataset. According to feature values, melodies are grouped into 30 bins that equally divide the whole range of feature values. In each bin, the mean absolute error (MAE) between the predicted score and the label of the melody (0 for generated and 1 for human-composed) was used as the measurement of system performance.

4.2.1 Interval Mean

Figure 2a compares how the MAEs were distributed on different IM ranges for different submissions. A dashed KDE plot was also used to show IM distribution for all melodies in the dataset. The majority of the dataset has a IM value in the range of $[-0.75, 0.75]$.

Among all the models, as plotted in the Figure 2a, the two LSTM-based models submitted by Li *et al.* (the blue and the orange curves) produced comparatively lower errors than the others. Xia (the pink curve) submitted another LSTM-based model, with a similar performance to

[4] https://www.reddit.com/r/datasets/comments/3akhxy/the_largest_midi_collection_on_the_internet/

[5] Numerically, IM equals the starting pitch subtracted from the ending pitch.

Rank	Submission Name	Alias	Model	Dataset	Flags	Bach	Pop	All

Table 3: A list of all submissions with AUC scores for the Bach subset, Pop subset and the entire set presented.

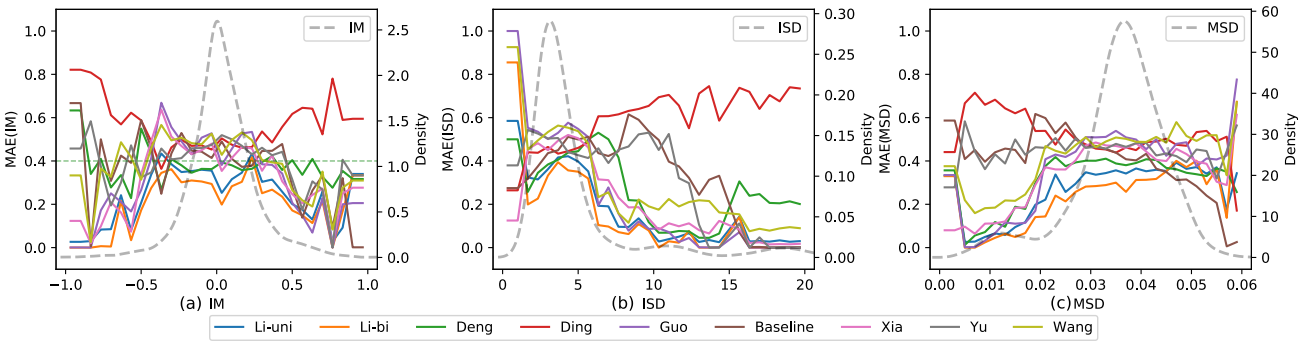

Figure 2: Model MAE on different features. The feature KDE is plotted in a dashed line style to characterise the distribution of music features.

the previous two when IM > 0.5, but higher errors when IM < 0.5. Deng's system (the green curve) makes prediction by counting the bars that modulate to a distant key. As a visual aid, a horizontal dashed green line was plotted to show that the MAE of Deng's model stays around 40%. Especially for IM in $[-0.5, 0.5]$, Deng's model surpassed a few DNN models with low errors only second to Li's models. This model also displayed a stable and consistent performance even with the melodies that have extreme IM values.

4.2.2 *Interval Standard Deviation*

ISD roughly measures the evenness of the melody. Melodies with low ISD are extremely stable and repetitive thus harder to distinguish. Melodies with high ISD tend to be stochastic and more random, which are relatively simpler to distinguish.

Figure 2b illustrates the MAE distributions of different models in different ISD bins. The leftmost highlighted area indicates that most DNN-based models (LSTM, CNN and AE) have poor performance when ISD is within $(0, 2.5]$. However, on the right hand side of Figure 2b, when it comes to melodies with ISD in $[15, 20]$ (which is extremely high), the system performance improves. This evidence shows that most models have successfully learned to recognise some melodies as the outliers if they are stochastic and contain many jumping intervals.

For melodies with higher ISD (ISD > 5), where neighbour pitches are less likely to be fully covered by the convolutional kernel, Yu's CNN-based model (grey curve) produced noticeably more errors than the rest of the models. Ding's BERT-based model (red curve) has an even higher error when ISD is high, indicating that the model is possibly over-fitted with poor generalisation.

4.2.3 *Major-scale-rate Standard Deviation*

A melody with a higher MSD tends to be more diatonic and less chromatic. Figure 2c reveals the performance of submissions regarding different MSD ranges. With lower MSD value (MSD < 0.02), all the LSTM models [7–9] retained relatively lower MAEs than the others, hinting some potential relationship between recognising atonal melodies and the characteristics of LSTM network itself.

Deng's proposed rule-based system, designated to inspecting the tonal properties of a melody also showed a low-error curve, only behind the top-ranked LSTM systems. The stability and strong generalisation property of Deng's system enabled its survival of the rare test cases. For instance, around MSD $= 0.06$, (very high, the melody being too diatonic), some ML or DNN models suddenly collapsed with high errors while Deng's system only had a slight increment in error, with the absolute value remaining less than 0.4.

IM, ISD and MSD can effectively reveal the melody characteristics and hence can be used to explain the model performance using different aspects. The distributions of these features can guide the training process of a music generation system, or as a series of a-priori weights to refine the predictions in a discriminative model according to how common the melody is.

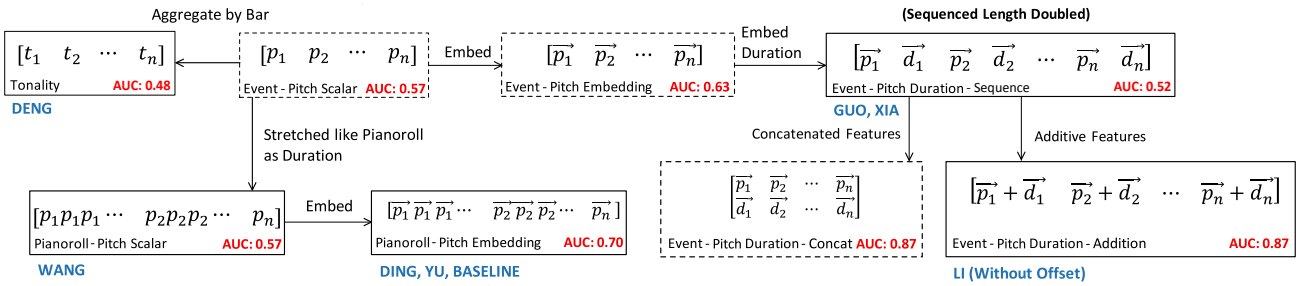

Figure 3: Representation relationship diagram. The edge label denotes the transformation from a representation to another. The aliases of the participants who used a certain type of representation are listed on the left beneath the box, uppercase bold. The AUC score in the bottom right corner refers to the results of the experiment mentioned in Section 5.1.

5. IMPACT OF MUSIC REPRESENTATION

From the submissions, the differences in music representation are focused on two aspects: the input representation and the metric unit of time. Various music representations can be distinguished mainly by what features of notes are selected and how they are organised in structural data. The metric unit of time refers to the minimal time unit to denote the music data. In this study, the top-ranked system by Li *et al.* [7], an LSTM-based binary classifier, has been slightly revised to adopt different types of music representations in order to investigate the impact of music representation on the same task. All re-implemented models are trained 50 epochs using the same training dataset used by Li, (as listed in Table 3) and are evaluated on the evaluation dataset. ROC AUC is used as the evaluation strategy.

5.1 Melody Representations

Three aspects of a melody representation will be discussed in section 5.1: the evenness along time steps, the subsets of features regarding notes and the method of feature fusion.

Evenness of time steps (ETS) The term *Pianoroll* is used if the duration is implicitly represented in the form of pianoroll. One step in these always stands for a constant length of time. Otherwise, the term *event* will be used.

Subset of note features (SNF) Features regarding notes include pitch, duration, velocity [6], *etc*. Particularly in this challenge, only "*Pitch*" and "*Duration*" are used.

Feature fusion method (FFM) Feature fusion is usually achieved in the following three ways if more than one note features is used:

1. Use separate events in consecutive time steps (sequentially), *e.g.*, $\left[\vec{p_1}, \vec{d_1}, \vec{p_2}, \vec{d_2}, \cdots\right]$
2. Concatenate the embedded vectors of different features of the same note into a higher-dimensional vector, *e.g.*, $\left[\vec{p_1} \| \vec{d_1}, \vec{p_2} \| \vec{d_2}, \cdots\right]$
3. Add the embedded vectors of different features of the same note, *e.g.*, $\left[\vec{p_1} + \vec{d_1}, \vec{p_2} + \vec{d_2}, \cdots\right]$

where $\vec{p_i}$ and $\vec{d_i}$ are the embedded vectors (in the same dimension) of the pitch and duration event token for the i-th note in the melody. The representation methods will be named in a format of *ETS-SNF-FFM* as shown in Figure 3.

The only exception of representation is *Tonality* representation, as used by Deng *et. al*. Deng's system represents the input data via the tonality distributions of all bars in a melody [6]. The tonality distribution, denoted by the set of all possible key candidates, summarises the tonal characteristics at a bar level rather than a single note. This leads to the representation name *Tonality* representation.

All the melody representations used by the submitted models can be categorised into 5 types according to the three aspects, plus the extra *tonality*. Besides these that have been used, another three representations were added to better illustrate the relationship among different representations, namely *Event-Pitch-Scalar*, *Event-Pitch-Embedding* and *Event-PitchDuration-Concat*. The former two contain only pitch information, differentiated by whether embedding is used. The *Event-PitchDuration-Concat* representation concatenates pitch vectors and duration vectors instead of element-wise adding. In Li's model [7], the embedding dimension is chosen to be 128.

Figure 3 reveals how a melody representation is related to another through a certain transformation. For instance, starting from the most simple pitch-only *Event-Pitch-Scalar* representation, grouping the pitches by bar gives the *Tonality* representation. Stretching the sequence according to the note position and duration will yield a pianoroll. Using embedding will produce *Event-Pitch-Embedding* and *Pianoroll-Pitch-Embedding*.

5.2 Metric Unit of Time in Music Representation

The metric unit of time in a representation refers to the minimal time unit that the positions and durations of all notes in a melody are always the multiples of. This concept is also known as midi resolution. Quantisation is the procedure that re-samples a midi file to a specific resolution. 3 submissions chose a specific metric unit of time for pre-processing all the melodies before the model input. The results suggest that the unit of metric should be carefully determined according to the specific model. Generally, a larger metric unit will result in fewer rhythmic patterns and time steps, especially for pianoroll representations. This reduces the difficulty in modelling rhythmic and temporal features at the cost of ignoring the nuances.

[6] This paper will not discuss the velocity feature since it was not involved in the data challenge.

As some officially provided melodies were generated without clear beats due to the flaws of some generation systems, the choice of metric unit can be vital in this challenge.

12th of a quarter note is a commonly used metric unit of time, where durations are multiples of 8th notes and 8th triplets, as default used by the Python package `music21` when opening midi files [5]. 12th was adopted by Li [7] and Xia [9]. 24th was adopted by Yu [14] and Guo [8], as used in the Python package `pypianoroll` [16]. Ding's [10] and Wang's [11] submissions used only 4th, a much wider step, which resulted in much lower AUC scores. However, Deng's system [6] did not use the note duration. These facts and the rankings suggest that the choice of larger metric unit could potentially increase the task difficulty of this challenge due to the loss of rhythmic details.

5.3 Effects of Melody Representations on Model Performance

Another experiment was conducted to support the assumption that melody representation impacts the model performance of this task. The top-ranked system by Li, an LSTM-based binary classifier, was re-implemented so that all the 8 representations aforementioned can be used as the model input. For all the re-implemented and re-trained models, the dataset specification remained unchanged as listed in Table 3. The resulting AUC scores are presented in Table 4 and also at the bottom right corner in the boxes of Figure 3. The quantisation options are selected based on the best system performance. For example, the *Pianoroll-Pitch-Scalar* and the *Pianoroll-Pitch-Embedding* representations must use a 3-time larger quantisation grid compared to others so that the sequence length is decreased from around 400 (8 bars, 4 beats and 12 subdivisions per beat) to 100 (4 subdivisions per beat), which allowed the model to converge. The model failed to converge for representations *Event-PitchDuration-Sequence* and *Tonality*. The former failed probably because the doubled sequence length exceeded the network's capacity. The later, despite being short enough, seemed not to help the model learn advanced tonal features purely from the bar tonality distributions. By Deng *et. al*'s report [6], the bar tonality scores, before being used as features, are adjusted according to the confidence of each bar having a clear tonal center, which may be difficult to be learnt by Li's model.

#	Representation	AUC
1	Event-Pitch-Scalar	0.57
2	**Tonality** [6]	0.48
3	**Pianoroll-Pitch-Scalar** [11]	0.57
4	Event-Pitch-Embedding	0.63
5	**Pianoroll-Pitch-Embedding** [10, 14]	0.70
6	**Event-PitchDuration-Sequence** [8, 9]	0.52
7	**Event-PitchDuration-Addition** [7]	0.87
8	Event-PitchDuration-Concatenation	0.87

Table 4: Different input representations tested on the same system. Bold ones came from the submissions.

The results are basically consistent to the assumption that melody representations will impact the model performance in this data challenge. Notice that *Tonality* and *Event-PitchDuration-Sequential* used on the top-performing model did not result in effective classifiers with the AUC-ROC score being only 0.48 and 0.52, which was possibly due to the limited information represented by the tonality vectors and the over-long sequential representation respectively. Figure 3 combined with the results also to some extent displayed the advantages and drawbacks of different melody representations applied to the same model. This provides a reference to researchers when choosing input representations for their music data.

5.4 Effects of Metric Unit on Model Performance

Another set of experiments were conducted to investigate the influence of metric unit on the model performance. The system is modified to accommodate different unit metrics used with the original representation methods of **Event-PitchDuration-Addition**. The attempted metric units are 8th, 12th, 16th and 24th of a quarter note.

#	Metric Unit	Vocab Size	AUC
1	8th	89(p) + 8(d)	0.83
2	12th	89(p) + 15(d)	0.87
3	16th	89(p) + 16(d)	0.88
4	24th	89(p) + 94(d)	0.86

Table 5: Model performances using different metric units of time. The framed line refers to the original representation used by Li's submitted systems.

The results from Table 5 indicates the influence of metric unit of time on the model performance. When the metric unit is small, more rhythmic nuances are preserved and the corresponding vocabulary size (the number of tokens needed to donate all possible duration [or positional] information in the *training* dataset, in Li's manner [7]) will usually be larger. The accordingly changing AUC-ROC scores suggest the necessity of carefully choosing the metric unit of time for a specific music representation.

6. CONCLUSION

The CSMT 2020 Data Challenge evaluated objective systems that identify generated melodies from human compositions. With no limitation on the methodologies and external dataset, participants designed and submitted a wide range of systems utilising DNNs, heuristic methods, and traditional ML models. According to the challenge results, this paper investigated the influence of music style, pitch features and music representations on the model performance. Minor influence of the two music styles (*Bach* and *Pop*) are observed from the results. However, noticeable impacts are observed regarding pitch features and input representation of melodies. This paper suggests that the pitch features could be effectively used to diagnose the model performance for both music generation systems and objective evaluation systems. Besides, melody representations are also important factors that should be carefully selected in related tasks.

7. ACKNOWLEDGEMENT

The authors acknowledge the contribution from all members in the organisation committee of the CSMT Data Challenge 2020. This work is partially supported by Beijing Zhongwen (Xiamen) Law Firm.

ABSTRACT

Existing multi-instrumental datasets tend to be biased toward pop and classical music. In addition, they generally lack high-level annotations such as emotion tags. In this paper, we propose YM2413-MDB, an 80s FM video game music dataset with multi-label emotion annotations. It includes 669 audio and MIDI files of music from Sega and MSX PC games in the 80s using YM2413, a programmable sound generator based on FM. The collected game music is arranged with a subset of 15 monophonic instruments and one drum instrument. They were converted from binary commands of the YM2413 sound chip. Each song was labeled with 19 emotion tags by two annotators and validated by three verifiers to obtain refined tags. We provide the baseline models and results for emotion recognition and emotion-conditioned symbolic music generation using YM2413-MDB.

1. INTRODUCTION

Music generation has been regarded as an attractive research topic for decades. Due to the revival of neural networks, the trend of music generation research has moved from rule-based to data-driven music approaches [1, 2]. In the data-driven approaches, the dataset determines music styles of the generated output and thus it is desired to have a wide assortment of datasets that cover diverse music genres and styles. However, the majority of music datasets are limited to a single instrument, particularly the piano [3–7]. Multi-instrumental datasets mainly cover popular music [8, 9] or classical music [10]. In this regard, we introduce a new dataset from 80s FM video game music originally played for YM2413, a programmable sound generator based on FM sound synthesis. We name it the YM2413 Music Database or YM2413-MDB.

Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

YM2413-MDB provides not only a unique flavor of retro game music but also addresses two important issues in music generation research: the fixed number of instruments and the lack of high-level annotations. The most widely used multi-instrumental music dataset is the Lakh MIDI dataset (LMD). While it is the only large-scale MIDI dataset so far, the musical quality of MIDI files is not consistent within the dataset because it is gathered from public sources. Therefore, most studies using LMD generated music with a limited number of instruments for pop music [11–18]. Other datasets, such as JSB Chorale [10] and NES-MDB [19], have only four fixed instruments. Furthermore, the majority of these datasets lack high-level annotations such as genre or mood, which can be used for conditional music generation. Although songs in LMD are matched to entries in the Million Song Dataset (MSD), which has high-level tag annotations, the labels are rather noisy. There exist two symbolic emotion music datasets manually labeled [5, 20]. However, they include only piano music. YM2413-MDB tackles the two issues with the following characteristics.

- **Multi-instrumental 80s FM Game Music**: The dataset consists of 80's Sega game music played by YM2413, where 9 out of 16 instruments can be played at once, which improved the quality of the played game music at that time. From this advancement, the music played by YM2413 contains rich harmonic and rhythmic information.
- **Multi-modal**: The dataset contains 669 songs in various formats: binary video game music (VGM) files that contain FM synthesis parameters, converted MIDI files, and rendered audio files which restore the original game music sound. Also, the generated MIDI files can be rendered to audio using an FM-synthesizer plug-in.
- **Emotion-annotation**: We annotated the entire dataset with 19 emotion tags in the game context. To make a tag vocabulary with high agreement, each song was annotated by two dedicated annotators and verified by three reviewers. We also confirmed that these tags can be classified using the baseline classification approach.

We first describe the details of dataset collection and statistical analysis of musical features. Then, we provide

Name	Label Type	Music Style	# Inst	# Avg Tracks	# Songs	# Hours
LMD [8]	None	General	128	8.8 / no limit	178K	9K
DadaGP [9]	None	Band (Guitar Pro)	9	3.3 / 9	26.2K	1.2K
VGM-RNN [21]	None	Game music (NES, crowd source)	128	6.6 / no limit	4.2K	101.7*
JSB Chorale [10]	None	Classic (Bach Chorale)	4	4	382	3.9*
NES-MDB [19]	None	Game music (early 80s)	4	2.8 / max 4	5.2K	46.1
MOODetector [22]	28 adjectives	General	128	9.2 / no limit	196	12.1*
VGMIDI [20]	Valence	Piano-arranged game music	1	1	200	6.3*
EMOPIA [5]	Russell's 4Q	Pop piano covers	1	1	1,078	11
YM2413-MDB **(ours)**	19 adjectives	Game music (late 80s)	16	7.2 / max 9	669	15.4

Table 1: Comparison with existing multi-instrumental or emotion-labeled symbolic music datasets. When the dataset do not limit the instrument, # Inst is 128. When the dataset has no information of size in hours, it was estimated using the MIDI max tick (denoted as *).

baseline results of music emotion recognition in both audio and MIDI domains and emotion-conditioned symbolic music generation using a music generation model. We release YM2413-MDB in the online repository [1] . Examples of generated music are accessible in our demo webpage [2] .

2. RELATED WORK

2.1 Characteristics of Game Music

Starting with the single sound effect used in the first video game, *Pong* (1972), the development of game music is in line with the development of computer sound technology [23]. Today's game music is not much different from music from other media, such as dramas and movies. However, early video game music has a distinct characteristic from other genres of music due to technical constraints at the time. A musicological study on early game music found that some unique composition characteristics are found in the form of arpeggio patterns, compound melodies, and simulated reverb effects using delayed instruments [24]. Another characteristic of video game music is that it is composed to be played as a loop [25]. In addition, the transition of playing music occurs when the game context is changed, such as a triggered event: map transition, battle with a boss monster, mission completion, ending, and so on.

2.2 Game Music Generation

There are several studies that focus on computer-generated game music. For example, Prechtl used a music generation model based on Markov Chain, which changes the model state in real-time aligned with in-game parameters [25] They tested the model in a live game context. Mauthes generated video game music using an RNN-based model by collecting video game music crowd-sourced by the game user community [21]. Ferreira and Whitehead used piano-arranged video game music to generate music using LSTM and a genetic algorithm with sentiment as a condition [20]. Donahue et al. generated game music using Transformer-XL [26] with the Lakh dataset [8] pre-training and NES-MDB fine-tuning [19, 27].

[1] https://github.com/jech2/YM2413-MDB
[2] https://jech2.github.io/YM2413-MDB/

2.3 Multi-instrumental Symbolic Music Dataset

There are a handful of multi-instrumental datasets that cover different music genres, including pop [8, 22], classic [10, 28], band [9], and game [19, 21] genres. Table 1 compares the datasets to YM2413-MDB. Among them, the most widely used one is LMD [8]. Since LMD is a large-scale dataset and has a wide variety of instruments, most multi-instrumental research has used LMD with a set of simplified instruments [11–18] so far. Recently, large-scale datasets with a Band [9] or Orchestra [28] style have been released. In the game music genre, NES-MDB, the early 80's Nintendo Game Music Dataset [19] is most similar to our study. All songs in NES-MDB have four monophonic instruments because of the technical constraints of NES's Audio Processing Unit. Songs in NES-MDB have a unique style as retro game music and have expressiveness represented with note timings in the precise time units. However, such expressive characteristics require metric analysis such as beat tracking to extract score-level information.

2.4 Symbolic Music Dataset with Emotion Annotation

There are a few symbolic music datasets with emotion annotation [5, 20, 22]. MOODetector contains audio, MIDI, and lyrics for 193 music files [22]. The music was annotated according to the emotion category used in the MIREX Mood Classification Task [29]. VGMIDI contains 200 MIDI files of piano-arranged video game music with arousal-valence annotations [20]. EMOPIA contains 1087 pop piano music with annotations according to Russell's 4Q [5]. All of these datasets include both MIDI and audio formats.

3. THE YM2413-MDB

3.1 Dataset Description

The dataset consists of game music played by the YM2413 sound chip. YM2413 is a programmable sound generator based on FM synthesis developed by *Yamaha*. FM synthesis can generate diverse musical tones with rich harmonics. YM2413 can play a maximum of 9 instruments simultaneously from 16 instrument presets and one user tone register. The names of the instruments are shown in Figure 1(c). YM2413-MDB contains songs with a short

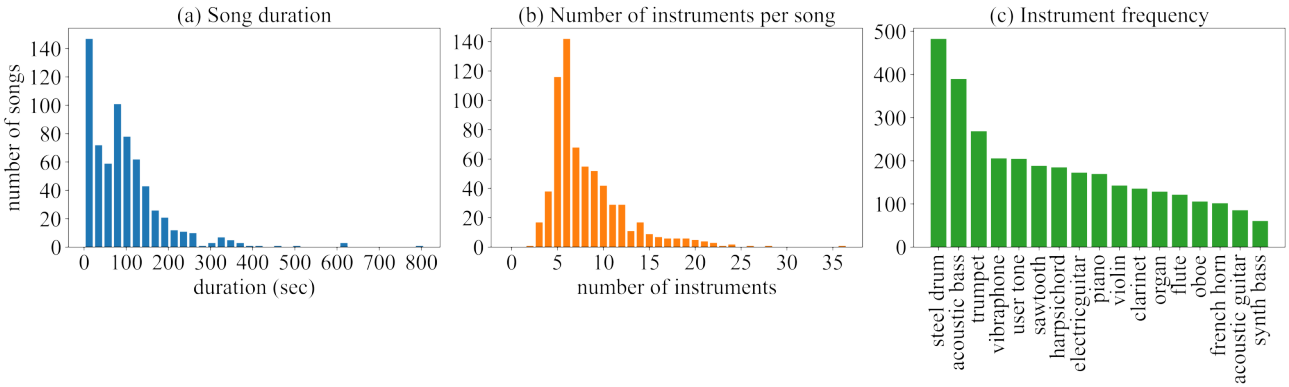

Figure 1: General statistics of YM2413-MDB. (a) Song duration of all songs, (b) Number of instruments per song considering the all program change in single channel, (c) Instrument frequency of whole dataset.

duration for specific game events similar to those in NES-MDB. The statistics are shown in Figure 1(a). In addition, we observed two unique composition patterns: unison playing and simulated reverb using delay. Unison playing is a pattern of the same melody with single or multiple instruments. This technique renders a rich tone by overlapping the same voices of the FM instrument. The delay pattern is also observed in the NES music to express the reverb by using the delayed same voice [24]. These patterns show how the composers at that time were concerned about expressing various tones. Therefore, the role and use of each instrument observed in YM2413-MDB seem to be quite different from those in today's composition style.

3.2 Dataset Collection & Preprocessing

We collected Video Game Music (VGM) files from the game music community websites [3] [4]. After data collection, we translated all the game music files to the MIDI format. Since the original VGM files are written as binary command sequences read by the sound chip, the VGM commands are different for all sound chips; for YM2413, there are non-standard commands for time wait, instrument note on/off, program change, volume change, and FM synthesis parameters for one user's custom tone. We conducted the conversion by emulating the YM2413 sound chip following the FM Operator Type-LL (OPLL) Application Manual [30]. For the VGM disassembly process and sound chip emulation, we referred to the source code of VGMPlay [5], a software that reads the VGM file and reproduces the sound of hardware sound chips. Also, we exported the VGM files as audio files using this software.

The original VGM file format expresses all time-related information as ticks with no tempo-related event. In the case of NES-MDB, they converted all MIDI files with 120 beats per minute (BPM) and 22050 ticks per beat to preserve the temporal resolution of 44100Hz without precise tempo calculation. However, the converted MIDI files were not aligned with the metrical structure that standard MIDI files have. This has hindered the use of bar-based music representation, chord recognition, and further music analysis [4, 16, 31, 32]. Therefore, we conducted the metrical alignment using the extracted down-beat information of rendered audio files using Madmom [14]. For each music file, tempo events were added using estimated tempos from all downbeats. Since most of the pieces had a fixed tempo, we used the median value of the beat-wise estimation of tempo.

In addition, the sound chip synthesizes sounds using frequency values rather than MIDI note numbers; in practice, a frequency is expressed as an F-Number, a discrete value that maps the frequency using 9 bits [30]. Therefore, some of the songs in YM2413-MDB were intentionally detuned for the song's ambiance, and instruments had pitch bends and vibratos for more expressiveness. These characteristics make it difficult to map the right MIDI pitch without careful consideration. We treated such cases using the MIDI pitch bend event, such that the integers and decimal points of the calculated MIDI note number are mapped to the MIDI pitch and pitch bend value.

3.3 Emotion Annotation

During the annotation and verification process and analysis, we referred to [33] for tag vocabulary refinement, verification procedure, and tag visualization. Two researchers participated in both initial tagging and annotation. Once the dataset was collected, we first listened to the entire game music audio files in the dataset and freely described them with the perceived emotion words. From this process, we found several game-specific emotion words that cannot be directly mapped into both the conventional emotion arousal-valence model and emotion tags used in MIREX music classification [22]: fluttered (war-inspiring), grand, bizarre, frustrating, comic, faint, and touching. As discussed in [34], the categorical approach is suitable for these complex emotions rather than the dimensional approach. Therefore, we decided to annotate the emotions as word tags.

From the emotion descriptions of all songs in the dataset, we obtained 35 emotion-related tags. We grouped similar emotion words according to a Korean crowdsource BGM repository [6] and finally obtained 19 emotion tags.

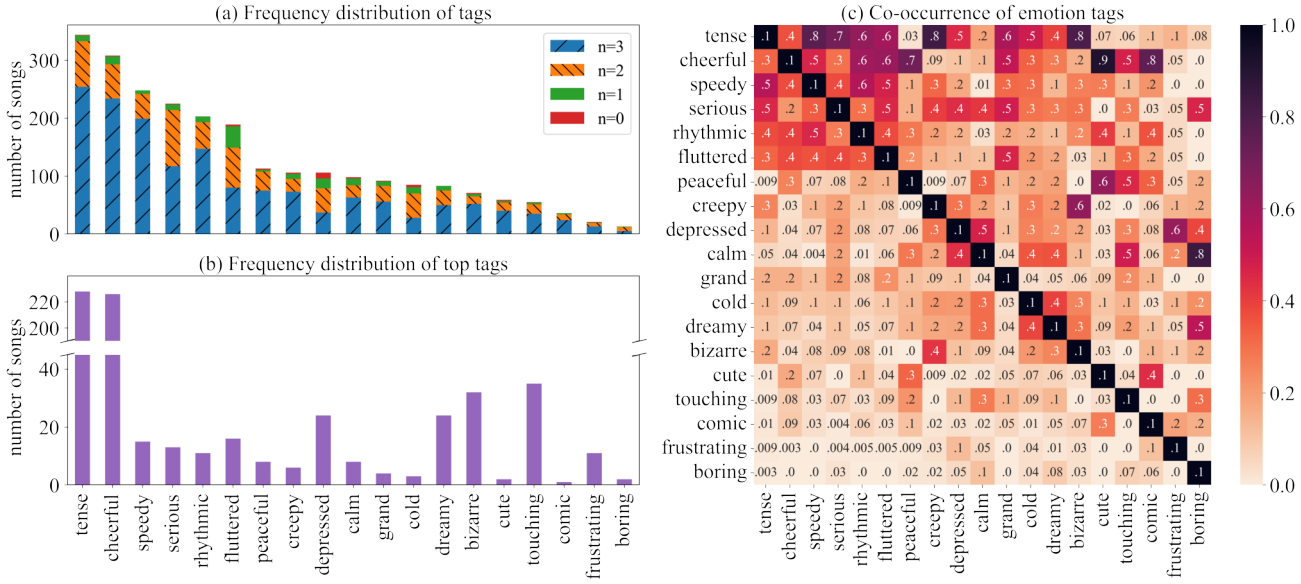

Figure 2: Emotion annotation and verification results. (a) Frequency distribution of emotion tags where n is the number of agreements of verifiers, (b) Frequency distribution of top tags, (c) Co-occurrence of emotion tags. Each column is normalized by the frequency of each tag.

After the tag vocabulary was refined, we conducted the labeling. While annotating the dataset, each of the annotators selected one dominant emotion tag for each music which we call "top tag" in this paper. Among the top tag annotated by the two annotators, the final top tag was selected as having a higher agreement after verification.

3.4 Emotion Verification

After the annotation step, each music file was validated by three verifiers; in total, ten people participated as verifier. During verification, verifiers were asked to mark the emotion tag if they disagree with the annotation. We provided verifiers with the annotator's description of each emotion tag to reduce the ambiguity of each emotion tag. After verification, tags with low agreement (lower than two) were excluded from the annotation of each music. When the top tag was excluded after verification (26 songs), the tag with the highest agreement was chosen as the new top tag.

Figure 2(a) shows the overall emotion tag distribution of the YM2413-MDB after verification. Also, the agreement portion of verification explains the subjectivity of each tag. In particular, 'serious', 'fluttered', 'depressed', and 'cold' tags have less agreement than other tags. The frequency distribution of top tags is shown in Figure 2(b), in which the imbalance is more noticeable than the frequency distribution of each tag. In Figure 2(c), we investigated the independence of each tag by calculating the co-occurrence of emotion tags. The words that often appear together(>0.8) are as follows: 'speedy'-'tense', 'creepy'-'tense', 'bizarre'-'tense', 'cute'-'cheerful', 'comic'-'cheerful', and 'boring'-'calm'.

Annotation and verification for the Korean tags were operated since all participants were native Korean. They are aged from twenty-four to thirty-one, with at least one retro video game-playing experience.

3.5 Data Representation

For the baseline symbolic-domain classification and generation, we used the event-based representation called Multi-Track Music Machine (MMM) [35]. The MMM representation can handle arbitrary instrument combinations. As discussed in Section 3.1, our dataset contains unison patterns; the same instrument appears in multiple tracks. To apply representations suggested for multi-instrumental music that assume each instrument appears at most once [16, 27, 32], we should discard instrument tracks that appear multiple times in a song. However, we did not apply the strategy due to the small dataset size. In our preliminary study, experiments with multi-instrumental representation suggested by [27] only generate a drum with a large number of notes. We speculate that it was due to the frequency imbalance of tokens; since the representation suggested by [27] combines musical instruments and pitch tokens, the number of tokens increases in proportion to the number of instruments, making the model difficult to learn pitch information. Therefore, we did not use those non-MMM style representations.

To re-implement MMM, we calculated the note density for each instrument by dividing the total number of note counts by the active bar number, which is the number of bars in which at least one note is played. Also, we quantized the music samples with 48 grids per bar. After removing the bar-fill-related vocabulary of MMM which is not necessary for our tasks, we used a total of 447 tokens: five tokens for the piece, track, and bar; 48 tokens for time delta tokens; 128 tokens for each instrument, note on, and note off. Since the MMM representation can express a fixed number of bars, we used four bars with a maximum of six instruments, which the transformer attention window size of 1024 can handle. Fixing the length of generated music is suitable for game music because the game

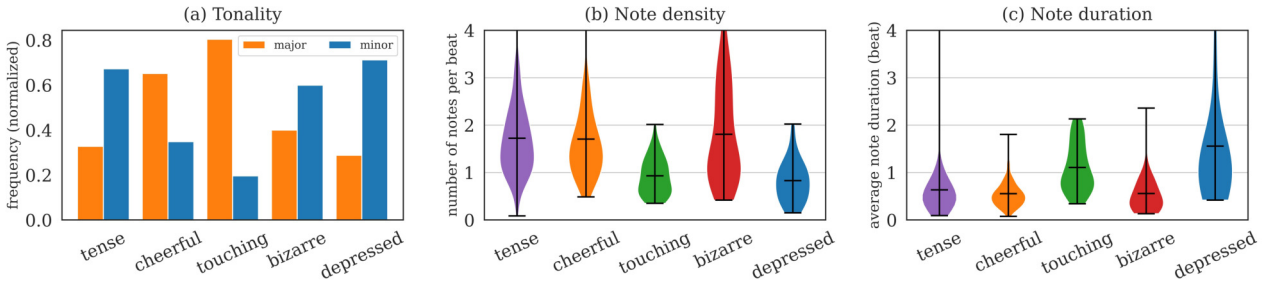

Figure 3: Data distribution for different top tag classes. (a) Normalized frequency of tonality histogram, (b) Note density, (c) Note duration. The outlier sample points were omitted for clear visualization.

music is loop-based, as discussed in Section 2. We sampled the instrument when the number of instruments was greater than six. Due to the sparsity issue, we adapted the dataset for training. The instruments were mapped into six categories during training: piano, string, woodwind, brass, guitar, bass, and drum. Tracks that change within the same channel are all adapted to be treated as one instrument.

4. DATASET ANALYSIS

Emotion is associated with various musical features such as harmony, rhythm, and loudness [36]. We investigated how the musical elements extracted from YM2413-MDB are correlated with the collected emotion tags. We used note density, note duration, and tonality following the previous work [5]. Due to the imbalanced distribution of top tags, we focused on songs with five top tags: 'tense', 'cheerful', 'touching', 'bizarre', and 'depressed'. When extracting the features, we excluded drum tracks to consider the pitch information only when estimating tonality and fairly compared songs with and without drums.

4.1 Tonality

The major/minor tonality is generally connected to positive/negative emotional states [37]. We measured tonality using the Krumhansl-Schmuckler key-finding algorithm [38] implemented in music21 [39]. Figure 3(a) shows a clear trend that the major tonality is frequently used for positive emotions (e.g. 'cheerful', 'touching'), and the minor tonality is frequently used for negative emotions (e.g. 'tense', 'bizarre', 'depressed').

4.2 Note Density and Duration

Another musical feature related to emotion is rhythm [40]. We use note density and note duration as indirect cues to extract the rhythmic characteristics. The note density refers to the number of notes per beat, which was obtained by dividing the total number of notes by the total number of beats. It was normalized by the number of instruments per song. The note duration was calculated by averaging the note duration value in beat units. As shown in Figure 3(b-c), songs with 'tense', 'cheerful', and 'bizarre' tags showed higher note density than the 'touching' and 'depressed' tags. Most songs with 'tense', 'cheerful', and 'bizarre' tags consisted of notes shorter than one beat, whereas songs with 'touching' and 'depressed' tags were widely distributed with longer notes. We also measured the note velocity, but all tag groups maintained a similar distribution. It is because songs in YM2413-MDB do not utilize the velocity features well; in most cases, the velocity of notes is changed together only when program change events occur.

Model	Emotion			Top Tag	
	4Q	Arousal	Valence	Tense	Cheerful
Logistic regression	0.48	0.76	0.56	0.66	0.66
LSTM-Attn [41] + MMM [35]	0.44	0.69	0.59	0.68	0.70

Table 2: Symbolic-domain classification accuracy. 4Q indicates Russell's four quadrants.

Model	Emotion			Top Tag	
	4Q	Arousal	Valence	Tense	Cheerful
Logistic regression	0.38	0.72	0.54	0.60	0.66
Short-chunk ResNet [42]	0.65	0.78	0.60	0.69	0.65

Table 3: Audio-domain classification accuracy. 4Q indicates Russell's four quadrants.

5. MUSIC EMOTION RECOGNITION

We provide our baseline symbolic and audio-domain emotion recognition results using YM2413-MDB. For both symbolic- and audio-domain classification, we used the source code and experimental setting (4Q, Arousal, Valence) of [5] and adapted it to our dataset configuration. We used the same model for classification (logistic regression, LSTM-Attn [41], and short-chunk ResNet [42]). For symbolic domain classification, we used a re-implemented MMM representation with 8 bars and 6 instrument chunks. Due to the small volume with imbalanced emotion tags, it was difficult to use the original emotion tags for emotion recognition directly. Instead, we mapped the top tags into Russell's four quadrants and classified a song into one of the four categories; for tags that do not appear in Russell's circumplex model, we manually mapped to one quadrant of the most similar emotion according to the subjectivity of the annotator [7]. We also provide the baseline binary classification results using 'tense' and 'cheerful' top tags. Other tags showed low classification results due to severe imbalance. We split the dataset with an 8:1:1 ratio for train, validation, and test via stratified sampling.

The emotion classification results of symbolic- and audio-domain are shown in Table 2 and Table 3. Both

[7] https://github.com/jech2/YM2413-MDB/blob/main/emo4Qmap.png

symbolic- and audio-domain classification results of top tags show that these emotions can be recognized by the baseline models. Since the dataset is multi-instrumental and the class imbalance is more severe than EMOPIA, the baseline classification was lower than those reported in [5]. Also, we note that the symbolic-domain classification performance of the LSTM-Attention model with MMM was poorer than that of the logistic regression. We conjectured that it was difficult to learn the temporal relations between instruments when using MMM representation.

6. EMOTION-CONDITIONED SYMBOLIC MUSIC GENERATION

6.1 Data Preparation

We provide the baseline emotion-conditioned symbolic music generation results using YM2413-MDB. Due to the emotion tag class imbalance, emotion conditioning was ineffective when using the entire set of emotion top tags. Instead, we selected 'cheerful' and 'depressed' as representative emotion conditions that showed contrasting features in the dataset analysis (Fig 3) and conducted conditional generation using the data with the two tags. Similar to [27], as our dataset size was small to train the deep learning model from scratch, we used LMD for pre-training the music generation model and fine-tuned it using YM2413-MDB. We filtered too short MIDI files which are less than 3 secs. We also filtered short samples annotated as sound effects. After filtering, we used 10K samples for validation and test sets when we trained the LMD. A total of 286 songs were used for fine-tuning, and four songs containing both 'cheerful' and 'depressed' tags were excluded.

6.2 Model & Train Setting

Transformer-XL [26] is widely used in music generation studies with language modeling approach [4, 9, 27, 43]. GPT2 [44] is a language model that showed high fine-tuning performance in NLP without changing the model structure and was also used in several music generation studies [35,45]. In our preliminary study, we observed that GPT2 generated better quality samples than Transformer-XL. In addition, the generation samples from lakh pre-train were better when adding more layers than [35] used (six layers).

Therefore, we used the 12-layer GPT2 [44] with an attention window size of 1024 for our baseline generation model. Before passing the main architecture, each token of event sequence input was embedded as 512 dimensions. To maintain the dimension while calculating attention, the number of attention heads and attention head dimensions were set to 8 and 64, respectively. For all layers, the dimension of the feed-forward layer after the attention module was 1024. The initial learning rate was set to 5e-5, and we used the AdamW optimizer with a linear scheduler. To generate music with emotion condition, we fine-tuned the pre-trained GPT2 model using YM2413-MDB.

Also, by using the in-attention mechanism proposed in [18], we projected the emotion tag embedding to the same space as the hidden states, then summed the projected condition with the hidden states at each self-attention layer. For emotion tag embedding, we used the pre-trained Word2Vec embedding [46] of 'cheerful' and 'depressed' tags, which were also updated during fine-tuning.

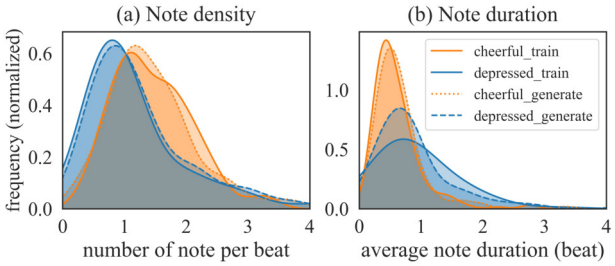

Figure 4: The note density and note duration distribution of the train set and generated results when emotion condition contains 'cheerful' and 'depressed'. Each histogram is smoothed using kernel density estimation.

6.3 Generated Results

Although we provided the baseline classification results, the performance was not sufficient to evaluate conditional music generation. Therefore, in this section, we show the overall tendency of the generation model through the objective measure. To see the validity of emotion conditioning in music generation, we compared 100 model-generated songs conditioned on 'cheerful' and 'depressed' emotions. We compared the histogram of note density and note duration of the generated results with the model inputs. For model inputs, the first 4 bars of each of the 284 songs were analyzed. As shown in Figure 4, given 'depressed' conditions, the model generates samples with a longer note duration and lower note density than when using 'cheerful' condition. However, when we listened to the generated samples, we found some of the generated samples struggled with temporal information, such as note onset time. It seems delayed notes in the dataset hindered learning the overall beat structure of the music. Although the model inputs had distinct distributions for major/minor tonalities, the generated results did not reflect these features. We suppose that it is due to the characteristics of game music that we observed in YM2413-MDB; the appearance of whole-tone or chromatic patterns makes it difficult for the model to learn tonality.

7. CONCLUSION

In this paper, we introduced YM2413-MDB, a multi-instrumental FM video game music dataset annotated with emotion tags. Using this dataset, we conducted a basic statistical analysis of musical features and provided the baseline results for emotion recognition and conditional music generation. We plan to study retro game music compositional styles further and improve music emotion classification and emotion-conditioned music generation. Also, we will investigate other uses of YM2413-MDB such as multi-instrumental music transcription, source separation, and structure analysis.

DETECTING SYMMETRIES OF ALL CARDINALITIES WITH APPLICATION TO MUSICAL 12-TONE ROWS

avenkatesh@adelphi.edu

ABSTRACT

Popularized by Arnold Schoenberg in the mid-20th century, the method of twelve-tone composition produces musical compositions based on one or more orderings of the equal-tempered chromatic scale. The work of twelve-tone composers is famously challenging to traditional Western tonal and structural sensibilities; even so, group theoretic approaches have determined that 10% of certain composers' works contain a highly unusual classical symmetry of music. We extend this result by revealing many symmetries that were previously undetected in the works of Schoenberg, Webern, and Berg. Our approach is computational rather than group theoretic, scanning each composition for symmetries of many different cardinalities. Thus, we capture partial symmetries that would be overlooked by more formal means. Moreover, our methods are applicable beyond the narrow scope of twelve-tone composition. We achieve our results by first extending the group-theoretic notion of symmetry to encompass shorter motives that may be repeated and reprised in a given composition, and then comparing the incidence of these symmetries between the work of composers and the space of all possible 12-tone rows. We present four candidate hierarchies of symmetry and show that in each model, between 75% and 95% of actual compositions contained high levels of internal symmetry.

1. INTRODUCTION

The Viennese composers Arnold Schoenberg, Anton Webern, and Alban Berg produced a combination of 86 twelve-tone compositions in the early-to-mid 20th century [1–3]. Each of these compositions is constructed from some permutation of the twelve pitch classes of the equal-tempered chromatic scale, which then guides the order of notes in the melody and harmonies. Figure 1 shows musical notation for one such permutation of the pitch classes that was selected by Schoenberg. Each such permutation is called a *tone row*, and we will take the *Viennese tone rows* to mean those that underlie the compositions of Schoenberg, Webern, and Berg, the principal members of the Second Viennese School. Using Hauer's arrangement of the pitch classes at the hour marks of an analog clock diagram [4], each tone row can be visualized as a directed graph that visits each vertex once, and the set of these directed graphs is in bijection with the set of tone rows [5,6].

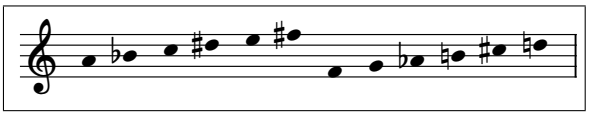

Figure 1. Musical notation for the row from Schoenberg's Serenade, opus 24, movement 5. Note that each pitch class is used once.

The strict rules of twelve-tone composition and its inherent relation to permutations have inspired formal mathematical study, both combinatorial and group theoretic. Recent work by von Hippel and Huron applied a key-finding algorithm to subsets of all lengths within certain tone rows in order to quantify their degree of "tonalness" [7]. This combinatorial approach construes the tone row as the union of many shorter overlapping subsets whose individual properties imply properties of the tone row as a whole. By contrast, Hunter and von Hippel treated tone rows more like indivisible algebraic objects in their group-theoretic study, showing that the action of the dihedral group (rotations and reflections) on clock diagrams, together with the operation of reversing the diagram's arrows, encompass the classical music-theoretic symmetries of *translation*, *inversion*, and *retrograde* [8].

The composers of the Second Viennese School considered tone rows to be equivalent under these symmetries so it makes sense to study equivalence classes of tone rows instead of the rows themselves. The resulting *row classes* of Schoenberg and Webern can therefore be visualized as unlabeled, undirected clock diagrams (start and end points need not be distinguished due to equivalence under retrograde). Berg also considered a fourth symmetry, *cyclic shift*, so his row classes are larger: they are equivalent to unlabeled, undirected clock diagrams whose endpoints connect [3]. Figure 2 shows clock diagrams of the twenty-one row classes used by Webern, with the four diagrams that possess dihedral symmetry set apart from the others. These four diagrams correspond to row classes that are isomorphic to their retrograde. The fact that Berg considered an extra symmetry has the practical effect of making his row classes larger, and hence the set of row classes smaller,

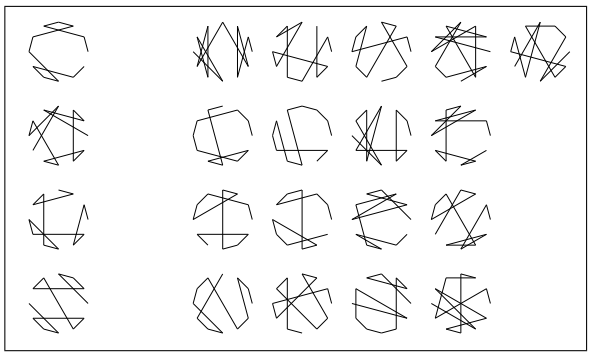

Figure 2. Clock diagrams of the twenty-one tone rows used by Webern, with the four symmetric diagrams on the left.

than those of Schoenberg and Webern. In this work, we follow convention by studying the two alternatives in parallel as the methods of study are otherwise unaffected by the use of an extra symmetry.

Hunter and von Hippel posed and resolved the following question: are there more symmetric Viennese tone rows than would be expected by chance alone? By the numbers, symmetric rows comprise just 5% of Schoenberg's works, 19% of Webern's, and 9% of Berg's. However, symmetric rows are *exceedingly* rare among all row classes: just 0.13% of row classes possess dihedrally symmetric clock diagrams (the figure is 1.16% when Berg's cyclic shift symmetry is included). Hunter and von Hippel made this idea rigorous by using a hypergeometric test to conclude that these composers showed a statistically significant preference for symmetry, whether intentionally or not [8].

Results of this kind can be concretely informative to music scholars as well as mathematicians. Most directly, Hunter and von Hippel offered analytical evidence that the three composers preferred symmetric row classes, a fact that had already been believed widely among music scholars [2, 3]. However, their results also contradicted certain beliefs, for example that Webern preferred non-palindromic symmetry [2]. They found that non-palindromic symmetry is simply much more common than palindromic symmetry, more than accounting for its higher incidence in Webern's corpus. In short, the enumeration of row classes and their symmetries is a truly interdisciplinary undertaking with promise to inform music scholars in ways that are relevant to their practice.

The main question left open by Hunter and von Hippel relates to the fact that just 10% of the Viennese tone rows are symmetric. While this figure is already surprisingly high compared to the incidence of symmetry among all row classes, it still leaves the fact that the Viennese twelve-tone composers evidently had some priorities beyond symmetry alone. Indeed, music scholars have posited many other properties of tone rows that may have attracted the composers' interest: "combinatorial," "all-interval," "tonally colored," and particularly "derived" rows have all been subject to study [9, 10]. Derived rows are those that consist of a sequence of $12/d$ notes repeated d times under the various transformations available to the composer [10]. The Gotham and Yust Serial Analyzer project [11] has yielded a catalog of rows in the repertoire classified by these traditional properties as well as more novel harmonic properties deduced from the discrete Fourier transform approach of Krumhansl [12]. The set of all possible derived rows has also been enumerated algebraically. Fripertinger and Lackner generalized the work of Hunter and von Hippel by constructing a group action and classified all tone rows according to the traditional properties in the Database of Tone Rows and Tropes [10]. To our knowledge, this database has yet to be studied in the sense of Hunter and von Hippel to determine whether the Viennese tone rows contain statistically significant quantities of derived rows, for example.

The combinatorial study of tone rows has led to the enumeration of rows with various traditionally studied properties as well as measurements of "tonalness" and other harmonic properties. Meanwhile on the group-theoretic side, Fripertinger and Lackner's group action has helped enumerate the derived rows, a much richer set than the fully symmetric rows of Hunter and von Hippel. Missing from the literature is a combinatorial attack on the *definition* of symmetry in tone rows: just as Yust [13] extended von Hippel and Huron's study of tonal fit to pairs of tonal, atonal, and mixed dimensions, this paper uses combinatorial means to generalize the concept of derived row, capturing nuances that are impractical to detect with group theory. For example, if we permute just the last two notes of a derived row, the resulting tone row will most likely not possess any group theoretic symmetries. The rigidity of group-theoretic symmetries causes this type of partial symmetry to be overlooked. In this work, we introduce a combinatorial alternative to the group-theoretic definitions of symmetry, scanning each tone row for partial symmetries of all cardinalities. Our approach results in a complete catalog of recurring motives within each tone row, from which we argue that the vast majority of the Viennese tone rows contain unusually high levels of symmetry. Moreover, we believe the flexibility of our approach grants it applications beyond the narrow scope of twelve-tone composition.

2. DETECTING INTERNAL SYMMETRY

For the purpose of this work, a *motive* within a tone row is any consecutive sequence of notes that recurs at least once within the same row (transposed and possibly inverted or in retrograde). For example, the row $(0, 1, 10, 5, 2, 3, 6, 7, 8, 11, 4, 9)$ contains the motive $(0, 1, 10, 5)$ which repeats transposed under retrograde inverse as $(10, 5, 2, 3)$, as shown in the top line of Figure 3. This particular row also contains the motive $(3, 6, 7, 8)$ and its transposed retrograde inverse $(6, 7, 8, 11)$. Motives can be as short as two notes or as long as twelve; whereas motives of length 2 occur whenever the same musical interval (or its inverse) is reused in a tone row, motives of length 12 are only found in the rare palindromic rows. The highest incidence of motives can be found in the *chromatic scale* and the *circle of fifths*, each of which consists of a single length-2 segment whose corresponding musical interval is

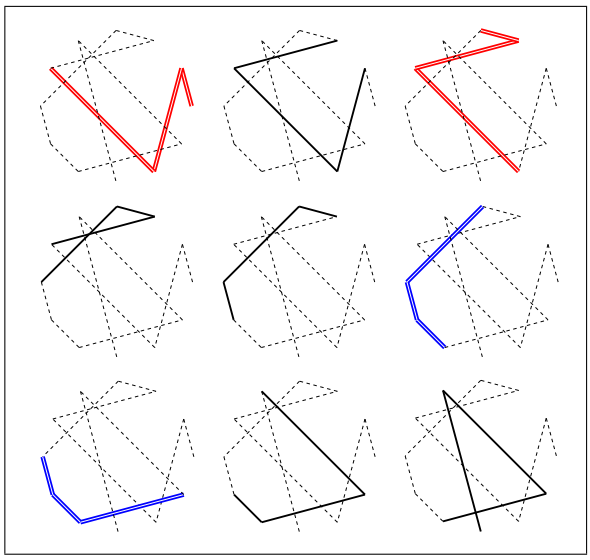

Figure 3. Clock diagrams of the tone row $(0, 1, 10, 5, 2, 3, 6, 7, 8, 11, 4, 9)$ showing the nine sequences of length 4. The two recurring motives are indicated with doubled lines.

repeated eleven times to form the row. In the opposite case, the *all-interval rows* consist of every different musical interval and consequently possess very few motives. Figure 4 shows clock diagrams for the circle of fifths (containing the maximum number of motives of all lengths) and an all-interval row that contains no motives above length 2 at all.

Our approach has two stages: first, we enumerate the motives of all lengths for every row class; then, we advance four plausible models for assigning an overall symmetry rating to any set of motives, with attention to the music-theoretic and mathematical literature to ensure consistency of our results with existing knowledge. We begin the first stage by treating each tone row as a collection of length-d sequences of notes, with d ranging from 2 to 12. Figure 3 shows a particular tone row's nine sequences of length 4, of which two pairs are found to be separate recurring motives. In general, the set of length-d motives of a tone row can be quantified by a partition of $12 - d + 1$ (the total number of length-d sequences) based on which sequences appear multiple times. Figure 3 shows that the depicted tone row corresponds to the partition $9 = 2+2+1+1+1+1+1$ since there are two motives that each appear twice, plus five other length-4 sequences that do not form motives. As d varies from 2 to 12, the corresponding sets of motives fully encode the symmetrical properties of a tone row at every cardinality. Therefore, the symmetrical properties of any tone row can be represented by a list of partitions of the integers from 1 to 11, corresponding to values of d ranging from 12 down to 2. We refer to such a list of partitions as the *full symmetry data* of a row class.

Generalizing symmetry in this way encodes a tremendous amount of information. Hunter and von Hippel identify three types of rows (eight, when cyclic shift is included) [8]. Friptertinger and Lackner extend this to a few thousand by introducing tropes [10]. But a naïve upper bound on the number of distinct full symmetry data is the product of the first eleven partition numbers, about 5.379×10^{10} or five thousand times the number of row classes! There are many principled ways to simplify the full symmetry data while maintaining consistency with the literature. One promising approach (not explored in this paper) would map each partition to its length, summarizing the symmetry data of a tone row with an integer 11-tuple. Under this scheme, rows whose 11-tuple values are small exhibit more repetitive motives (hence, greater symmetry) than those whose 11-tuple values are large. In an extreme example, the chromatic scale and the circle of fifths achieve scores of all 1's in this scheme. In this paper, we choose to map the full symmetry data to a differently defined 11-tuple: the maximum values of the partitions. The reason for using the maximum value instead of the length is subjective as both schemes capture essential information about the partition. Figure 5 depicts a tone row whose most-repeated motives of length 2, 3, and 4 have multiplicities of 3, 4, and 2, respectively. This particular tone row has no motives of length 5 or greater, meaning that its symmetries are quantified by the tuple $(3, 4, 2, 1, 1, 1, 1, 1, 1, 1, 1)$. We refer to this tuple as the *symmetry score* of the row class.

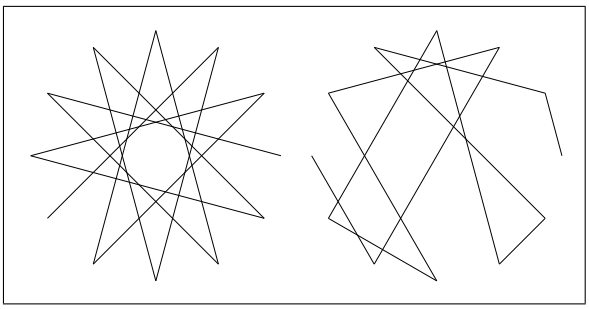

Figure 4. Clock diagrams of the maximally symmetric circle of fifths and a minimally symmetric all-interval row.

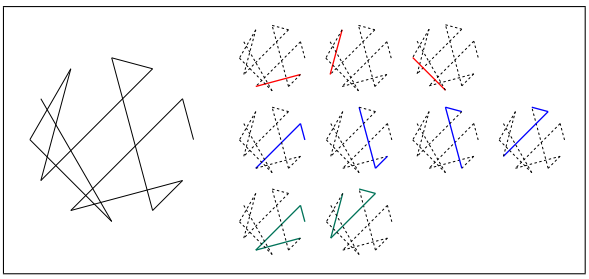

Figure 5. Clock diagrams of the tone row $(0, 1, 8, 11, 10, 3, 2, 7, 4, 6, 9, 5)$ showing that it achieves symmetry scores of 3, 4, and 2 for the lengths of 2, 3, and 4, respectively.

3. ANALYSIS

In Section 2 we established a map from the set of row classes to an 11-dimensional lattice with the property that greater values correspond to higher multiplicity of motives. The two clock diagrams in Figure 4 illustrate this property:

whereas the circle of fifths maps to a symmetry score of $(11, 10, 9, 8, 7, 6, 5, 4, 3, 2, 1)$, the depicted all-interval row maps to a symmetry score of $(2, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1)$ which is in fact the lowest possible multiplicity of motives among all row classes. The next step is to assess whether the Viennese tone rows contain unusually high levels of symmetry, but this depends on how we compare symmetry scores to each other. Instead of presenting just one possible interpretation of "high symmetry," we give four reasonable candidates that span a wide range of interpretations of symmetry while still respecting musical intuition and the mathematical literature on the topic. In each model, we conduct hypergeometric tests to gauge whether the incidence of high symmetry in the composers' corpora was significantly greater than would be predicted by chance alone. While these tests are exploratory in nature, the models in Sections 3.1 and 3.2 admit a conservative Bonferroni correction to adjust for the issue of multiple testing [14].

3.1 Reverse-Lexicographic Model

The most direct extension of Hunter and von Hippel's results is to introduce a sensible total order on the set of symmetry scores, then split the scores into "low" and "high" bins in music-theoretically sound ways and apply a hypergeometric test. A natural candidate for the total order is reverse-lexicographic order (RLEX), prioritizing longer motives over shorter ones. This choice has the advantage of seamlessly reproducing known results in its base case; moreover, it yields a natural definition of low and high symmetry: for each length d, the valid splits are the locations in the total order at which the d-symmetry score increments. For example, we can split the set of tone rows according to whether any length-4 motive is present; in the set of all row classes, 23.62% have a length-4 motive, yet fully 50% of Schoenberg's tone rows exhibit this symmetry. The associated hypergeometric test gives a p-value of $p < 0.0002$, so the prevalence of motives of length at least 4 in Schoenberg's work is unlikely to have arisen by chance alone. This model has 38 splits (40 for Berg) and the adjusted p-values are computed by multiplying by these numbers. Table 1 shows a selection of significant results for the three composers. Notably, more than 90% of Webern's corpus exhibits a statistically significant level of symmetry in the RLEX sense and both Schoenberg and Webern's corpora exhibit significant levels of symmetry under the multiple testing correction. Berg's use of a fourth symmetry and the correspondingly smaller space of row classes makes it more difficult to obtain significant results for his corpus, as already noted by Hunter and von Hippel. However, even in this case a few notable results are seen, although only on an exploratory basis.

3.2 Lattice Rank Model

The RLEX model faithfully reproduces known results, yet strongly penalizes row classes that contain many short motives but few long ones. The Lattice Rank model delivers on the opposite extreme by using a grading according to the sum of the symmetry score, thereby equally weighting motives of all lengths. Here, the natural divisions of "high" and "low" symmetry are determined by the rank function with 54 distinct levels (109 for Berg). For example, two-thirds of Webern's tone rows have lattice rank of 6 or greater (that is, 6 more multiplicity of motives than the lowest symmetry score), while only 11.17% of the set of all row classes has this property. The quantity of tone rows in Webern's corpus with at least this lattice rank almost certainly did not arise by chance alone ($p = 2.5 \times 10^{-9}$). Table 2 shows that the Lattice Rank model obtains remarkably similar results to the RLEX model in spite of being agnostic to motive length. Again, Schoenberg and Webern's corpora exhibit statistically significant levels of symmetry even under the multiple testing correction, while Berg's corpus only does so on an exploratory basis.

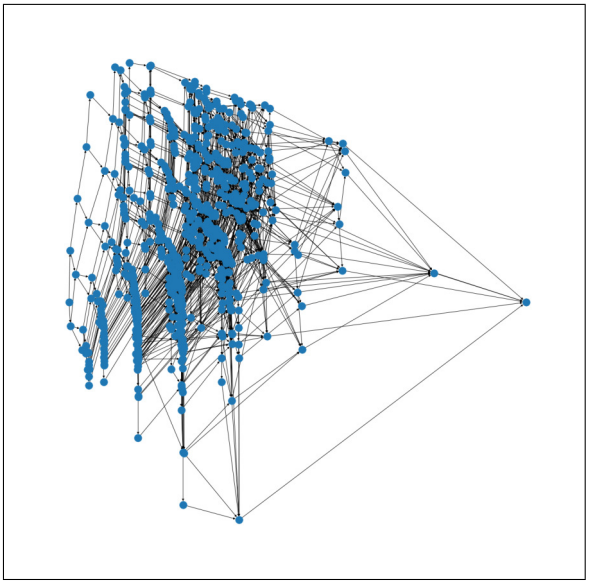

Figure 6. Directed acyclic graph representation for the partially ordered set of symmetry scores relevant to Schoenberg and Webern.

The fact that the RLEX and Lattice Rank models yield similar results in spite of applying diametrically opposed weighting schemes to motives of different lengths suggests that the Viennese tone rows simply contain a lot of internal symmetries no matter how you count them. Still, these models impose value judgments on the relative importance of each internal symmetry, possibly affecting the outcome of the analysis. To validate our findings, we offer a non-parametric alternative that makes no assumptions at all about the relative importance of the different motives. Instead, this alternative is based on the single intuitive assumption that the symmetry scores form a partially ordered set: a row class whose symmetry score is no greater in any component than the symmetry score of a different row class cannot be said to exhibit greater symmetry overall. Abstracting from the lattice structure in this way results in the diagrams in Figures 6 and 7, where each vertex is a symmetry score and the directed edges (all running left-to-right) run from lesser to greater in the partial order.

Schoenberg	All	p-value	Webern	All	p-value	Berg	All	p-value

3.3 Partial Order Rating Models

In order to set up a hypergeometric test on the poset of symmetry scores, we still need to choose some linear extension of the poset to a total order. The RLEX and Lattice Rank models accomplish this by appealing to music intuitions on the relative importance of different kinds of motives. However, the fact that our poset has a unique least and greatest element gives us a non-parametric alternative. Given any symmetry score v, we count the number of row classes with strictly lesser scores (ascendants) and strictly greater scores (descendants) in the poset. If v has relatively few descendants compared to ascendants, then few row classes have strictly greater symmetry than v and we may say that v possesses a relatively high level of symmetry. To make this idea precise, let A_v be the number of row classes assigned to strictly lesser scores than v, and D_v be the number of row classes assigned to strictly greater scores than v. Lastly, let M be the total number of row classes. The formula

$$\frac{1}{2}(1 + (A_v - D_v)/M))$$

ranges from 0 to 1 as v ranges from the least to greatest elements of the poset. We define the Solo Poset Rating of v by renormalizing this formula to range from 0 to infinity, like so:

$$\begin{aligned} PR_s(v) &= -\log\left(1 - \frac{1}{2}(1 + (A_v - D_v)/M))\right) \\ &= -\log\left(\frac{1}{2}(1 - (A_v - D_v)/M)\right). \end{aligned} \quad (1)$$

In Figure 7, the symmetry score marked by the black vertex would receive a relatively high Solo Poset Rating because it has many ascendants but relatively few descendants. This imbalance is further amplified by the fact that scores near the minimum symmetry score are generally assigned to many more row classes than scores near the maximum symmetry score.

For example, two of Berg's tone rows have a symmetry score of $(6, 2, 1, 1, 1, 1, 1, 1, 1, 1, 1)$, whose Solo Poset Rating is 0.695. An additional ten of Berg's tone rows achieve a greater Solo Poset Rating than this, so $12/23$ or 52.17% of Berg's tone rows exhibit a Solo Poset Rating of 0.695 or greater. Meanwhile, just 29.42% of all tone rows achieve a Solo Poset Rating of at least 0.695. If Berg had selected row classes at random, the probability that twelve or more of his corpus would have a Solo Poset Rating of at least 0.695 is just 0.018.

Figure 7 shows that for any given symmetry score, there are many other scores in the poset that are incomparable. We define the Cohort Poset Rating of a particular score as the average of the Solo Poset Ratings of all scores that are incomparable with the chosen score. Both variants of the Poset Rating quantify how close a given score is to the highest possible symmetry score, compared to its closeness to the lowest possible symmetry score. The two ratings yield nearly identical results when analyzing the corpora of Schoenberg and Webern (Tables 3 and 4). Due to Berg's smaller space of row classes, the only noteworthy finding for his corpus under the Poset Rating models is the one given in the previous paragraph (the Solo and Cohort models coincide in this case).

4. DISCUSSION

Our work takes a flexible approach to detecting patterns within tone rows, uncovering partial symmetries that cannot be detected by group theory. The trade-off is that we also find many internal structures that have no name in music theory. Whether this is a true disadvantage depends on

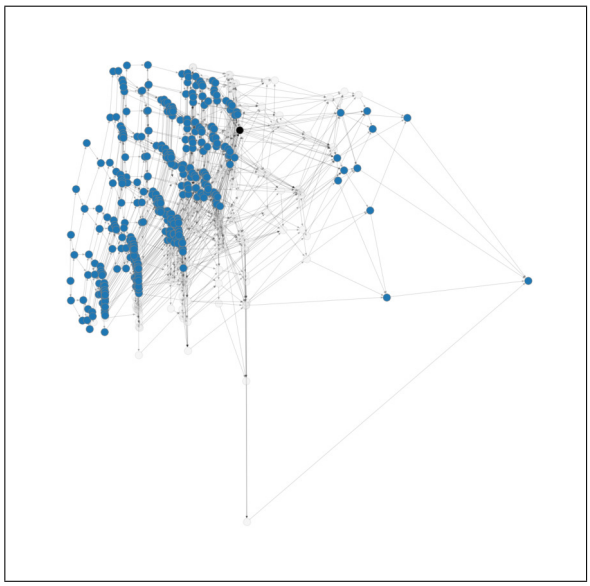

Figure 7. Directed acyclic graph representation of the symmetry scores relevant to Berg with highlighted ascendants and descendants of the black vertex, and incomparable scores greyed out.

Schoenberg	All Solo (Cohort)	p-value
83.33%	65.87%	0.010
52.38%	26.23%	2.73×10^{-4}
33.33%	12.85% (11.65%)	5.13×10^{-4}
9.52%	0.74% (0.60%)	2.73×10^{-4}
4.76%	0.74% (0.13%)	9.08×10^{-3}

Table 3. Selected Poset Rating results for Schoenberg, comparing his corpus to the set of all row classes with respect to various "high" and "low" symmetry bins. When the Solo and Cohort ratings do not coincide, the larger of the two p-values is displayed for brevity.

Webern	All Solo (Cohort)	p-value
95.24%	45.35%	1.62×10^{-6}
66.67%	12.85% (16.03%)	2.78×10^{-7}
52.38%	2.85%	2.67×10^{-12}
33.33%	1.03% (1.06%)	1.51×10^{-9}
19.05%	0.12% (0.25%)	2.39×10^{-7}

Table 4. Selected Poset Rating results for Webern, comparing his corpus to the set of all row classes with respect to various "high" and "low" symmetry bins. When the Solo and Cohort ratings do not coincide, the larger of the two p-values is displayed for brevity.

the validity of our basic premise: that the presence of a recurring motive is noteworthy in itself. We believe that this premise is supported by the preexisting scholarly interest in derived rows, those tone rows that are fully generated by a shorter repeating motive [10]. Since small adjustments to a derived row result in similar rows that yet lack any official symmetry, it seems natural to extend the concept of derived row to any tone row that is at least partially generated by a motive.

In bringing new methods to this topic, we have made particular effort to situate our work in the literature and reproduce known results where possible. Indeed, all our models agree with the existing knowledge that roughly 5% of Schoenberg's corpus and 19% of Webern's corpus have significant incidence of symmetry at the highest level. The RLEX model in particular achieves exact replication of known results. Where it was necessary for us to make a value judgment on the relative importance of different motives, we have followed the literature (in the case of RLEX) and also explored the diametrically opposed value judgment (in the case of Lattice Rank) in order to provide maximum contrast. In each case, we performed a multiple testing correction and still found significant levels of symmetry in much of the tone rows of Schoenberg and Webern. We also developed two non-parametric models to further validate our findings. Moreover, our approach to defining symmetry by the presence of shorter motives is analogous to von Hippel and Huron's measurement of the "tonalness" a row by the tonal properties of its subsets [7].

As for whether the Viennese twelve-tone composers favored symmetry in their work, our models support this across the board. We find that all three composers made extensive use of symmetry in their work, decidedly beyond what can be explained by chance alone. We found that 76%–83% of Schoenberg's corpus and 90%–95% of Webern's corpus contained significant levels of symmetry (up from 5% and 19%, respectively.) Even in the case of Berg, whose much smaller space of row classes limits the power of the hypergeometric test, we can extend the previously determined figure of 9% to the range of 48%–57% of his corpus although only on an exploratory basis.

Our combinatorial approach has one other advantage over the group-theoretic approaches in the literature. By forgetting the permutation group structure and studying motives on a purely combinatorial level, we no longer restrict ourselves to studying tone rows. Indeed, our methods apply just as well to any data series together with a relevant group of symmetries, with the one concession that there is no clear analog for the hypergeometric test. Still, the n-tuple symmetry score can serve as a feature for classification of melody and rhythm that encodes information of many different cardinalities, evoking concepts from persistent homology and wavelet analysis. While we assert no formal connection between these fields and our work, we take inspiration from the concept of studying an object at many different scales and hope that our success in the enumeration of tone row motives may find broader application in music information retrieval.

ABSTRACT

In the previous decade, Deep Learning (DL) has proven to be one of the most effective machine learning methods to tackle a wide range of Music Information Retrieval (MIR) tasks. It offers highly expressive learning capacity that can fit any music representation needed for MIR-relevant downstream tasks. However, it has been criticized for sacrificing interpretability. On the other hand, the Bayesian nonparametric (BN) approach promises similar positive properties as DL, such as high flexibility, while being robust to overfitting and preserving interpretability. Therefore, the primary motivation of this work is to explore the potential of Bayesian nonparametric models in comparison to DL models for music representation learning. More specifically, we assess the music representation learned from the Hierarchical Dirichlet Process Gaussian Mixture Model (HDPGMM), an infinite mixture model based on the Bayesian nonparametric approach, to MIR tasks, including classification, auto-tagging, and recommendation. The experimental result suggests that the HDPGMM music representation can outperform DL representations in certain scenarios, and overall comparable.

1. INTRODUCTION

Deep learning became one of the most popular and successful methodologies to tackle a various range of MIR tasks; music classification [1], music generation [2], recommendation [3] and more. Some of the known benefits are 1) the high expressiveness towards any data structure, 2) effective ways to handle the overfitting, and finally, 3) the rapidly improving infrastructural supports, including both hardware (i.e., accelerators such as GPU) and software (i.e., deep learning frameworks). Fuelled by these benefits, DL models can learn useful representations of diverse data, which is one of the key reasons for its success [4]. On the other hand, DL models often are criticized for their lack of interpretability [5], also for applications within the MIR domain [6, 7].

A study of HDPGMM music representation learning", in *Proc. of the 23rd Int. Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

According to [8, 9], interpretability of a machine learning model can be defined as the degree to which a user can understand the underlying mechanism of its operation. In this regard, DL models would be substantially less interpretable due to their complex internal structure than simpler—yet may be comparably expressive—alternatives such as hierarchical probabilistic models.

The Bayesian Nonparametric (BN) approach is such an alternative to achieving what DL does well in an interpretable way. As a nonparametric method, it can overcome underfitting by unlimited model capacity, while resisting overfitting through its Bayesian nature [10]. At the same time, the model can be interpretable, as the probabilistic model structure hypothesizes the data generation process in a relatively simple and humanly understandable manner.

In past decades, BN models have been applied in various MIR tasks. For example, they were applied to a latent representation of music audio in estimating music (self-) similarity [11, 12]. They also were employed to conduct harmonic and spectral analyses by decomposing the time-frequency representation of the music audio into a mixture of countable infinite latent components [13, 14]. These analyses also have shown to be useful for downstream tasks such as structural analysis [15] or music recommendation [16]. Further, a discriminative model based on the BN was developed for music emotion recognition [17].

While DL gained considerable popularity, it is striking BN models did not gain as much attention. As they promise similar high-level properties and strengths to DL, it will be worthwhile to explore to what extent they compare to modern DL models for MIR-relevant tasks. Therefore, in this work, we will assess music representations learned from BN models, and compare them under similar experimental control with modern deep neural network models. In particular, we consider the Hierarchical Dirichlet Process Gaussian Mixture Model (HDPGMM) [16, 18, 19] as our model of interest. To concretize the comparison, we employ the transfer learning experimental framework [20–22], which is commonly used for assessing the potential of learned representations. The contributions of this work can be listed as follows:

1. We explore and suggest insight into how "good" and transferable the HDPGMM representation is for a range of MIR tasks.
2. We provide an implementation of an efficient, GPU-

accelerated inference algorithm for HDPGMM, which can handle large-scale music datasets.

2. HDPGMM

In this section, [1] we introduce the Hierarchical Dirichlet Process Gaussian Mixture Model (HDPGMM) [12, 19]. We first discuss the Dirichlet Process Mixture Model (DPMM) upon which the HDPGMM is extended.

2.1 Dirichlet Process Mixture Model

The Dirichlet Process (DP) is an well-known stochastic process that draws random probability distributions, which often is described as a distribution over distributions [10]. One of the most common applications of DP is the infinite mixture model, thanks to the property of DP that one can draw distributions of an arbitrary dimensionality. Thus, the Dirichlet Process Mixture Model (DPMM) can find the appropriate number of components K based on the set of observations as part of the learning process.

Among several ways to represent DP, we introduce the stick-breaking construction [24] [2]. Stick-breaking constructs DP in a simple and general manner. Formally, it is as follows:

$$\begin{aligned} \beta'_k &\sim \text{Beta}(1,\gamma) & \phi_k &\sim H \\ \beta_k &= \beta'_k \prod_{l=1}^{k-1}(1-\beta'_l) & G_0 &= \sum_{k=1}^{\infty} \beta_k \delta_{\phi_k} \end{aligned} \tag{1}$$

where the two equations in the left column represent the draw of infinite dimensional weights β_k which sums to one. Notably, the distribution for β is also referred to $\beta \sim \text{GEM}(\gamma)$ [25]. In the right column, H denotes the base distribution from which variable $\phi_k \in \Phi$ is drawn. The right bottom equation defines the draw of the probability measure G_0, where δ_{ϕ_k} means the point mass centered at the component ϕ_k. Altogether, Eq. (1) constructs the DP $G_0 \sim \text{DP}(\gamma, H)$. Figure 1 depicts the process in a graphical way.

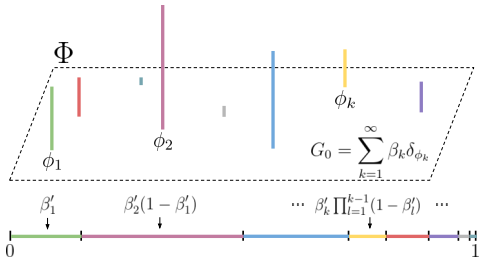

Figure 1: Illustration of stick-breaking construction.

In the mixture model context, we want to infer mixture components $\{\phi_1, \phi_2, \cdots, \phi_k, \cdots\}$ that fit to the data observations $\{x_1, x_2, \cdots, x_n\}$, which are assumed to be drawn from distributions $F(\phi)$ parameterized with variable ϕ (i.e., for a multivariate Gaussian F, $\phi = \{\mu, \Sigma\}$). We now can use DP for drawing the component ϕ that corresponds to x_i by introducing the cluster assignment variable $y_i \sim \text{Mult}(\beta)$:

$$\begin{aligned} \beta|\gamma &\sim \text{GEM}(\gamma) & \phi_k|H &\sim H \\ y_i|\beta &\sim \text{Mult}(\beta) & x_i|y_i, \{\phi_k\} &\sim F(\phi_{y_i}) \end{aligned} \tag{2}$$

where ϕ_{y_i} denotes the component parameter ϕ indexed by the assignment variable y_i corresponding to the ith observation x_i.

2.2 Hierarchical DPMM

In many data structures, groupings of atomic data points arise naturally (i.e., audio frames within a song, songs from an artist, words of lyrics). Hierarchical DP (HDP) is an extension of DP that models the "groupings" by imposing group-level DPs derived from the "corpus-level" DP as the global pool of components [19]. Following [18], the jth group-level DP can be expressed as follows:

$$\begin{aligned} \pi'_{jt} &\sim \text{Beta}(1,\alpha_0) & \psi_{jt} &\sim G_0 \\ \pi_{jt} &= \pi'_{jt} \prod_{s=1}^{t-1}(1-\pi'_{js}) & G_j &= \sum_{t=1}^{\infty} \pi_{jt} \delta_{\psi_{jt}} \end{aligned} \tag{3}$$

As seen above, HDP appears as the recursion of multiple levels of DPs [3]. Notably, the base distribution G_0 of each group-level DP is from the corpus-level DP. This relationship allows mapping group-level atoms ψ_{jt} to the corpus-level atoms ϕ_k. Wang et al. [18] introduce indicator variables $c_{jt} \sim \text{Mult}(\beta)$ which maps ψ_{jt} and ϕ_k by $\psi_{jt} = \phi_{c_{jt}}$, where β is drawn from the corpus-level DP in Eq. (1). It simplifies the model as we do not need to represent ψ_{jt} explicitly. Finally, we can represent HDPMM by introducing another indicator variable $z_{jn} \sim \text{Mult}(\pi_j)$ for the nth observation x_{jn} within the jth group, similarly to Eq. (2):

$$\begin{aligned} \pi_j|\alpha_0 &\sim \text{GEM}(\alpha_0) & \theta_{jn} &= \psi_{jz_{jn}} = \phi_{c_{jz_{jn}}} \\ z_{jn}|\pi_j &\sim \text{Mult}(\pi_j) & x_{jn}|z_{jn}, c_{jt}, \{\phi_k\} &\sim F(\theta_{jn}) \end{aligned} \tag{4}$$

where we use the indicator z_{jn} to select ψ_{jt}, which eventually is mapped as $\phi_{c_{jz_{jn}}}$ that represents the parameter θ_{jn} to draw the observation x_{jn}. HDPGMM is then defined by simply setting F as the (multivariate) Gaussian distribution and setting H as one of the distributions from which we can sample the mean and covariance (i.e., Gaussian-inverse Wishart distribution). Figure 2 depicts the HDPGMM graphically.

2.3 Inference Algorithm

We employ the online Variational Inference (VI) [18], which is a common and significantly faster choice than the Markov Chain Monte Carlo (MCMC) method to infer fully Bayesian models. VI approximates the true posterior by

[1] We adopted most of the notations from [18, 23].

[2] Literature commonly chooses the Chinese Restaurant Process (CRP) as an illustrative metaphor for DP, as it is intuitive and explains various properties of DP well [10]. We discuss DP with the stick-breaking construction, due to its further usage in the model inference within the work. Other metaphorical descriptions of DP are given in [10, 12]

[3] It implies naturally that multiple levels are possible (i.e., corpus - author - document) if it suits the data structure.

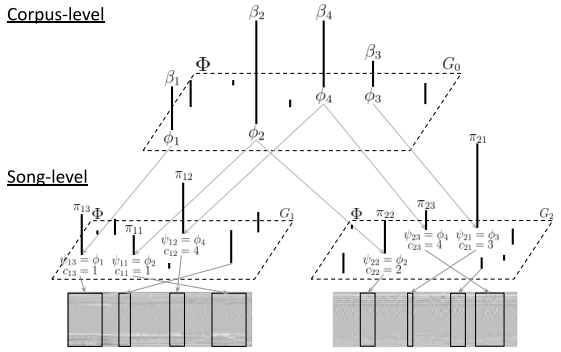

Figure 2: Illustration of 2-level HDPMM within corpus-song context. The top row depicts the corpus-level DP. The second row describes the draw of second-level (song-level) DPs per song from the corpus-level DP. Frame-level features are drawn from each song-level DPs, as depicted in the third row of the image.

minimizing the Kullback-Leibler (KL) divergence between the approximation $q(Z)$ and the true posterior $p(Z|X)$, where Z denotes the set of latent variables and parameters that we want to find, and X refers a set of observations [23]. One of the popular simplifications is the full factorization of the distribution $q(Z) = \prod_{i=1}^{|Z|} q_i(Z_i)$. In the context of HDPGMM, we have the following:

$$q(\beta', \pi', c, z, \phi) = q(\beta')q(\pi')q(c)q(z)q(\phi) \tag{5}$$

where β', π', c, z denote the corpus-level and group-level stick proportions, group-level component selection variable, and finally the observation-level component selection variable, respectively. ϕ refers to the parameter(s) for the F which draws the atomic observation, set as (multivariate) Gaussian in our context. Thus, ϕ includes the means μ and precision matrices Λ of each Gaussian component. We adopt the result from [23], where the Gaussian-Wishart distribution is used for the prior.

Each variational distribution further factorizes into:

$$\begin{aligned} q(\beta') &= \textstyle\prod_k^{K-1} \text{Beta}(\beta'_k|u_k, v_k) \\ q(\pi') &= \textstyle\prod_t^{T-1} \text{Beta}(\pi'_t|a_t, b_t) \\ q(c) &= \textstyle\prod_j \prod_t \text{Mult}(c_{jt}|\varphi_{jt}) \\ q(z) &= \textstyle\prod_j \prod_n \text{Mult}(z_{jn}|\zeta_{jn}) \end{aligned} \tag{6}$$

where u_k, v_k, a_t, b_t denote the variational parameters for the Beta distributions for corpus-level and group-level stick proportions, respectively. $\varphi_{jt} \in \mathbb{R}^K, \zeta_{jn} \in \mathbb{R}^T$ are the variational parameters for the Multinomial distribution to draw the selector c and z. Also, we truncate the infinite Beta distributions by K and T, which is a common way to avoid actually computing the infinite dimension [18]. With a sufficiently large number for the truncation, the model will still not be limited to the truncation and will only use the number of components optimal for the dataset. The final variational distribution is the Gaussian-Wishart distribution which draws the Gaussian parameters ϕ for F:

$$q(\phi) = \textstyle\prod_k^K \mathcal{N}(\mu_k|m_k, (\lambda_k\Lambda_k)^{-1})\mathcal{W}(\Lambda_k|W_k, \nu_k) \tag{7}$$

where we draw the precision $\Lambda_k \in \mathbb{R}^{d\times d}$ from the Wishart distribution with the variational parameter $W_k \in \mathbb{R}^{d\times d}$ and $\nu_k \in \mathbb{R}$, and the mean $\mu_k \in \mathbb{R}^d$ is drawn by the precision weighted by $\lambda_k \in \mathbb{R}$ and mean $m_k \in \mathbb{R}^d$.

We then can obtain the optimal model by maximizing the lower bound of the marginal log likelihood $\log p(X|Z)$ [23, 26, 27]:

$$\begin{aligned} &\log p(X|Z) \geq \mathbb{E}_q[\log p(X, \beta', \pi', c, z, \phi)] + H(q) \\ &= \textstyle\sum_j \big\{\mathbb{E}_q[\log\left(p(X_j|c_j, z_j, \phi)p(c_j|\beta')p(z_j|\pi'_j)p(\pi'_j|\alpha_0)\right)] \\ &\qquad + H(q(c_j)) + H(q(z_j)) + H(q(\pi'_j))\big\} \\ &\qquad + \mathbb{E}_q[\log p(\beta')p(\phi)] + H(q(\beta')) + H(q(\phi)) \end{aligned} \tag{8}$$

where $H(\cdot)$ denotes the entropy of given distribution, and $X_j = \{x_{j1}, x_{j2}, \cdots, x_{jN_j}\}$ is a set of observations within the jth group. [4]

Using the standard result of VI [18, 23, 27], the update rules for group-level parameters are derived as follows:

$$a_{jt} = 1 + \textstyle\sum_n \zeta_{jnt} \tag{9}$$

$$b_{jt} = \alpha_0 + \textstyle\sum_n \sum_{s=t+1}^T \zeta_{jns} \tag{10}$$

$$\varphi_{jtk} \propto \exp(\textstyle\sum_n \zeta_{jnt}\mathbb{E}_q[\log p(x_{jn}|\phi_k)] + \mathbb{E}_q[\log \beta_k]) \tag{11}$$

$$\zeta_{jnt} \propto \exp(\textstyle\sum_{k=1}^K \varphi_{jtk}\mathbb{E}_q[\log p(x_{jn}|\phi_k)] + \mathbb{E}_q[\log \pi_{jt}]) \tag{12}$$

Similarly, the update rules for the corpus-level parameters are as follows [23]:

$$u_k = 1 + \textstyle\sum_j \sum_{t=1}^T \varphi_{jtk} \tag{13}$$

$$v_k = \gamma + \textstyle\sum_j \sum_t^T \sum_{l=k+1}^K \varphi_{jtl} \tag{14}$$

$$\lambda_k = \lambda_0 + N_k \tag{15}$$

$$m_k = \lambda_k^{-1}(\lambda_0 m_0 + N_k \bar{x}_k) \tag{16}$$

$$W_k^{-1} = W_0^{-1} + N_k S_k + \frac{\lambda_0 N_k}{\lambda_0 + N_k}(\bar{x}_k - m_0)(\bar{x}_k - m_0)^\intercal \tag{17}$$

$$\nu_k = \nu_0 + N_k \tag{18}$$

where $\lambda_0 \in \mathbb{R}, m_0 \in \mathbb{R}^d, \nu_0 \in \mathbb{R}, W_0 \in \mathbb{R}^{d\times d}$ are the hyperparameters corresponding to the weight, location, degrees of freedom, and scale of Gaussian-Wishart distribution. The "sufficient statistics" and expectations in the update rules are defined as follows:

$$\begin{aligned} &\mathbb{E}_q[\log \beta_k] = \mathbb{E}_q[\log \beta'_k] + \textstyle\sum_{l=1}^{k-1} \mathbb{E}_q[\log(1 - \beta'_l)] \\ &\mathbb{E}_q[\log \beta'_k] = \Psi(u_k) - \Psi(u_k + v_k) \\ &\mathbb{E}_q[\log(1 - \beta'_k)] = \Psi(v_k) - \Psi(u_k + v_k) \\ &\mathbb{E}_q[\log \pi_{jt}] = \mathbb{E}_q[\log \pi'_{jt}] + \textstyle\sum_{s=1}^{t-1} \mathbb{E}_q[\log(1 - \pi'_s)] \\ &\mathbb{E}_q[\log \pi'_{jt}] = \Psi(a_{jt}) - \Psi(a_{jt} + b_{jt}) \\ &\mathbb{E}_q[\log(1 - \pi'_{jt})] = \Psi(b_{jt}) - \Psi(a_{jt} + b_{jt}) \\ &N_k = \textstyle\sum_j \sum_n r_{jnk} \\ &\bar{x}_k = \frac{1}{N_k} \textstyle\sum_j \sum_n r_{jnk} x_{jn} \\ &S_k = \frac{1}{N_k} \textstyle\sum_j \sum_n r_{jnk}(x_{jn} - \bar{x}_k)(x_{jn} - \bar{x}_k)^\intercal \end{aligned}$$

[4] Thus, the terms inside the sum over the group would further factorize into sums of per-group observations. We do not write these out for legibility and space considerations.

where $\Psi(\cdot)$ refers to the digamma function, and $r_{jnk} = \sum_{t=1}^{T} \zeta_{jnt}\varphi_{jtk}$ is the inferred "responsibility" of the nth observation of the jth group on the kth component. A standard batch update would compute statistics across the entire corpus, and update the corpus-level parameters. However, it may be slow or may suffer from too large or small numbers accumulated from a large-scale corpus.

We therefore employ the online VI, where corpus-level parameters are updated per mini-batch of groups passed. In this way, the early phase of model inference can be accelerated substantially compared to the full-batch update [18, 28]. The corpus-level update is then controlled by the learning rate $\rho_t = (\tau_0 + t)^{-\kappa}$, which is decayed over iterations parameterized by the offset $\tau_0 > 0$ and the rate $\kappa \in (0.5, 1]$:

$$Z_t = (1 - \rho_t)Z_{t-1} + \rho_t \tilde{Z}_t \tag{19}$$

where $\tilde{Z}_t$ denotes one of the corpus-level parameters from Eq. (13) to (18), which is updated by the given mini-batch at tth iteration, while Z_{t-1} is the current parameter. To scale the update with respect to the mini-batch size, we weight $\tilde{Z}$ by the factor of $w = \frac{|\tilde{X}|}{|X|}$, where $|X|, |\tilde{X}|$ denote the number of groups within the entire observation set X and the mini-batch of groups $\tilde{X}$. The overall inference algorithm is described in Algorithm 1.

Algorithm 1: Online VI for HDPGMM

```
Initialize φ = (φ_k)_{k=1}^K, u = (u_k)_{k=1}^K, v = (v_k)_{k=1}^K
  randomly and set t = 1.
while Stopping criterion is not met do
    Fetch a random mini-batch of groups X̃
    repeat
        Update a_j, b_j, ζ_j and φ_j using Eq. (9) to (12)
    until mini-batch likelihood stops improving;
    Compute u_k, v_k, λ_k, m_k, W_k, and ν_k using Eq. (13)
      to (18)
    Set ρ_t = (τ_0 + t)^{-κ}, t ← t + 1
    Update u_k, v_k, λ_k, m_k, W_k, and ν_k using Eq. (19)
end
```

Inspired by the implementation of [18, 27], we apply further regularization to the model. Specifically, we "splash" the uniform noise to the inferred responsibility r_{jn} as it can be biased if the groups are corrupted or incomplete, such as the preview audio of the entire song:

$$\tilde{r}_{jn} = (1 - \eta_t)r_{jn} + \eta_t e \tag{20}$$

where η_t is the regularization coefficient that determines the extent uniform noise $e = (e_k)_{k=1}^K$ is mixed into r_{jn}. $\eta_t = \frac{\eta_0 * 10^3}{(t+10^3)}$ also is defined as decaying function similar to the learning rate ρ_t.

3. EXPERIMENTAL SETUP

The overall experimental design is adopted from the recent music representation learning studies [20, 21, 29], where multiple downstream MIR tasks are tested with the feature set learned from the representation models. [5]

[5] The source code can be found at `https://github.com/eldrin/hdpgmm-music-experiments`.

3.1 Datasets, Features & Evaluation

We use a subset of Million Song Dataset (**MSD**) [30] as the dataset for the representation learning; more specifically, the audio preview excerpts from the MSD "train" subset introduced by [31, 32] [6]. For the evaluation of the representation, we employ three downstream tasks encompassing *music genre classification*, *music auto-tagging*, and *music recommendation*. For each target task, we chose the **GTZAN** dataset [33] with the fault-filtered split [34], the MagnaTagATune (**MTAT**) dataset [35] with the split from [36], and finally the Echo Nest taste profile subset as part of MSD (**Echonest**) [30] filtered by user and item frequency [37].

We evaluate the modeling using the cross-validation of task-specific prediction models. We fit the logistic regression models for GTZAN and MTAT datasets, taking the learned music representation as input and predicting the genre or music tags. We find the hyper-parameters of the logistic regression model by a randomized parameter search [38] for each run. As for the recommendation, we apply the item *K* Nearest Neighbor (*item-kNN*) method [39] where the song-song similarity is measured by the cosine similarity of the learned music representation. We adopt the data split introduced in [37]. For every trial, disjoint validation and test users are uniformly sampled, which includes 1142 users for each. Then 30% of listening records of these users are held out as testing records. We find the best *K* by conducting a grid search on the range $K \in \{2^4, 2^5, 2^6, 2^7, 2^8, 2^9\}$ by measuring the accuracy on the validation users. Using the best *K*, we compute the final score on the held out test records of testing users. We take the average score over 5 repetitions for each run to incorporate the random split effect.

We repeat 5 evaluation runs for each learning trial to consider the various random effects (i.e., initialization, randomized search). We employ the commonly used accuracy measures in each task to assess them, which are further elaborated in Table 1.

Id	# Samples	# Classes/# Users	Acc. Measure
MSD	$213,354$	N/A	N/A
Echonest	$40,980$	$571,355$ [7]	nDCG [40]
GTZAN	$1,000$	10	F1 [41]
MTAT	$25,863$	50	AUROC [42]

Table 1: Details on the datasets. We use the *macro* average strategy for F1 and Area Under Receiver Operating Characteristic curve (AUROC) measure, and we consider the top 500 recommended songs for computing the normalized Discounted Cumulative Gain (nDCG).

We select a set of audio features to infer the HDPGMM and non-DL baseline models inspired by [17]. The further details of the features can be found in Table 2. We use the implementation of `librosa` [43] with the default parameters for all the features.

[6] Length of preview audio differs per clip, where about 70% of samples are approximately 30 seconds and the rest are 1 minute, with a small subset longer than 1 minute.

[7] This refers the number of users in the dataset.

Feature	Aspect	Dim.	Transform
MFCC	Timbre	13	-
ΔMFCC	Timbre	13	-
ΔΔMFCC	Timbre	13	-
Onset Strength [44]	Rhythm	1	log
Chroma [45]	Tonal	12	log

Table 2: Details on the base audio features we employed for the experiment.

3.2 Comparisons

We evaluate 4 comparisons against HDPGMM, including DL-based and non-DL-based models.

- **G1** is the simplest model among the comparisons. The song-wise feature is represented by the concatenated parameters $\phi = \{\mu, \Sigma\}$ of the single multivariate Gaussian fitted on the frame-level base audio feature vectors within a song. We chose the square root of the diagonal in covariance, which means the feature is the concatenation of mean $\mu \in \mathcal{R}^{52}$ and standard deviation $\sigma \in \mathcal{R}^{52}$ of features.
- **VQ Codebook** can be deemed as the approximation of HDPGMM models [12]. First, a corpus-wise K-means clustering is fitted on the frame level features. Then, song-level feature is represented by the normalized frequency of cluster assignment of each frame-level feature within the song. [8] We set $K = 256$.
- **KIM** is a DL-based music representation trained in a simple self-supervised learning framework with a *VGG-like* [46] architecture [20]. We use the original implementation of the work, which takes the stereo mel-spectrogram of a 2.5 second-length clip as input. The representation is extracted from the last hidden layer before the prediction and summarized with global average and standard deviation pooling through the entire song.
- **CLMR** [29] is a recent DL-based music representation employing self-supervised learning through the contrastive learning method [47]. We employ the original implementation of [29] that uses the 2.67 second-length raw audio samples as input feature. [9] The representation is drawn from the last hidden layer and pooled with the global average over the entire song excerpt.
- **HDPGMM** uses the base audio feature with the whitening following [48]. As for song-level representation y_j, we employ the exponentiation of $\tilde{y}_{jk} = \exp(\mathbb{E}_q[\log p(X_j|c_j, z_j, \phi_k)])$ and normalize it over components and the length of the clip $y_{jk} = N_j^{-1} \frac{\tilde{y}_{jk}}{\sum_{k'=1}^{K} \tilde{y}_{jk'}}$. We adopt many hyper-parameter setups from the result of [18]; we set the truncation of components on the corpus level K and the song level T as 256 and 32 respectively, mini-batch size to 1024, learning rate parameters $\kappa = 0.6$ and $\tau_0 = 64$. We, however, explore the regularization rate $\eta_0 \in \{10^{-4}, 10^{-3}, 10^{-2}, 10^{-1}\}$ and total corpus size $|X| \in \{2 \times 10^3, 2 \times 10^4, 213354\}$ to examine their effect on the representation. [10]

For all the comparisons except G1, we repeat 3 learning trials in consideration of random effects. Within a trial, we iterated the update for 100 epochs for KIM, CLMR, and HDPGMM. Further, we set the representation's dimensionality to 256, homogeneous across all comparisons except $G1$. Finally, we take the logarithm of the representation $\hat{y}_j = \log(\max(y_j, 10^{-8}))$ if it is given as the probability simplex (i.e., VQCodebook, HDPGMM).

4. RESULT AND DISCUSSION

4.1 Effect of Learning Factors

Overall, we observe that the learning factors of HDPGMM can make a substantial difference. As Figure 3 shows, the result suggests that the additional regularization in Eq. (20) generally affects positively the performance of all the downstream tasks we tested. It implies that the entire song inputs would likely improve the representation further, as the regularization crudely masks the effect of the missing data due to the preview clipping to some extent.

Further, we find that the number of training samples positively affects the performances in general. We measured the effect by repeatedly sub-sampling the training data 5 times in two different sizes mentioned in Section 3.2, and conducted the same evaluation applied for the full training set. The result shows that the positive effect is logarithmic, suggesting that the model should be learned with an exponentially larger dataset to get a linear improvement in the performance. The recommendation task, on the other hand, indicates the effect may not be linear, as we observe that the learning with 2×10^3 samples outperforms the 2×10^4 samples. However, the largest dataset leads to a better representation than the smallest datasets.

4.2 Model Comparison

Dataset	Measure	Model	Mean (±SD)
Echonest	nDCG	G1	0.0237 (± 0.0011)
		VQCodebook	0.0155 (± 0.0003)
		KIM	0.0257 (± 0.0015)
		CLMR	**0.0362 (± 0.0012)**
		HDPGMM	0.0221 (± 0.0006)
GTZAN	F1	G1	0.5396 (± 0.0049)
		VQCodebook	0.5777 (± 0.0022)
		KIM	0.5420 (± 0.0290)
		CLMR	**0.6375 (± 0.0368)**
		HDPGMM	**0.6467 (± 0.0069)**
MTAT	AUROC	G1	0.8441 (± 0.0006)
		VQCodebook	0.8386 (± 0.0013)
		KIM	0.8014 (± 0.0045)
		CLMR	0.8262 (± 0.0026)
		HDPGMM	**0.8482 (± 0.0020)**

Table 3: Evaluation results on downstream tasks.

[8] It can be interpreted similarly to the inferred cluster assignment variable π_j in Eq. (4).

[9] Unlike the original work, we reduce the dimensionality of the hidden layer, from which we extract the representation, from 512 to 256 to control the representation dimensionality with other comparisons. Also, we do not apply the data augmentation for a fair comparison and also as it is beyond the main scope of the work. However, as it is reported that it can meaningfully improve the representation, we assume that applying the method would benefit other models similarly.

[10] The implementation can be found at `https://github.com/eldrin/pytorch-hdpgmm`.

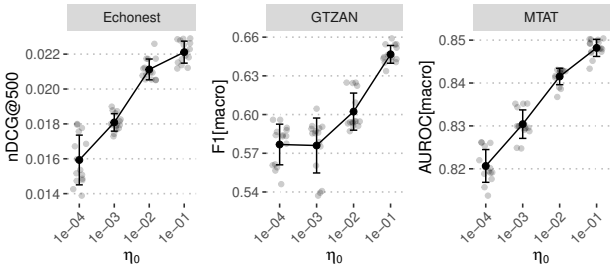
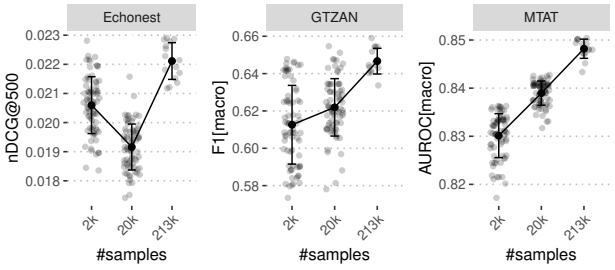
Table 4: Top tags for a few mostly "loaded" components (column-wise). The last row is the normalized total responsibility $\tilde{N}_k = \frac{N_k}{\sum_{k'}^{K} N_{k'}}$, meaning the proportional amount of songs having the component.



(a) Effect of regularization factor η_0. ($|X| = 213,354$)



(b) Effect of the number of training samples. ($\eta_0 = 10^{-1}$)

Figure 3: Effect of the learning factors on HDPGMM. Error bars indicate the standard deviations, and the grey dots are the raw data points.

Model comparison suggests that the HDPGMM model is comparable to the DL representation on average and can outperform it in a few specific scenarios. For the comparison, we chose the best HDPGMM model according to the result in Section 4.1 by setting $\eta_0 = 10^{-1}$ and using the entire dataset. As reported in Table 3, KIM achieves worse performance than HDPGMM on GTZAN and MTAT while performing better at recommendation (Echonest). On the other hand, CLMR, which adopts a more sophisticated learning strategy, achieves the best performance in Echonest, but performs worse than HDPGMM on MTAT and comparable on GTZAN. It is notable that the mixture model variants (VQCodebook, HDPGMM) perform particularly worse on the recommendation task. We hypothesize that the cosine similarity might not be an optimal choice for the probability simplex representation, or the feature set we consider may lack aspects that are crucial for the recommendation; this requires further study.

Except for this case, HDPGMM outperforms the other non-DL comparisons in general. It especially achieves significant improvement over its simplified version (VQCodebook) for all tasks, and mostly outperforms G1.

4.3 Component Interpretability

Finally, we explore the interpretability aspect of the HDPGMM model. To achieve it, we employ the *Lastfm-MSD* music tag dataset [30] where we find the mapping between the MSD songs and the social music tags. All our MSD training samples have mappings to the social tags, whose vocabulary size reaches roughly half a million. We compute the most relevant music tags for each corpus-level component found by the HDPGMM model. We estimate the relevance by a proxy measure $\alpha_{tk} = \sum_{j \in X: t \in j} N_j^{-1} \sum_n r_{jnk}$, where t denotes the tag index and r_{jnk} refers the responsibility computed in Eq. (20). To improve the clarity, we filter the most popular tags by weighting the measure by the Inverse Document Frequency (IDF) for each tag.

Table 4 shows an example from one of the HDPGMM with high regularization ($\eta_0 = 10^{-1}$). It suggests that the most frequent component (the first column) can be interpreted as the corpus-wide, universal topic. From second to the rest it represents a few other topics of music, such as *country-rock (column 1)*, *pop-female vocalist (column 2, 3, 5)*, and *electronic-dance (column 4)*. Notably, several compatible topics (i.e., columns 2, 3, and 5) exist, which can be interpreted as the collection of slightly different sub-clusters of an umbrella topic. It suggests that the advanced BN methods such as the hierarchical latent component models using the nested HDP [49] would further improve the representation.

5. CONCLUSION AND FUTURE WORK

In this work, we explore the potential of a BN model in the MIR task space. The results suggest that the HDPGMM representation achieves comparable effectiveness over the DL equivalents and outperforms a few scenarios. It implies that the method can be as effective as DL models when used in the supervised learning setup as well, by, for instance, jointly maximizing the variational lower bound both for the data generation and the prediction tasks. It has already been shown that such a joint objective approach can outperform the separated feature learning and transfer strategy that we demonstrate in this work [17].

Notably, HDPGMM is one of the more simple models in the BN approach. As mentioned above, there are models that are "deeper" such as nested DP models, which allow for a hierarchical structure of latent components [49]. The model also can be improved by introducing a sequential model such as Hidden Markov Models (HMM) as a base distribution [11], as the HDPGMM model assumes the exchangeability of tokens (feature frames), which is not ideal for a music signal. We left these possibilities to future work.

6. ACKNOWLEDGEMENT

A part of this work was carried out on the Dutch national e-infrastructure with the support of the SURF Coorperative.

ABSTRACT

Research on music generation using deep learning has attracted more attention; in particular, Transformer-based models have succeeded in generating coherent musical pieces. Recently, an increasing number of studies have focused on phrases that are smaller musical units, and several studies have addressed phrase-level control. In this study, we propose a method for sequentially generating a piece that enables the control of each phrase length and, consequently, the length of the entire piece. We added PHRASE and a new event, BAR COUNTDOWN, which indicates the number of bars remaining in the phrase, to the existing event-based music representations. To reflect user input indicating the phrase lengths of the piece being generated, we used an autoregressive generation model that adds these two events to the generated event-token sequence based on the user input and uses it as input for the next time step. Subjective listening tests revealed that the pieces generated by our methods possessed designated phrase lengths and ended naturally at the determined length. [1]

1. INTRODUCTION

Music generation has been studied for more than half a century [1] and has advanced significantly in recent years with the development of deep learning. In many studies, deep neural sequence models such as recurrent neural networks (RNNs) and Transformers [2] have been used to model music. Transformer-based methods [3–7] have succeeded in generating coherent music throughout a piece. To apply these sequence models to music generation, it is necessary to represent a piece as a sequence of tokens. Event-based representations such as MIDI-like [8] and its advanced versions, REMI [6] and CP [7], have been used.

More recently, an increasing number of studies have focused on phrases and sections [9–14], which are smaller musical segments. These studies aimed to generate a structured piece that was divided into several segments and developed through repetition and transformation. Several studies addressed phrase-level control [11–13] and allowed the control of phrase attributes such as melody, rhythm, and harmonic fullness. Length is another important phrase attribute and is controllable with a phrase-by-phrase generation policy [13], which means that each phrase is generated independently and joined. However, this phrase-by-phrase generation policy has a limitation in that natural transitions between phrases are not guaranteed.

Therefore, we worked on controlling the phrase lengths with a sequential generation policy. The sequential generation policy, unlike the phrase-by-phrase or section-by-section generation policy [9, 13], is a method of sequentially generating an entire piece at once. We aim to create a model that outputs a piece according to user input regarding the configuration of the phrases and the length of each phrase, as shown in Figure 1 (the detailed generation process is described in Sections 3.3 and 3.4). The controllability of each phrase length implies that the length of the entire piece can be controlled. To control the length of each phrase and the entire piece, we extended two recently used event-based music representations, REMI [6] and CP [7]. The random timing of the switching of phrases and the end of the generation in the existing representations is likely due to the model not knowing which phrase and where it is generating. Therefore, we added PHRASE and a new event, BAR COUNTDOWN, which indicates the number of bars remaining in the phrase, to REMI and CP. To reflect the user input, we used an autoregressive generation method in which these two events were added based on the user input to the generated event-token sequence, and the sequence was entered into the model again. To evaluate this approach, two subjective listening tests were conducted for the length of each phrase and the entire piece. By comparing our methods with the dataset and existing methods, we demonstrate our methods are effective in length control.

Our contributions are summarized as follows:

- We extended the existing music representations (REMI [6] and CP [7]) by adding PHRASE and BAR COUNTDOWN events and showed that both events are necessary for length control.
- We enabled the reflection of the user input by an autoregressive generative model that adds the PHRASE and BAR COUNTDOWN events to the generated event-token sequence based on the user input and uses it as input for the next time step.

2. RELATED WORK

2.1 Event-based Music Representations

To apply neural sequence models to music generation, music must be represented using a token sequence. Many studies [3–5, 15] adopted MIDI-like [8]. NOTE ON and NOTE OFF events indicate the start and end of a note, respectively, and a TIME SHIFT event advances the time step.

In MIDI-like, bars and beats are implicit, which are clearly indicated in the score, and it is difficult for the model to learn beat regularity and rhythmic structure. The model also has difficulty learning that the NOTE ON and NOTE OFF events must exist in pairs. To address these problems, an improved music representation called REMI (revamped MIDI-derived events) [6] was proposed. In REMI, the TIME SHIFT event in MIDI-like is replaced with BAR and BEAT events, and the NOTE OFF event is replaced with a NOTE DURATION event. TEMPO and CHORD events are added for clear harmony and expressive rhythmic freedom.

Later, a further extension of REMI called CP (compound word representation) [7] was suggested. In CP, consecutive and related events are grouped and placed in the same time step. Specifically, BAR, BEAT, CHORD, and TEMPO events are grouped into a METRICAL family and note-related events into a NOTE family. Additionally, a new event, EOS, is added to mark the end of a piece.

2.2 Latest Transformer-based Music Generation

Recently, Transformer-based methods have successfully generated coherent music throughout a piece and have become common in automatic composition in the symbolic domain. The Music Transformer study [3] was the first to apply the Transformer model to music generation. This study used MIDI-like to generate pieces by autoregressively predicting an event token at each time step. The Pop Music Transformer study [6] proposed REMI and generated pieces with a better rhythmic structure. The Jazz Transformer study [16] addressed the generation of Jazz. An attempt was made to introduce structure by adding the following four structure-related events to REMI: PHRASE, MLU, PART, and REPETITION. The CP Transformer study [7] proposed CP. Predicting events of the same family simultaneously at each time step significantly reduces the length of the token sequence, resulting in faster learning and inference. In addition, the EOS event allowed the model to complete the generation with the natural closure.

HAT (Harmony-Aware Hierarchical Music Transformer) [14] focused on phrases and sections. It represents music in CP and uses three Transformers hierarchically to allow event tokens to interact at different levels. The structure of the pieces was improved by learning the texture and the form jointly bridged by the harmony.

MusicFrameworks [13] is a monophonic melody generation system that enables phrase-level control. Music is described using music frameworks, a hierarchical music structure representation, and melodies are generated through a multi-level generative process. The manipulation of music frameworks allows control over phrase attributes such as structure, melody, and rhythm. Phrase length can also be controlled by modifying the structural information and length of the rhythm and chord information in each phrase. However, because of the phrase-by-phrase generation policy, there is no guarantee that transitions between phrases are natural.

3. METHOD

3.1 Phrase-Length Designated Music Generation

In this study, we worked on an automatic composition task that allowed control over the length of each phrase (and the length of the entire piece) with a sequential generation policy. The user inputs the configuration of the phrases and the length of each phrase in units of bars, and a piece with the designated phrase lengths and total length is generated. For example, if the input is "i4 A8 B8 o4," then a piece is generated with four bars for the intro phrase, eight bars for phrase A, eight bars for phrase B, and four bars for the outro phrase, with a total length of 24 bars.

3.2 PHRASE and BAR COUNTDOWN Events

We added the following two events to REMI [6] and CP [7]: PHRASE and BAR COUNTDOWN.

The first one, PHRASE, is an event that indicates to which phrase a bar belongs, e.g., PHRASE (i) refers to the intro phrase. This event was first proposed in the Jazz Transformer study [16]. In our study, PHRASE (Start) and PHRASE (End) were used in addition to phrase labels in the

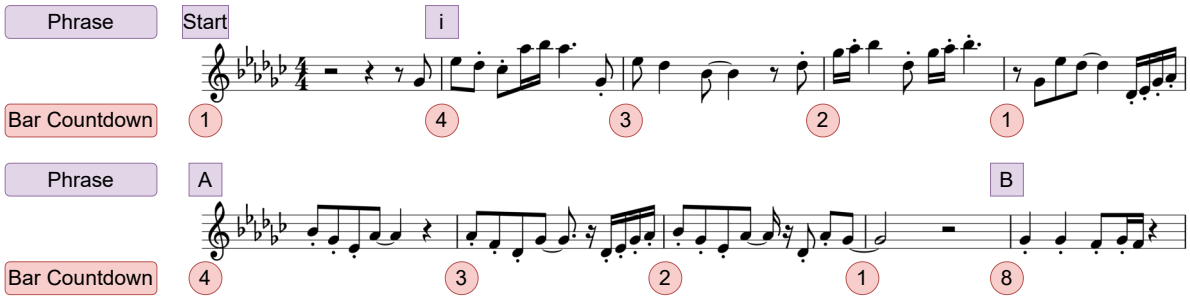

Figure 2: PHRASE and BAR COUNTDOWN events in the staff notation. This is the preprocessed melody part of '001.wav' in POP909 [17].

score. PHRASE (Start) represents one bar before the piece begins. This bar exists in all pieces to consider an anacrusis (or auftakt). Pieces that begin with an anacrusis have some notes in this bar, while those without an anacrusis promptly move to the next bar. PHRASE (End) is placed at the end of the event-token sequence and represents the end of the piece.

The second event, BAR COUNTDOWN, indicates the number of bars remaining in a phrase. If four bars remain, it is expressed as BAR COUNTDOWN (4), and the number of bars is counted for each bar.

These two events are expected to allow the model to know which phrase and where it is generating and to adjust the generation toward the turn of the phrase and the end of the piece. The correspondence between the two events and the musical score is shown in Figure 2. In REMI, the PHRASE and BAR COUNTDOWN events are placed just after the BAR event, which represents a bar line. In CP, these two events are placed along all the time steps. We slightly modified the original settings of CP in the CP Transformer [7] to decompose the METRICAL family into BAR and POS families. The BAR family represents a bar line instead of the BAR event, and the POS family groups the BEAT and CHORD events. In both REMI and CP, performance-related events, NOTE VELOCITY and TEMPO, were not used to reduce the burden of learning. We refer to these extended REMI and CP as **REMI + Ph&BC** and **CP + Ph&BC**, respectively (Ph and BC represent PHRASE and BAR COUNTDOWN, respectively). A list of events used in each representation is shown in Table 1, and an example of each event-token sequence is shown in Figure 3.

3.3 Reflection of User Input

We propose an autoregressive generation method to reflect user input regarding phrase lengths when generating pieces. As shown in Figure 1, event tokens are first predicted using the trained neural sequence model. Before using the predicted event-token sequence as the model input, the PHRASE and BAR COUNTDOWN events are added to the appropriate places based on the user input. This method is expected to enable the input of the phrase lengths that do not exist in the training data because they are present in BAR COUNTDOWN events.

REMI + Ph&BC	**CP + Ph&BC**	
Event	**Event**	**Family**
Note On Note Duration	Note On Note Duration	Note
Bar	-	Bar
Beat Chord	Beat Chord	Pos
Phrase **Bar Countdown**	**Phrase** **Bar Countdown**	[All]
-	Conti	[All]

Table 1: Events in REMI + Ph&BC and CP + Ph&BC.

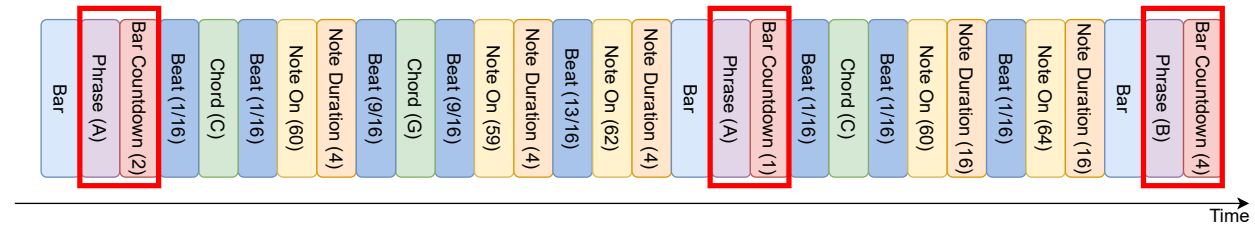
3.4 Pipeline

The same Transformer-based model was used as in the Pop Music Transformer [6] and the CP Transformer [7]. During the training stage, the MIDI file, chord annotation, and phrase annotation of each piece in the dataset are converted into the REMI + Ph&BC or CP + Ph&BC event-token sequence. The model is trained to predict the next event tokens from the input event-token sequence. The pipeline during the generation stage is illustrated in Figure 1. First, BAR, PHRASE (Start), and BAR COUNTDOWN (1) are input to the model to start the generation. Then, as described in Section 3.3, the next event tokens are predicted by the model, and after adding the PHRASE and BAR COUNTDOWN events based on user input, the event-token sequence is again entered into the model. By repeating this process to predict the event tokens sequentially, a piece is generated probabilistically. Once the model has generated the designated number of bars, it adds PHRASE (End) and terminates the generation.

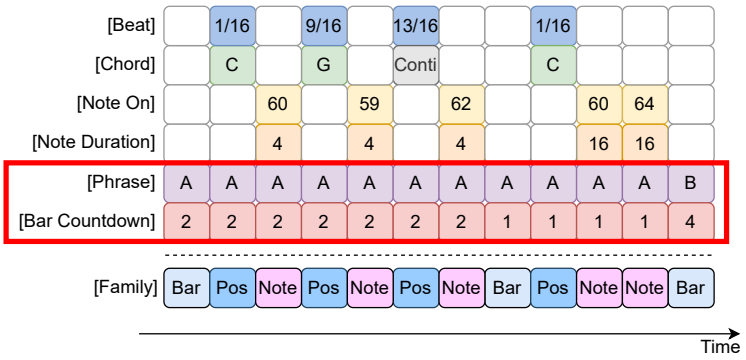
4. EXPERIMENTS

4.1 Dataset

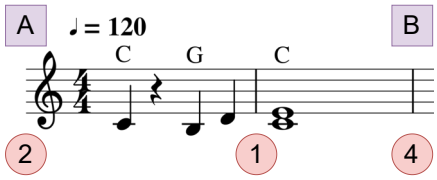
In this study, POP909 [17] is used as the MIDI dataset. The dataset consists of 909 pieces that are piano arrangements of pop songs by professional musicians and is divided into three parts: vocal melody, secondary melody or lead instrument melody, and piano accompaniment. We also used algorithmic chord annotations included in POP909 and the



(a) REMI + Ph&BC



(b) CP + Ph&BC



(c) Musical score

Figure 3: Examples of REMI + Ph&BC (a) and REMI + Ph&BC (b) event-token sequences and the corresponding staff notation (c).

human phrase annotations provided by Dai et al. [18].

After selecting pieces with 4/4 time signatures and excluding those whose downbeats were not aligned with the bar lines, 763 MIDI files were obtained. As a preprocessing step, we merged the three parts and quantized each piece into a 16th-note grid. Next, we shifted all pieces so that the first complete bar was the second to consider the pieces with an anacrusis, as described in Section 3.2. Furthermore, as the number of the intro and outro phrases was smaller than that of the other phrases, we extracted the first and last parts of the pieces and performed data augmentation by transforming their keys in the range of -3 to $+3$. We also modified the chord annotations. All flats on the root note were changed to sharps, and the chord types were limited to the following six types: maj, min, dim, aug, sus4, and sus2.

4.2 Overview of Evaluation Methods

In this study, the length of each phrase and the entire piece was evaluated. In the evaluation of each phrase length, we determined whether each phrase had a designated length by locating the boundary at which the phrase changed. The controllability of the overall length was determined based on whether it ended naturally or abruptly.

For an objective evaluation, methods that can automatically detect phrase boundaries and calculate a naturalness score for the end of a piece are required; however, no suitable methods are available (details are discussed in Section 4.6). In this study, we did not conduct an objective evaluation; rather, we conducted a subjective evaluation.

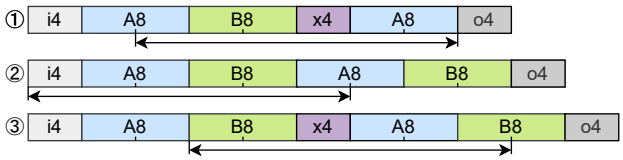
For the subjective evaluation, we administered two listening tests: one to divide a piece into several phrases and the other to evaluate the naturalness of the end. The details are provided in Section 4.4.

4.3 Comparative Methods

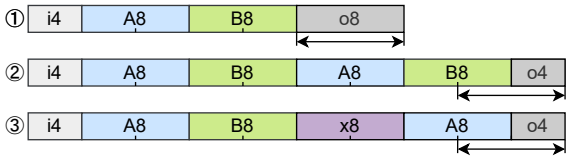
First, we compared our REMI + Ph&BC and CP + Ph&BC with the existing music representations, REMI [6] and CP [7]: **REMI** and **CP**. Since these cannot control the phrase lengths, we evaluated them only for closure. In these methods, we used the events and families shown in Table 1, excluding PHRASE and BAR COUNTDOWN, for comparison under the same conditions. In REMI, generation cannot be terminated by the model; instead, the model is forced to terminate when the number of generated bars reaches the target number. In CP, the model can naturally end a piece, although it cannot control the length of the piece. The final parts of the generated pieces were used for the evaluation.

Next, for the ablation studies, we compared REMI + Ph&BC and CP + Ph&BC with methods with a lower number of events. First, we compared REMI + Ph&BC with **REMI + Ph$_{\text{fewer}}$&BC**, a method that places PHRASE events only at the beginning of phrases. Note that in CP, the number of time steps does not change even if the number of PHRASE events is reduced, so CP + Ph$_{\text{fewer}}$&BC was not evaluated. We also compared our method with methods that used only one of the two events: **REMI + BC**, **REMI + Ph**, **CP + BC**, and **CP + Ph**.

The pieces in the POP909 dataset were also evaluated: **POP909**. Additionally, we intentionally created pieces that ended abruptly by cutting them off in the middle: **POP909$_{\texttt{cut}}$**. This method was used only when evaluating the closure.



(a) Test 1



(b) Test 2

Figure 4: Inputs of the generated pieces used for the evaluation. One division represents four bars. The segments indicated by arrows were extracted and used.

4.4 Subjective Evaluation

We conducted the following two online listening tests using Amazon Mechanical Turk:

Test 1 Phrase Boundary Detection
We investigated whether each phrase had a designated length or not. The participants listened to a piece while looking at the score and divided it into phrases. They were told in advance how many phrases there were, and they were asked to identify the phrase boundaries.

Test 2 4-Grade Evaluation of Closure
We examined whether the pieces ended naturally or abruptly. The subjects listened to a piece and answered whether the closure was natural or abrupt on a 4-point Likert scale: "Natural," "Somewhat natural," "Somewhat abrupt," and "Abrupt."

Since the majority of phrases in POP909 are four and eight bars in length [12], three inputs, consisting of four- and eight-bar phrases, were used for generation. The concrete inputs are shown in Figure 4. To reduce the burden on the subjects, in Test 1, 24 bars from the middle of a piece containing four phrases, and in Test 2, eight bars from the end were extracted and used for the evaluation. We generated 50 pieces per input and randomly selected two pieces, i.e., six pieces (three inputs $\times$ two pieces) were evaluated for each method.

First, qualification tests were conducted using the dataset to select those who understood each task and performed well, i.e., conformed to the dataset. In Test 1, 24 subjects correctly identified at least six of the nine phrase boundaries for three POP909 pieces, 13 of whom had more than one year of musical experience. In Test 2, 29 subjects answered "Natural" or "Somewhat natural" for two POP909 pieces and "Abrupt" or "Somewhat abrupt" for two $\text{POP909}_{\text{cut}}$ pieces, 12 of whom had more than one year of experience.

We then tested eight methods (except REMI, CP, and $\text{POP909}_{\text{cut}}$) in Test 1 and all 11 methods in Test 2. Each test was performed 60 times, and one piece per method was evaluated per test. In Test 1, the score was based on the percentage of correct answers, whereas in Test 2, "Natural" was scored as 4 points and "Abrupt" as 1 point.

Method	Test 1	Test 2
POP909	0.778	(3.67)
$\text{POP909}_{\text{cut}}$		1.29
REMI + Ph&BC (ours)	**0.633**	**3.00**
REMI + Ph_{fewer}&BC	0.550	2.34
REMI + BC	0.400	1.92
REMI + Ph	0.356	1.27
CP + Ph&BC (ours)	**0.583**	**3.28**
CP + BC	0.461	2.25
CP + Ph	0.306	1.78
REMI		1.35
CP		(3.17)

Table 2: Average percentage of correct answers for phrase boundaries in Test 1 and the average score of the four-grade evaluation of the closure in Test 2. For both tests, higher scores indicate better performance. The bracketed score in Test 2 indicates that it was evaluated with pieces that were not of the designated length.

4.5 Results

The average percentage of correct answers for phrase boundaries in Test 1 and the average score of the four-grade evaluation of the closure in Test 2 are listed in Table 2. In addition, the one-tailed t-test scores comparing our two methods to the other methods are shown in Table 3.

In Test 1, the scores of REMI + Ph&BC and CP + Ph&BC were much higher than 0.130 ($= 3/23$), the score when the phrase boundaries were answered at random. Compared with POP909, the scores were significantly lower (Table 3). It is suggested that our methods are effective in controlling the phrase lengths. When compared to methods used in the ablation studies, our methods scored significantly higher than methods with one of the two events. This indicates that both PHRASE and BAR COUNTDOWN events are required to control the phrase lengths. No significant differences were found between REMI + Ph&BC and REMI + Ph_{fewer}&BC. Thus, to control the phrase lengths, the number of events can be reduced by placing the PHRASE event only at the beginning of the phrase.

In Test 2, our scores exceeded 2.5, which was in the middle of the score range. They were significantly lower than the POP909 score but significantly higher than the $\text{POP909}_{\text{cut}}$ score (Table 3). Furthermore, they did not differ from the CP score, where the generated pieces ended naturally. Therefore, it can be said that our methods can end a piece naturally at a designated length. When compared to the methods used in the ablation studies, our methods scored significantly higher than all other methods. This indicates that both PHRASE and BAR COUNTDOWN events are required to control the length of the piece. These results

Method	Test 1		Test 2	
POP909	$\mu < \mu_m{}^{**}$	$(p = 0.0022)$	$\mu < \mu_m{}^{***}$	$(p = 3.2 \times 10^{-5})$

REMI			$\boldsymbol{\mu > \mu_m{}^{***}}$	$\boldsymbol{(p = 1.6 \times 10^{-27})}$
CP			$\mu > \mu_m$	$(p = 0.22)$

(b) Results of the t-test between CP + Ph&BC and other methods.

Table 3: One-tailed t-test scores comparing our two methods to the other methods in Tests 1 and 2. μ and μ_m denote the average score of our method and each of the other methods, respectively. ${}^{*}p < .05, {}^{**}p < .01, {}^{***}p < .001$. A p-value less than 0.05 was considered statistically significant.

also highlight the importance of placing the PHRASE event in every bar (REMI + Ph&BC), not just at the beginning of the phrase (REMI + Ph_{fewer}&BC).

4.6 Discussion

Comparing the method that uses only the PHRASE event and the one that uses only the BAR COUNTDOWN event, the BAR-COUNTDOWN-only method scored higher, regardless of the test or representation (Table 2). This means that the BAR COUNTDOWN event was more effective in controlling the length of each phrase and the entire piece. This is consistent with the role of the BAR COUNTDOWN event in teaching the model the number of bars until the end of the phrase. The reasons why adding the PHRASE event to BAR-COUNTDOWN-only method would improve scores are inferred as follows. In Test 1, the PHRASE event indicates that the phrase has changed and may play a role in making the boundaries of the phrase more distinct. In Test 2, the event can tell the model that the phrase being generated is the outro phrase, and the piece is almost over.

A two-tailed t-test was performed to determine whether there was a significant difference between REMI + Ph&BC and CP + Ph&BC. The results showed that there was no significant difference between these methods, with $p = 0.42$ for Test 1 and $p = 0.11$ for Test 2. We can say that both representations achieve equally good results. These two events could potentially be used for new event-based representations derived from REMI and CP. In addition, although the Transformer was used as the model in this study, it is expected to be widely applied to sequence models that perform autoregressive generation.

As mentioned in Section 4.2, there are no objective evaluation metrics suitable for this study; therefore, we did not conduct an objective evaluation but only a careful subjective evaluation. Although the fitness scape plot [19, 20] has been used in studies focusing on the generation of music structures [14, 16], it cannot be used for phrases that do not necessarily repeat, as in this study. Although several algorithms have been proposed to determine phrase boundaries [21], they cannot be adopted because of the low correctness rate when applied to POP909 pieces. The development of phrase-segmentation research and the establishment of objective evaluation methods are required.

One limitation of this study is that it was not possible to create repetitions by designating the same phrase labels in the input. For example, if the input is "A4 B4 A4," the two phrases A are completely different. A possible reason is that the model cannot refer to the next phrase label; therefore, the piece is not connected to the beginning of the next phrase, which was previously defined. A mechanism for making such distant phrases with the same label alike is necessary and is an issue for the future.

In addition, the following points need to be addressed in future studies: (1) combining our methods with music theory to achieve more natural pieces, especially in terms of phrase transition and closure. (2) evaluating length diversity because only a few types of lengths were used because of the convenience of the evaluation. (3) controlling other phrase attributes such as emotions.

5. CONCLUSION

In this study, we proposed a method to control the length of each phrase and the entire piece using a sequential generation policy. In this method, two events are added to the existing event-based music representations: the PHRASE event, which indicates the phrase to which the bar belongs, and the BAR COUNTDOWN event, which indicates the number of bars remaining in the phrase. To reflect the user input, an autoregressive generative model is used that adds these two events based on the user input to the previously generated event-token sequence and uses it as input for the next time step. Subjective listening tests indicated that adding two events effectively controlled the length of each phrase and the entire piece.

ABSTRACT

While generative adversarial networks (GANs) have been widely used in research on audio generation, the training of a GAN model is known to be unstable, time consuming, and data inefficient. Among the attempts to ameliorate the training process of GANs, the idea of Projected GAN emerges as an effective solution for GAN-based image generation, establishing the state-of-the-art in different image applications. The core idea is to use a pre-trained classifier to constrain the feature space of the discriminator to stabilize and improve GAN training. This paper investigates whether Projected GAN can similarly improve audio generation, by evaluating the performance of a StyleGAN2-based audio-domain loop generation model with and without using a pre-trained feature space in the discriminator. Moreover, we compare the performance of using a general versus domain-specific classifier as the pre-trained audio classifier. With experiments on unconditional one-bar drum loop and synth loop generation, we show that a general audio classifier works better, and that with Projected GAN our loop generation models can converge around 5 times faster without performance degradation.

1. INTRODUCTION

Generative adversarial networks (GANs) [1] are deep generative models that are composed of a *generator* and a *discriminator*. The discriminator can be considered as a classifier (or a "critic") which judges whether its input is a real sample, or a synthetic one created by the generator counterpart; the generator takes as input a random vector (sometimes plus additional conditional inputs [2]) and aims to create a synthetic sample that "fools" (i.e., appears to be realistic to) the discriminator. During the GAN training process, the discriminator and generator are updated in an iterative manner, fixing the parameters of one and updating those of the other each time. After the training converges, the generator can be used to generate original samples, leading to state-of-the-art (SOTA) results in image generation [3–7] and many other domains.

GANs have been extensively applied to music generation as well, including symbolic-domain generation [8–17] and audio-domain generation [18–28]. In particular, GAN-based models represent the SOTA in audio-domain music generation tasks such as single-note generation [18, 26], drum track generation [21], and loop generation [27].

Despite its widespread applications, GANs are notoriously difficult to train [29–33]. This is partly due to the fact that the generator and discriminator have opposite goals by design, with the generator aiming to *maximize* the discriminator loss and the discriminator aiming to *minimize* the same loss in different iterations, making the training dynamics complicated. As the parameters of the discriminator are constantly being updated over the training process, the generator has no single critic to improve its own performance over time. And, while the parameters of the generator and discriminator are typically initialized *randomly*, the GAN training process can be time-consuming. Using a pre-trained feature network as part of the discriminator has been shown to speed up the training process [34–36], but some modifications of the pre-trained feature network is needed to avoid the discriminator from being too strong and causing the gradients of the generator to vanish.

Projected GAN [37] is a new approach that is shown to effectively leverage the benefits of pre-trained feature networks, leading to SOTA results in unconditional image generation [7]. Projected GAN adds two *random projection* modules after the pre-trained feature networks, named "cross-channel mixing" (CCM) and "cross-scale mixing" (CSM), to prevent the discriminator from focusing only on a subset of features and thereby avoid mode collapse. They not only reduce the time of GAN training, but also improve the quality of the generated images.

This paper studies whether Projected GAN can also improve audio generation, by incorporating it to unconditional audio-domain loop generation [27] as a case study. We note that there are well-studied pre-trained feature networks in the image domain [34–36]. There are also studies on the choice of pre-trained network for retrieval and analysis of musical audio [38] and soundtracks [39]. However, we are less sure which pre-trained feature networks to use in the context of musical audio generation. Therefore, besides pioneering the use of Projected GAN for audio generation, an interesting aspect of our research is that we in-

Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

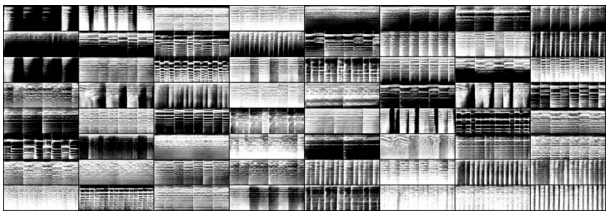

Figure 1. Mel-spectrograms of examples of synth loops generated by Projected GAN with a general classifier.

vestigate different types of pre-trained feature networks for Projected GAN-based musical audio generation, including general classifier and domain-specific classifiers.

Specifically, for the **general** classifier, we use the pre-trained VGGish feature networks trained on YouTube-100M [39], a huge collection of sounds and musical audio from YouTube. For **domain-specific** classifiers, we use short-chuck convolutional neural network (SCNN)-based models [40], which have led to SOTA accuracy across multiple music auto-tagging datasets. We use two SCNNs, one trained on the MagnaTagATune (MTAT) dataset [41] for tagging music of a wide range of genres, and the other trained on a collection of loops for genre classification of loops, which are domain-wise even closer to our generation task. We elaborate on the datasets and classifiers in Section 3, and then the usage of the classifiers as the pre-trained feature networks for loop generation in Section 4.

We report objective and subjective evaluations in Sections 5 and 6 studying the influence of different pre-trained feature networks for drum loop generation and synth loop generation following the approach of Projected GAN, finding that the use of a general classifier works consistently better. Moreover, we find slightly better result can be obtained if we "fuse" general and domain-specific pre-trained feature networks in our model. Objective and subjective evaluations both demonstrate that Projected GAN improves training speed and the final generation quality.

We share our code at `https://github.com/Arthurddd/pjloop-gan`, and examples of the generated loops at `https://arthurddd.github.io/PjLoopGAN/`. Illustrations of the Mel-spectrograms of the generated synth loops and drum loops can be found respectively in Figure 1 and later on in Figure 3.

2. BACKGROUND

Related Work. GANs have garnered great interest in recent years, leading to models that generate high-fidelity audio waveforms. WaveGAN [19] pioneers the use of GAN for audio; it can synthesize one-second raw audio waveforms of speech and music with coherence. Follow-up research applies GAN to other audio synthesis tasks. For example, MelGAN [42] and Parallel WaveGAN [43] use GAN to build neural vocoders that can reconstruct a waveform from the corresponding Mel-spectrogram. GAN-TTS [44] applies GAN to convert text to natural human speech. UNAGAN [23] uses GAN to synthesize singing voice.

GAN has also been used to synthesize audio samples of musical materials, including percussive and harmony ones, that can be used in music production. GANSynth [18] can synthesize harmony music notes with diverse timbre and controllable pitches. DrumGAN [24] can synthesize one-shot percussion sounds, allowing for the use of condition perceptual features to intuitively control the timbre of the percussion sounds. StyleWaveGAN [45] improves the audio quality and inference time of DrumGAN. However, the aforementioned models deal with only single notes or one-shot samples instead of longer phrases such as musical loops, limiting their applicability to creating loop-based music. In view of this need, Hung *et al.* [27] study the task of one-bar drum loop generation and benchmark the performance of UNAGAN [23], StyleGAN [4] and StyleGAN2 [5] for this task over the FreeSound Loop dataset [46], showing that the model based on StyleGAN2 [5] performs the best. However, Hung *et al.* [27] do not consider the training efficiency of their models. Moreover, while they focus on drum loops only, we consider also the generation of synth loops to encompass not only percussive but also harmonic musical materials in our work.

Specific to the GAN training technique, there are three main approaches to improve the discriminator. First, modifying the *architecture* of the discriminator to improve the discriminator's ability [47–49]. Second, assembling *multiple discriminators* to capture more comprehensive features, an approach that as been widely investigated in the audio domain for building the vocoder [42, 50–52]. The third approach introduces a *pre-trained feature network* to the discriminator to avoid learning its parameters completely from scratch, which helps speed up the convergence time and prevent model overfitting. Zhao *et al.* [34] use the pre-trained network in the large-scale dataset, adapt it to a small dataset, and propose adaptive filter modulation to deal with domain shift. Grigoryev *et al.* [35] and Kumari *et al.* [36] both find that pre-trained network selection can largely influence performance and propose a recipe to choose a suitable pre-trained network for a particular image-domain task. Projected GAN [37] is a very recent idea that combines the aforementioned approaches, using multiple discriminators and employing pre-trained feature networks simultaneously to improve the training stability and efficiency of the GAN. However, to our best knowledge, adapting Projected GAN to the audio-domain generation is still unexplored, for either speech or music.

Projected GAN. Projected GAN [37] introduces a set of $L = 4$ feature projectors $\{P_l, l = 1, \ldots, L\}$, each maps either real samples $\mathbf{x}$ or fake samples $G(\mathbf{z})$ to a fixed pre-trained feature space. It aims to minimize the following objective function to match the data distribution in the feature space, instead of matching data distributions directly:

$$\min_G \max_{\{D_l\}} \sum\nolimits_{l=1}^{L} \exp\big(E_x[\log D_l(P_l(\mathbf{x}))] + E_z[\log(1 - D_l(P_l(G(\mathbf{z}))))]\big), \quad (1)$$

where $\{D_l, l = 1, \ldots, L\}$ denotes the set of independent discriminators operating on different feature projections,

and G denotes the generator that converts a random vector $\mathbf{z}$ into a fake sample. Each projector P_l consists of three components: a pre-trained feature network C_l, the CCM modules, and the CSM modules. First, we extract features from L different layers of the feature network C_l, leading to L set of feature maps in different scales. Second, for each scale, the CCM mixes the features across channels by *random* (i.e., not-learned) 1×1 convolutions with an equal number of input and output channels, which can be viewed as the generalization of random permutation. Third, CSM further mixes features across scales by *random* 3×3 convolutions and bilinear upsampling layers, yielding a U-Net architecture that combines the feature maps of different scales. The features fused by CCM and CSM in L different scales would then be fed to each discriminator D_l. The random projections introduced by CCM and CSM have the effect of encouraging each D_l to take into account the entire feature space instead of overfitting to a sub-set of feature space, thereby avoiding mode collapse. Without using gradient penalties and any sophisticated training strategies, Projected GAN updates its loss simply by summing the output of the L discriminators.

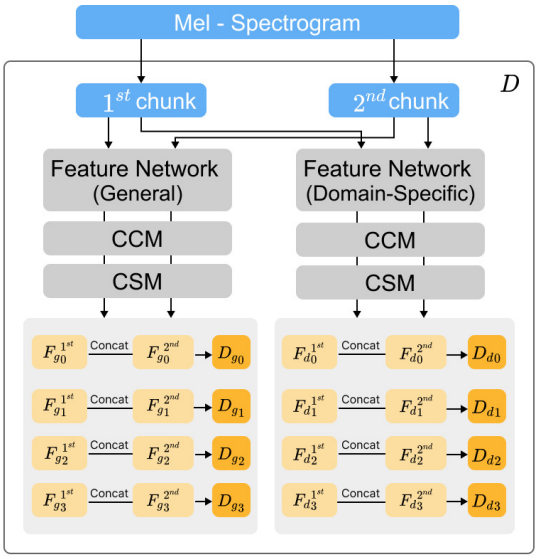

Figure 2. Diagram of the proposed discriminator architecture. A Mel-spectrogram is divided into two chunks and then fed to either a general or a domain-specific pre-trained feature network, or both (for "fusion"). Features computed for both chunks are aggregated at each scale l before feeding to the corresponding discriminator D_l.

3. DATSETS & CLASSIFIERS

Our work is built upon the use of the following datasets.

Youtube-100M [39] is a private dataset of Google, containing 100 million Youtube videos. Each video has on average 5 manually assigned tags, out of 30,871 possible labels. Hershey *et al.* [39] train a VGGish pre-trained network for large-scale audio classification using the dataset. While we are not able to have a copy of the dataset, we can use the pre-trained weights Gemmeke *et al.* [53] share publicly as our general audio classifier.

MagnaTagATune (MTAT) [41] is a dataset commonly-used in research on music auto-tagging. It contains 25,863 music clips, each 29-seconds long. We use MTAT to train one of our domain-specific pre-trained feature networks. We follow the original data split [41] and use only the top 50 tags, including genre and instrumentation labels, as well as decades (e.g., '80s' and '90s') and moods.

Looperman dataset is an in-house collection of loops from `https://www.looperman.com/`, a website hosting free music loops. We get the audio and uploader-provided metadata of 23,983 drum loops and 22,625 synth loops. According to the metadata, the drum loops and synth loops can be categorized to 66 and 58 genres, respectively. We use the Looperman dataset for not only building a domain-specific pre-trained feature network but also for building our audio-domain loop generation model.

Following the preprocessing steps of Hung *et al.* [27], we first apply downbeat tracking via `madmom` [54] to split every loop into single bars and then time-stretch each to 120 BPM (beats-per-minute) by `pyrubberband` [55] to unify their length to be always **2 seconds per loop**. After this preprocessing, we have 128,122 and 42,570 one-bar loops for drum and synth, respectively. We split the data by 80/10/10 for training the loop genre classifier, and use the entire data for music loop generation.

3.1 Pre-trained Feature Networks for Music

General. As aforementioned, we use the VGGish network trained on Youtube-100M [53] as the general pre-trained feature network. Taking the Mel-spectrogram as input, the model uses 2D convolutional blocks and 2D max-pooling layers to compute 128-dimensional features at the output.

Domain specific. Short-Chuck CNN (SCNN) [40] has a simple 2D CNN architecture with 3×3 filters and residual module but it has been shown to be remarkably effective for music auto-tagging. We use in our implementation 6 layers of CNN blocks with a fully connected layer and the residual module. Each CNN block comprises a 2×2 max-pooling layer. We use SCNN to train separate classifiers for MTAT and Looperman from scratch, and then used the trained classifiers as our domain-specific pre-trained feature networks. For MTAT, SCNN achieves 0.909 ROC-AUC and 0.445 PR-AUC. For genre classification of the looperman drum loops, the classification accuracy reaches 0.792. For synth loops, the accuracy attains 0.700.

Fusion. Fusing multiple pre-trained feature networks has also been shown useful for Projected GAN-based image generation [7]. Accordingly, we also experiment with a simple fusion strategy that allows the discriminator to consider both general and domain-specific features at the same time, as depicted in Figure 2.

4. AUDIO GENERATION BY PROJECTED GAN

Following Hung *et al.* [27], we use StyleGAN2 [5] as the backbone of our loop generation model. However, we improve their model in a number of aspects, regarding to not

only the discriminator (i.e., with Projected GAN) but also the generator. We provide the details below.

Improving the generator. The generator G consists of a mapping network G_m and a synthesis network G_s. We implement G_m with only 6 fully-connected layers instead of the 8 in the original StyleGAN2 architecture. Furthermore, echoing the finding in the image domain [56], we find that the length of the vectors $\mathbf{z}$ (i.e., the input of G_m) largely affects the model performance. Setting the length of $\mathbf{z}$ to 512 as done in [27] leads to mode collapse in our preliminary experiments, as shown in Figure 3(a). This may be related to the so-called "intrinsic dimension" of the data [56]; an overly large latent space of $\mathbf{z}$ introduces redundancy that distracts the generator. As smaller $\mathbf{z}$ empirically works better, we set its length to 32 in the experiments reported below. We similarly set the length of the "style code" $\mathbf{w}$ (i.e., the output of G_m) to a small value of 64.

Pipeline The training follows the procedure of the Projected GAN, but we use the following pipeline to match the input shape expected by the pre-trained feature networks. First, we compute the Mel-spectrogram with 512-point window size and 160-point hop size for short-time Fourier Transform (STFT) and 64 Mel channels. Second, we feed a latent $\mathbf{z}$ to the mapping network G_m to generate style codes that modulate the convolutions of the synthesis network G_s, using four upsampling blocks to generate a Mel-spectrogram that corresponds to a synthesized *2-second* loop. We note that our pre-trained feature networks are on *1-second* audio. To address the size mismatch, we split the Mel-spectrogram into **two chunks**, with the first half corresponding to the first second and the other the rest. As illustrated in Figure 2, we feed the two chunks separately to the discriminators, going through the pre-trained feature network, CCM and CSM. Moreover, we concatenate the features with the same scales but in different chunks to aggregate the features from individual chunks, yielding $L = 4$ aggregated features $\{F_l, l = 1...L\}$. We feed each of these features independently to the corresponding discriminators D_l. Additionally, if we consider two pre-trained feature networks simultaneously, referred to as "fusion" in Section 3.1, we have in total $2L$ aggregated features and $2L$ discriminators. Eventually, we sum the loss from these discriminators to update the network.

Similar to Hung *et al.* [27], at inference time, the Mel-spectrogram generated by the generator would go through a MelGAN vocoder [42] to become waveforms.

5. OBJECTIVE EVALUATION

We use the following objective metrics to evaluate the quality and diversity of the generated loops.

Inception Score (IS) [58, 59] measures the quality of the generated loops and detects whether there is a mode collapse by using a pre-trained domain-specific classifier, namely the loop genre classifier for each type of loops (i.e., drum or synth). It penalizes models whose samples cannot be reliably classified into a single class or that only belong to a few from all possible classes.

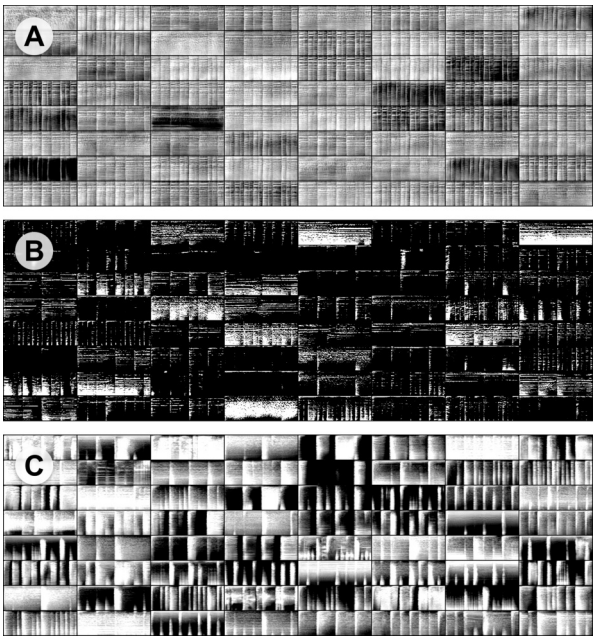

Figure 3. Mel-spectrograms of examples of drum loops generated (a) by a failed case using an overly large latent space for $\mathbf{z}$, leading to mode collapse (see Section 4); (b) Projected GAN with the MTAT domain-specific classifier; (c) Projected GAN with the VGG general classifier.

Fréchet Audio Distance (FAD) [60] reflects both quality and diversity as it measures the distance between continuous multivariate Gaussians fitted to the embeddings of the real and generated loops.

Density & Coverage (D&C) [57] are new metrics that measure respectively the quality and diversity of the generated data. D&C are considered to be more robust against the influence of outliers compared to older metrics such as precision and recall (P&R) [61]. 'D' is the average number of real-sample neighborhood spheres that contain each of the fake samples. It may be greater than 1 depending on the density of reals around the fakes. 'C' is the fraction of real samples whose neighborhoods contain at least one fake sample. In our implementation, we use the hyperparameters suggested by [57]. Moreover, following [57], we calculate D&C with a randomly-initialized VGG16 model that projects samples to VGG16 *fc2* space whose dimension is deliberately set to a small value 64.

We evaluate the following models here:

- **StyleGAN2**: the SOTA for drum loop generation [27].
- **StyleGAN2 (early-stop)**: the StyleGAN2 that stops training at the same point when Projected GAN converges, providing a reference demonstrating the possible advantage of the training efficiency of Projected GAN.
- **Projected StyleGAN2** with different pre-trained feature networks, including 1) the general VGG classifier alone, 2) the domain-specific SCNN classifier trained on MTAT alone (denoted as $\text{SCNN}_{\text{MTAT}}$), 3) the SCNN classifier trained on Looperman alone, using the drum or synth classifier depending on whether it is for generating drum or synth loops (denoted as $\text{SCNN}_{\text{Loop}}$), 4) "fusion" of

Models	Drum loops				Synth loops			
	IS ↑	FAD ↓	D ↑	C ↑	IS ↑	FAD ↓	D ↑	C ↑
A Real data	16.30	0.01	1.00	1.00	14.95	0.01	1.00	1.00
B StyleGAN2 [27]	5.58	2.50	1.01	**0.89**	4.80	3.60	1.19	**0.91**
C StyleGAN2 (early-stop)	5.21	3.40	0.56	0.43	4.55	7.97	1.01	0.75
D Projected StyleGAN2 (VGG)	5.87	3.03	1.06	0.70	4.70	**2.34**	1.31	0.82
E Projected StyleGAN2 ($SCNN_{MTAT}$)	4.75	8.18	0.00	0.00	3.97	7.14	0.001	0.002
F Projected StyleGAN2 ($SCNN_{Loop}$)	4.45	7.21	0.00	0.00	3.08	8.32	0.001	0.002
G Projected StyleGAN2 (VGG+$SCNN_{MTAT}$)	6.22	2.45	**1.11**	0.74	4.73	3.13	1.67	0.85
H Projected StyleGAN2 (VGG+$SCNN_{Loop}$)	**6.31**	**2.34**	1.08	0.73	**4.82**	2.56	**1.70**	0.85

Table 1. Objective evaluation result for the different settings of the Projected GANs trained on the Looperman dataset for loop generation. 'D' and 'C' stand for Density & Coverage [57] (↓/↑: the lower/higher the better; the best in bold).

VGG, $SCNN_{MTAT}$, and 5) "fusion" of VGG, $SCNN_{Loop}$.

Table 1 presents the objective evaluation results of models trained on drum loops and synth loops. Each model generates 10,000 random loops to compute the scores. We also compute the scores using the real data for setting a high anchor of the objective scores.

We see that the best-performing configurations of Projected StyleGAN2 can achieve higher IS and lower FAD than StyleGAN2 (i.e., row B). For drum loops, the IS can be improved from 5.58 to 6.31 (row H) ; for synth loop the FAD can be reduced from 3.60 to 2.34 (row D).

Interestingly and somehow surprisingly, when only a single pre-trained feature network is used (i.e., rows D–F), we find that *only* Projected StyleGAN2 (VGG) performs nicely. The domain-specific pre-trained feature networks actually degrade the performance of loop generation; either Projected StyleGAN2 ($SCNN_{MTAT}$) or Projected StyleGAN2 ($SCNN_{Loop}$) obtains lower IS and higher FAD, and even close-to-zero D&C. This suggests that a general pre-trained feature network works much better than a domain-specific pre-trained feature network in the context of Projected GAN-based unconditional loop generation. This is likely because the discriminator employing a domain-specific pre-trained feature network is too strong compared to the generator, leading to gradient vanishing. Figure 3(b) shows samples generated by Projected StyleGAN2 ($SCNN_{MTAT}$); we see that the model weirdly generates sparse samples most of the time.

Table 1 also shows that the "fusion" of general and domain-specific pre-trained feature networks (rows G & H) performs slightly better in some metrics than using a general pre-trained feature network alone (row D). In particular, we see that Projected StyleGAN2 (VGG+$SCNN_{Loop}$) achieves the highest IS score in both drum and synth loop generation. It also reaches the lowest FAD for drum loops and the second lowest FAD for synth loops. We show examples of its generated synth and drum loops in Figures 1 and 3(c), respectively.

Projected StyleGAN2 appears to have lower D&C compared to StyleGAN2, suggesting that Projected StyleGAN2 sacrifices a little diversity for higher quality of the generated samples. This is presumably because the feature space has been constrained by the pre-trained feature networks throughout the whole training process, making it

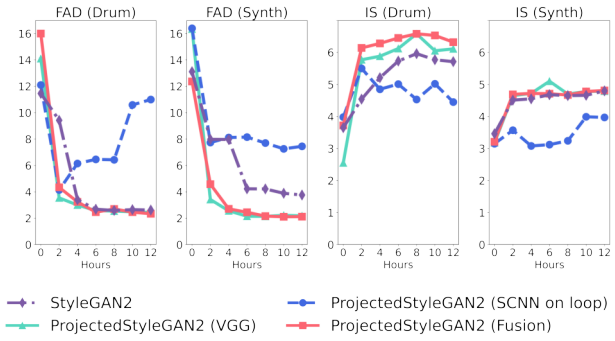

Figure 4. The FAD and IS as a function of training hours.

hard to capture the whole distributions. Future work can be done to remedy this and further improve the diversity of Projected StyleGAN2.

Figure 4 shows how the FAD and IS of four selected models (rows B, D, F, H in Table 1) varies as a function of training time, when all the models are trained separately and independently on a single V100 GPU. For both drum and synth loop generation, Projected GAN leads to lower FAD much faster than the StyleGAN2 baseline. For synth loops, Projected GAN with only 2-hour training reaches lower FAD than the StyleGAN2 baseline with 12-hour training. In general, Projected GAN converges at approximately 2 hours for both drum and synth loops, while StyleGAN2 converges x5 times longer at about 10 hours. Echoing the result in Table 1, using the epoch of StyleGAN2 corresponding to 2-hour training time (i.e., row C) obtains worse scores than the models corresponding to rows B and D in almost all the metrics for both drum and synth loops. Overall, these results nicely demonstrate how Projected GAN speeds up and improves GAN training.

6. SUBJECTIVE EVALUATION

To further assess the loops generated by the models, we conduct a subjective listening test through an anonymous online questionnaire. Each subject is presented with a randomly picked human-made loop from the Looperman dataset (i.e., 'Real') and a randomly-generated loop by each of the following four models: StyleGAN2, StyleGAN2 (early-stop), Projected StyleGAN2 ($SCNN_{Loop}$)

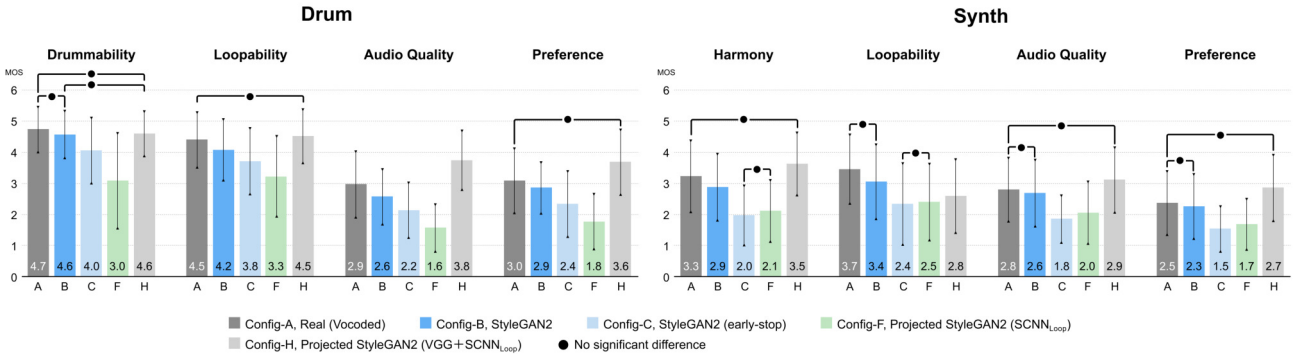

Figure 5. Subjective evaluation results. The performance difference between any pair of models in any metric is statistically significant (p-value< 0.001) under the Wilcoxon signed-rank test, except for the pairs that are explicitly highlighted.

and Projected StyleGAN2 (VGG+SCNN$_{\text{Loop}}$). The subject is then asked to rate each of these loops in terms of the following metrics, all on a five-point Likert scale.

- **Drummability or Harmony**: Drummability (for drum loops) means whether the sample contains percussion sounds, and Harmony (for synth loops) means whether the sample contains harmonic sounds.
- **Loopability**: whether the sample can be played repeatedly in a seamless manner.
- **Audio quality**: whether the sample is free of unpleasant noises or artifacts.
- **Preference**: how much you like it.

To evaluate loopability, we repeat each sample four times in the audio recording. Because the output of the models all goes through the MelGAN vocoder [42] to become waveforms, we do the same for 'Real' to be fair.

Figure 5 shows the averaged results from 35 participants. The responses indicate an acceptable level of reliability, Cronbach's $\alpha = 0.721$. The subjective evaluation result aligns nicely with the objective evaluation result. Projected StyleGAN2 (VGG+SCNN$_{\text{Loop}}$) performs the best and Projected StyleGAN2 (SCNN$_{\text{Loop}}$) performs the worst. Overall, Projected StyleGAN2 (VGG+SCNN$_{\text{Loop}}$) achieves results comparable to StyleGAN2 and even 'Real' for both types of loops. Somehow surprisingly, Projected StyleGAN2 (VGG+SCNN$_{\text{Loop}}$) can even outperform 'Real' in audio quality and preference for both drum and synth loops. We conjecture that this is because the 'Real' here actually stands for the "MelGAN-vocoded" version of the real data, whose quality may have suffered from the artefacts introduced by the vocoder.

Almost all models lead to higher subjective scores for drum loops than for synth loops, suggesting that synth loop generation is more challenging. We note that, for synth loops, Projected StyleGAN2 (VGG+SCNN$_{\text{Loop}}$) actually obtains higher harmony scores than StyleGAN2 and 'Real', but its loopability scores is lower. To further improve its performance for synth loop generation, future work may be done to explicitly consider loopability in model training.

7. LIMITATIONS

We only focus on one-bar loop generation with a specific BPM of 120 in our study, which is "convenient" as it gives us fixed-size Mel-spectrograms to be treated as images by StyleGAN2. However, to be applicable to loop-based music production, future work needs to consider variable BPMs and loops with more bars. As the size of the Mel-spectrogram would not be fixed when we consider variable BPMs, future work may need to adopt generative models other than StyleGAN2 as the backbone. Possible candidates are UNAGAN [23] and VQGAN [62], both of which may also benefit from the ideas of Projected GAN.

To apply Projected GAN, we need to take care of the *shape matching* between the pre-trained networks and the generative model. For example, in our work the pre-trained networks (e.g., the VGGish one) is trained on 1-second audio chunks, but our generator is to generate 2-second loops. The size mismatch can be easily addressed by simply splitting the Mel-spectrogram into two chunks in our work, but this is trickier if we consider BPMs other than 120.

8. CONCLUSION

In this paper, we have demonstrated that Projected GAN can be used to improve the training efficiency and overall performance of GAN-based models for audio generation, specifically the generation of drum loops and synth loops. Moreover, we demonstrated that using a domain-specific pre-trained feature network alone does not work well; we need to use either a general pre-trained feature network, or the fusion of multiple pre-trained feature networks.

This work can be extended in many ways. First, we can expand our work to generate variable-length loops, or to other GAN-based audio-related tasks. Next, we can explore unsupervised or self-supervised approaches (e.g., [63, 64]) to get the pre-trained feature network. Third, we are also interested in using class conditions or attributes for more controllable loop generation. Doing so may help improve the diversity of the generated loops as well, according to related work on image generation [7]. Finally, using diffusion probabilistic models [65, 66] as the generative model for loop generation also worth trying.

9. ACKNOWLEDGEMENT

We are grateful to Tun-Min Hung for helpful discussions during the project. We also thank the anonymous reviewers for their constructive feedbacks. Our research is funded by grant NSTC 109-2628-E-001-002-MY2 from the National Science and Technology Council of Taiwan.

MODELING THE RHYTHM FROM LYRICS FOR MELODY GENERATION OF POP SONG

ABSTRACT

Creating a pop song melody according to pre-written lyrics is a typical practice for composers. A computational model of how lyrics are set as melodies is important for automatic composition systems, but an end-to-end lyric-to-melody model would require enormous amounts of paired training data. To mitigate the data constraints, we adopt a two-stage approach, dividing the task into lyric-to-rhythm and rhythm-to-melody modules. However, the lyric-to-rhythm task is still challenging due to its multimodality. In this paper, we propose a novel lyric-to-rhythm framework that includes part-of-speech tags to achieve better text-setting, and a Transformer architecture designed to model long-term syllable-to-note associations. For the rhythm-to-melody task, we adapt a proven chord-conditioned melody Transformer, which has achieved state-of-the-art results. Experiments for Chinese lyric-to-melody generation show that the proposed framework is able to model key characteristics of rhythm and pitch distributions in the dataset, and in a subjective evaluation, the melodies generated by our system were rated as similar to or better than those of a state-of-the-art alternative.

1. INTRODUCTION

Setting lyrics to a melody is a common but complex task for a composer. The form, articulation, meter, and symmetry of expression in lyrics can inspire, or set constraints on, the melodic arrangement. Given the importance of melody, it is unsurprising that the decades-long history of Music Metacreation systems includes countless melody-creation systems (see [1] for a review). However, less attention has been paid to the lyric-to-melody generation task (i.e., generating a melody for given input lyrics). The task is challenging for many reasons, including but not limited to: the need to handle the prosody of the text correctly (e.g., one should avoid setting an unstressed word like 'the' on a stressed note in the melody); the need to reflect the structure of the lyrics in the melody; and the need to create a good melody to begin with.

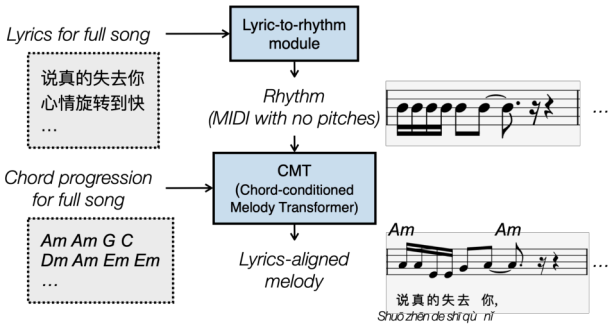

Figure 1: Diagram of the proposed system.

With the rapid growth of deep learning tools, this task has gained more attention, and there are many recent examples of lyric-to-melody creation systems, most using an end-to-end approach [2–5]. Modeling the relationship between lyric syllables and musical notes is a complex, cross-modal task, but it is hoped that we can succeed with a large amount of paired examples (i.e., lyrics aligned to their corresponding melodies). However, acquiring such data is expensive, and using unsupervised learning has shown limited performance gains [3]. All the systems mentioned here are trained on fewer than 200,000 examples of song lyrics; by contrast, the text-to-image system DALL-E has 12 billion parameters and involved hundreds of millions of paired text-image training data [6].

One alternative, suggested in [7], is to pick an intermediate representation and adopt a two-stage approach: one model to convert lyrics to the chosen representation, and a second to convert that to a melody. The motivation is that there is sufficient data to train each model separately, without the paired lyrics-melody data required by the end-to-end approach.

We choose 'rhythm' as the intermediate step because, if we disregard melismas and expressive singing techniques, we can assume there is a one-to-one correspondence between syllables and onsets, and between onsets and melody pitches. Also, there is plenty of data to model each step: first, from karaoke-style scrolling lyrics data, we can obtain an alignment between syllables in lyrics and note onsets in music, and thus note durations and metrical positions, too. Second, there are multiple public datasets from which to learn to assign pitches for each note given their duration. Our goal is then to solve two sub-tasks, namely lyric-to-rhythm and rhythm-to-melody, with an as-

sumption that the rhythm generation process is independent of the pitch generation one [7].

There are many recent melody generation models [8–11], but lyric-to-rhythm modeling is rarely attempted. In this paper, we introduce a novel framework for converting lyrics to rhythms using an encoder-decoder Transformer architecture [12]. The proposed system is outlined in Fig. 1: given an input set of lyrics, a lyric-to-rhythm module assigns onset times and durations for each syllable. This rhythm, along with a user-provided chord progression, is fed into a Chord-conditioned Melody Transformer (CMT) [13], a state-of-the-art melody generation system, to predict the pitch for each note. The details of the lyric-to-rhythm module and the CMT are provided in Sections 3.3 and 3.2, respectively.

2. BACKGROUND

Lyrics and melody are not arbitrarily combined; common sense suggests and prior analysis [14] indicates that patterns in lyrics and melodies are related and can be modeled, in part, with features of the melody (e.g., note duration) and lyrics (e.g., syllable stress). One of the earliest lyric-to-melody systems was designed to handle Japanese prosody [15]: first, the input text was segmented into phrases; next, a set of pre-composed rhythms was searched for one that fit the syllable count and matched the accent pattern of the text; finally, pitches were assigned using dynamic programming to optimise the interval directions with the natural prosody of the words. An earlier lyric-to-rhythm system also leveraged a dataset of pre-composed rhythms that were scored based on their match to the input syllable-stress and word-rarity patterns [16]. Although our system has little in common with these works, we do share the use of rhythm as an intermediate representation.

Algorithms for automatic music generation are a subset of Music Metacreation systems [1], which have been present in Western music in many forms, including being used for the creation of standalone pieces and, either offline or in real-time, as part of the human composition process. With the help of machine learning and deep learning architectures, many such systems have shown to be capable of generating a plausible outcomes that match the musical characteristics of given datasets. Supervised generative models aim to learn a representation of the underlying characteristics of a training set distribution. Depending on the model, this representation can be either explicitly depicted or implicitly used to generate samples from the learned distribution [17].

Some systems aim to generate a part of a musical piece with the aid of another given part (including melody-to-lyrics creation [18], the inverse of the task we consider). Conditioning the choice of parameters in a generative model on data from other modalities, such as a bass line or a structure, can yield controllable generation systems [19][p.82-83]. For the case of using chords to condition melody generation, a recent system adjusting a general adversarial network architecture has been presented in [20] with the option of generating melody lines over a given

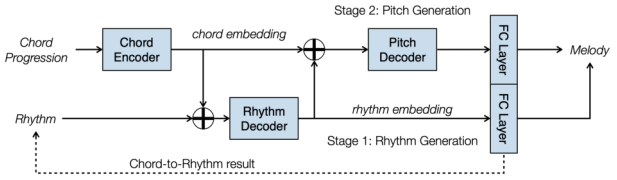

Figure 2: A two-stage structure of CMT, where $\oplus$ represents concatenation. Stage 1: chord-to-rhythm. Stage 2: rhythm+chord-to-pitch based on the result of Stage 1.

accompaniment. The Chord-conditioned Melody Transformer (CMT) [13] is the most recent effort in this area; we adapt much of the design of this system, extending it to accept both lyrics and chords as input. Details of this system, and how we adapt it, follow in Section 3.

3. METHODOLOGY

3.1 System Overview

Our system design is motivated by the Chord-conditioned Melody Transformer (CMT) [13]. The authors of CMT proposed a two-stage system, assuming a hierarchy that the process of generating melodies is two-phase, as depicted in Fig. 2: *Stage 1*, generating the rhythm of notes from chord progressions; *Stage 2*, generating the pitch for each note depending on the chord progressions and generated rhythm. Our proposed system augments CMT by replacing chord-to-rhythm (i.e., Stage 1) with a novel *lyric-to-rhythm module*. As a result, users can input the lyrics and chord progression of a full song in our system (see Fig. 1). Then, the lyric-to-rhythm module generates the MIDI (with empty pitches). Second, CMT processes the MIDI and chord progression to generate the melody. As a result, the rhythm is generated with a global view of the lyrics, while the melody is generated with a causal view of the rhythm and chords.

In the following subsections, we will first review CMT and explain the difficulties of modifying it to handle the lyric-to-melody task in Section 3.2. Then, we will detail our solution in Section 3.3.

3.2 Chord-Conditioned Melody Transformer (CMT)

CMT adopts a pianoroll-like representation [13, 21] that includes chord, rhythm, and pitch (CRP) information. It splits the timeline into semiquaver-length frames (1/4 of a beat), each described by three vectors: a 12-dimensional binary *chord* vector (pitch classes in the chord get a 1); a 3-dimensional one-hot *rhythm* vector (onset, hold state, rest state); and a 22-dimensional one-hot melodic *pitch* vector (for this part we restrict MIDI pitches to between 48 and 67, plus a hold state and a rest state, giving a total dimension of 22). Please refer to [13][Fig. 1] for an illustration.

CMT contains three main modules: *Chord Encoder (CE)*, a bidirectional LSTM [22]; *Rhythm Decoder (RD)*, a stack of self-attention blocks; and *Pitch Decoder (PD)*, another stack of self-attention blocks. In Stage 1, given an input chord progression, the chord embedding encoded

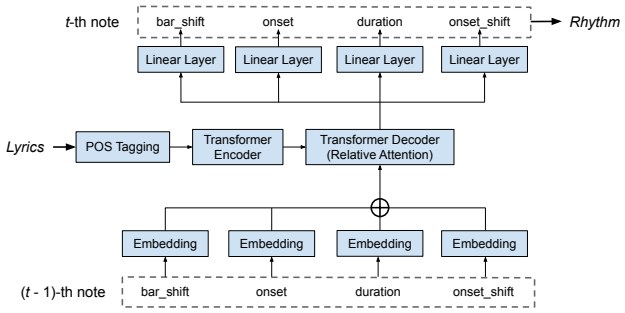

Figure 3: The proposed lyric-to-rhythm framework.

by CE is autoregressively sent into RD to output the rhythm embedding, followed by a fully-connected layer ("FC Layer" in Fig. 2) to predict the sequence of rhythm vectors for the entire song. In Stage 2, the concatenation of the chord and rhythm embeddings is autoregressively fed into PD, followed by a fully-connected layer to predict the sequence of pitch vectors. Finally, rhythm and pitch vectors are combined and converted to the melody.

However, to leverage CMT for the lyric-to-melody task, we face three problems. (1) *Multimodality*: CMT was designed to take the input of a chord progression to generate the melody. However, it is non-trivial to directly add a lyric encoder for lyrics input, as lyrics are more complicated sequential data than chords. (2) *Representation*: CMT uses a pianoroll-like (i.e. CRP) representation to encode melody, where the time axis is evenly scaled (e.g., 1/16 beat), so a note may require multiple tokens to carry the duration. This makes it difficult to create a one-to-one mapping that ties a syllable (or character) to a single note token. (3) *Constraint on length*: in CMT, the CE generates the melody on a segment-to-segment basis (e.g., 8 bars at a time) without exploiting the global context of a full-song chord progression. However, we believe the structural information carried in the input lyrics is crucial to determine the repetitive pattern for the output melody. The next subsection details how we address these problems: (1) is addressed with a POS tagger that compactly encodes useful lyrics information; and (2) and (3) are addressed by adapting a Compound Word representation.

3.3 Lyric-to-Rhythm Framework

Fig. 3 shows our lyric-to-rhythm framework, which is analogous to a language translation task: i.e., an input sequence of lyrics is translated into an output sequence of notes. In this work, we assume that each syllable (or character) is mapped onto one note as a simplification; handling melismas remains a future challenge. To this end, we adapt an encoder-decoder Transformer architecture [12]. To enhance the repetitive coherence modeling in note sequences, we incorporate relative self-attention [23, 24].

To extract the features of lyrics, we employ *part-of-speech (POS) tagging* with a Transformer encoder. Following prior works [25, 26], we characterize the rhythmic features of a note with a tuple of `(bar_shift, position, duration, onset_shift)`, and model the sequence of tuples using the *Compound Word (CP)* Transformer decoder [27]. The lyric-to-rhythm module generates the t-th note based on the full context of lyrics and the previously generated notes (from the first to (t-1)-th) in an auto-regressive manner, with the future notes being masked. We describe the POS tag representation and CP Transformer in the next subsections.

Token Name	Vocab.	Description
`bar_shift`	0, 1, 2	Time shift in bar to current bar
`onset`	0 – 15	Onset in 1/4 beat in current bar
`duration`	0 – 31	Duration in 1/4 beat
`onset_shift`	0 – 15	Time shift in 1/4 beat to previous note's onset

Table 1: Rhythmic features for a note.

3.3.1 Part-of-Speech (POS) Tagging

In natural language processing, POS tagging refers to the process of labeling every word in a text with its part of speech. The taxonomy of POS tags varies by language, but commonly includes 'noun,' 'verb,' 'adjective,' 'adverb,' and others. POS tags can augment the text information by indicating the structure of sentences [28], and thus plays an important role in tokenizing the input words in conventional text-to-speech (TTS) systems [29, 30].

POS are word-level descriptors, but we want syllable-level descriptors in order to align the lyrics with the rhythm. (When dealing with Chinese lyrics, we can also say 'character-level' since each Chinese character is one syllable.) Thus, we combine each POS tag with the syllable index to create a POS 'token': e.g., the input English sentence "Why not tell someone," would result in: ['adverb-0', 'adverb-0', 'verb-0', 'noun-0', 'noun-1'], where the two syllables in "someone" are represented by ['noun-0', 'noun-1'].

3.3.2 Compound Word Transformer

In contrast to the CP proposed in [27], we do not distinguish between *note*- and *metre*-related events. Instead, we include four tokens in every compound word (see Table 1), so that we can have one set of tokens per syllable. From karaoke scrolling lyrics data, we can obtain the onset and duration of each syllable, and by tracking the downbeats, we can obtain the metric position in the bar. Following [27], each of the four tokens is converted into an embedding, and then the embeddings are concatenated before being sent to the Transformer decoder. Each of the four output embeddings is linearly projected to predict the value for the associated token of the t-th note.

Once all the notes are ready, we convert them to MIDI (with unspecified pitch) with the following steps:

1. Place an empty note at bar 0 and position 0.
2. Determine the onset by shifting (`bar_shift`$\times 16+$ `onset_shift`) units from the previous onset.
3. Set the duration by $min($`duration`, next note's `onset_shift`$)$.
4. Repeat 2 and 3 until all the notes are processed.

We note that `onset` is not used for generating MIDIs. Instead, we use the position shifted to determine the onset so that notes are placed in an incremental order. Nevertheless, we suspect that `onset` can help regularization in training. Using the CP representation addresses the "constraint on length" issue mentioned in Section 3.2, as it permits a more compact sequence of tokens that can model a longer duration, such as a full song.

4. SYSTEM CONFIGURATION

This section describes how we trained the lyric-to-rhythm and rhythm-to-melody models. For each model we explain what data were used and how they were collected. We focus on Chinese pop songs to validate our system, but the framework could be adaptable to other languages since parts of speech and syllables are broadly useful concepts.

4.1 Lyric-to-Rhythm Model

We collected data for 45K Chinese pop songs using a similar pipeline as [31] and [7][Appendix A]. That is, we crawled online to obtain paired lyrics and audio, with timestamps indicating the onset of each line of the lyrics. Then, for each song, we performed the following steps: (1) isolate the vocal audio using source separation; (2) convert lyrics to phoneme sequences; (3) estimate the phoneme onset timestamps using forced phoneme alignment; and (4) estimate the time signature and beat and downbeat times. From the phoneme and beat data, we can derive the syllable onsets and thus the bar-shift, onset, duration and onset-shift attributes required by the model. The steps were performed using in-house tools comparable to those used in [7]: Spleeter [32], Phonemizer [33], Montreal Forced Aligner [34], and Madmom [35], respectively.

We kept songs with a detected time signature of 4/4 (around 90%), and quantized the timestamp of each syllable in quarter beats. Errors in automatic lyrics alignment, in beat tracking, and in the detected time signature can all degrade the model quality, so we selected 330 songs to manually adjust the timestamps. This subset was used to fine-tune the model.

For POS tagging, we adopted Jieba [1], an open-source tool that supports 56 tags commonly used in Chinese. Without POS tags, the vocabulary size for our dataset was 5,368 unique characters. Reducing to POS and then adding the syllable index resulted in a vocabulary of 123 unique POS tokens. In Sec. 5.2, we will compare a model using this 123-dimensional POS vector to an ablated version of the system that encodes the raw characters index in a 5368-dimensional vector.

In Chinese pop songs, symmetric expression of text structure is commonly reflected in melody repetition. Fig. 4 shows one example: the chorus melody of "Goodbye Kiss" [2] by Jacky Cheung. The two phrases outlined in solid boxes are identical in melody, and nearly identical in text; but even where the lyrics are different (in the dotted boxes), they have the same POS tags. With the POS tagging representation, we believe the lyric-to-rhythm model can learn to generate similar rhythms for two text phrases if they have a common structure.

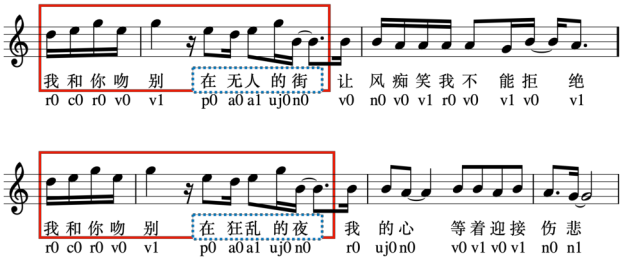

Figure 4: The melody-lyrics-POS example in the chorus section of "Goodbye Kiss". POS abbreviation key: {'r': pronoun, 'c': conjunction, 'v': verb, 'p': preposition, 'a': adjective, 'n': noun, 'uj': auxiliary}.

4.2 Rhythm-to-Melody Model

To train the rhythm-to-melody model, we used POP909 [36] and Lead-Sheet-Dataset [37]. POP909 contains data on 909 Chinese pop songs including chords, melody in MIDI format, and other information not used here. Lead-Sheet-Dataset (LSD), a collection of symbolic content sourced from HookTheory, [3] contains lead-sheets (i.e., melodies and chords) of 16K song segments in MIDI format. We used the songs in 4/4 time (dropping roughly 10% of the data) and transposed all pieces to the key of C major or A minor. This resulted in about 30K bars of music from POP909 and about 40K from LSD.

We followed [13] to train the model, setting the input length to be 8 bars but reducing the pitch range from 48 to 20; any pitches outside the range were octave-shifted to lie within the range. After obtaining the rhythm MIDI of a full song from the lyric-to-rhythm module, pitches were generated for 8 bars autoregressively, with a 4-bar sliding window, i.e., the model composes the next 4 bars given the previous 4 bars already composed.

5. EVALUATION

We would like to answer two questions: first, does our system succeed in emulating basic musical qualities of the training data? And second, does it produce pleasing, viable

[1] `https://github.com/fxsjy/jieba`
[2] `https://www.youtube.com/watch?v=bJRkEmrkIO4`
[3] `https://www.hooktheory.com/`

settings of lyrics? To answer the first, we compare the output melodies of our model (denoted 'pop-melody') to the held-out training data and discuss their similarity. For the second, we conducted a listening test in which participants rated the quality of the lyric settings of our model as well as those of a state-of-the-art alternative, TeleMelody [7].

5.1 Objective Results

We analyze the melodies created by our system in two objective evaluation strands. The first one is to demonstrate how similar the rhythms generated by our model are to the original data (see Fig. 5); the second is to look for and characterize the differences between the melodies produced by the two models (see Fig. 6). We compare statistics over several musical quantities computed on the dataset and compositions generated by both systems. For this comparison, we have generated 400 scores from each system and used the same amount of scores from the dataset.

Most of the musical quantities we compute are adapted from [38] and [39]. These symbolic descriptors have been shown to enhance melodic expectation when embodied in a cognitively plausible system for music prediction. Expectation and memorability have been shown to be important characteristics for identifying a plausible melody, and surprise and repetition are measurable elements that relate to these charactertistics. (For more background on such descriptors and on the concepts of predictability and uncertainty in the pleasure of music, see [40, 41].)

We showcase two sets of descriptors, one for each evaluation strand. The first contains: the *duration* of the melody notes; their *inter-onset intervals* (IOIs; the distance between the start of a note to the start of the preceding one); and their metrical *position in bar*. Fig. 5 shows the distributions of these descriptors for the dataset and for the outputs of our system (tagged as "pop-melody") before and after fine-tuning (see Section 4.1). Note that we exclude TeleMelody from this comparison since it was trained on a different dataset (of around 110K samples), so it is not meaningful to compare it to our training data.

Judging from the distributions, the outputs of both models are broadly similar to the melodies in the dataset. However, there is clearly a surfeit of short notes (0.25 crochets, or sixteenth notes) in the generated melodies, which skews the distribution of IOIs as a result. Also, regarding note position in the bar, there is a subtle variation of the likely onset positions in the dataset that is not reflected in the generated data, which, prior to fine-tuning, has an almost uniform distribution.

The other set of descriptors contains: the *pitch contour*, which gives the likelihood that the next note in the melody will be lower (descending), higher (ascending) or the same; *note sparsity*, which gives the fraction of the timeline which has no note in the melody (a value of 0 indicates no rests in the melody); and the *pitch-in-chord-triads ratio*, a kind of 'consonance' metric, calculated as the fraction of notes in the melody that belong to the accompanying chord triad.

These descriptors are illustrated in Fig. 6, comparing

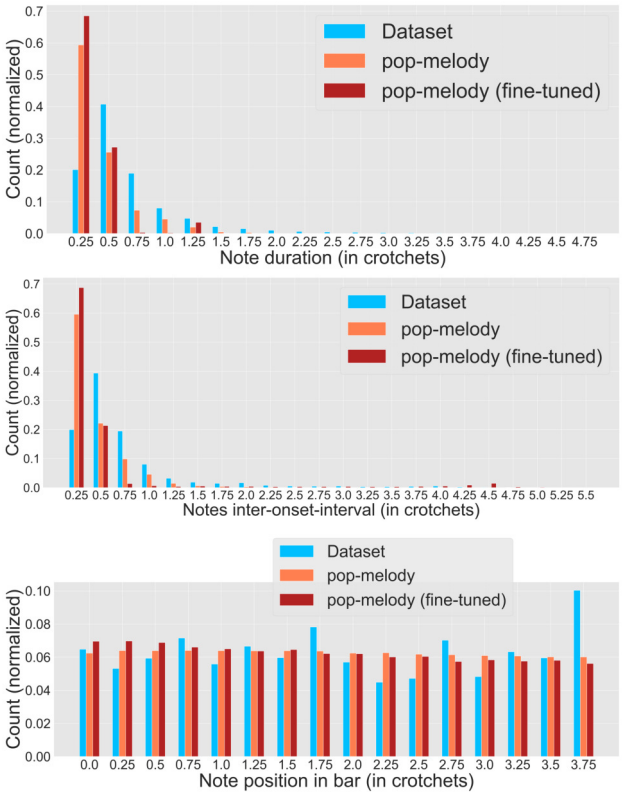

Figure 5: Distributions of descriptors values derived from melodies from the dataset and melodies generated by the proposed pop-melody system.

the melodies from our fine-tuned system ("pop-melody") with TeleMelody. Here, the purpose is not to compare the systems to the data—they were trained on different data, and may each reflect their training set well—but to assess how the melodies of the systems differ. From the contour descriptors, it is clear that TeleMelody is more likely to generate many consecutive notes with the same pitch, whereas melodies from the proposed system have more variation. The melodies from our system also tend to have fewer rests, and tend to include more notes that appear in the underlying chord. The latter can be interpreted as a tendency to stay in consonance and limiting the space of "dissonant" or "unexpected" moments.

5.2 Subjective Results

We conducted a subjective listening test using a similar design as [3, 7, 42]: we selected lyrics from ten random songs from the test portion of the dataset of 45K songs and used these as input to three systems to generate melodies: "TeleMelody"; "Pop-melody", the proposed system; and "Baseline", an ablated version of our system that does not use POS tokens (see Sec 4.1). This resulted in 30 full songs: ten triples with the same lyrics, chords, and tempo. We rendered the lyrics and melodies to audio with an in-house singing voice synthesis comparable to Xiaoice [42] and rendered a simple accompaniment with the chords.

We had 20 participants, all of whom had some musical background and could read musical scores and play an in-

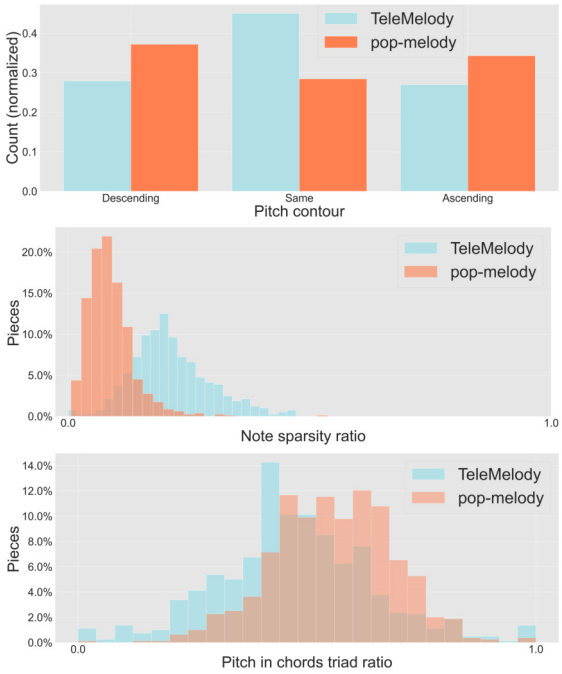

Figure 6: Distributions of descriptor values derived from melodies generated by TeleMelody [7] and by the proposed pop-melody system.

strument. Participants listened to a triple at a time, where the system identities were masked and the order is at random. Then, they rated each song on four criteria on a Likert scale from *Bad* (1) to *Excellent* (5):

1. **Rhythm**: is the timing of notes suitable for the lyrics?
2. **Harmony**: do the pitches fit the chords and key?
3. **Melody**: does the melody line sound natural with the lyrics?
4. **Overall**: what is the overall quality of the melody?

After rating each triple, listeners also rated their familiarity with the original song of the input lyrics on a 5-point Likert scale. The average rating here was 1.5: somewhere between "1. Never heard the title or melody" and "2. Heard the song title, but not the melody".

The results of the study are shown in Table 2. Overall, listeners gave the three systems similar average ratings: all lie within 3.6 ± 0.25. However, Wilcoxon signed-rank tests reveal small but consistent differences between the systems; see Table 3 for the p-values of all comparisons. First, we see that the proposed system is consistently better than Baseline, suggesting that POS-based tokenization is effective. Second, we find that the proposed system also matches or outperforms TeleMelody; the difference is greatest for rhythmic quality. Despite the broadly positive ratings, mostly between *Fair* (3) and *Good* (4), comments from the participants mostly cited shortcomings of the output. TeleMelody and Pop-melody both earned comments that the "melody is a little weird" and sometimes "too repetitive", but only the TeleMelody outputs earned comments that the "rhythm is a little weird" and "fragmented".

System	Rhythm	Harmony	Melody	Overall
Baseline	3.42(.93)	3.67(.86)	3.46(.93)	3.42(.82)
TeleMelody	3.58(.96)	3.69(.90)	3.38(.85)	3.57(.73)
Pop-melody	3.84(.87)	3.87(.81)	3.64(.89)	3.68(.72)

Table 2: Subjective result and comparison.

Comparison	Rhythm	Harmony	Melody	Overall
Pop vs Tele	0.0006	0.007	0.001	0.1
Pop vs Baseline	1.1e-08	0.002	0.006	1.8e-05
Tele vs Baseline	0.01	0.89	0.22	0.02

Table 3: P-values of the subjective result comparison.

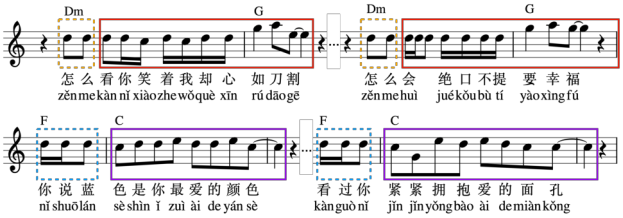

Figure 7: Output examples (a) above and (b) below.

Two output examples from our system are shown in Figs. 7(a) and 7(b). In both cases the melodies follow the input chord progressions and we find parallelism and variation in the melody when the lyric structure recurs. E.g., in Fig. 7(a), the similar lyrics begin with the same two melody notes (dashed boxes), and the remainders have similar rhythm and contour (solid boxes). Similarly, in Fig. 7(b), the similar lyrics are given identical openings (dashed boxes) with rhythmically identical continuations (solid boxes).

6. CONCLUSION AND FUTURE WORK

In this paper we proposed a new approach to generate melody for a given lyric by combining lyric-to-rhythm and rhythm-to-melody modules. We found that listeners rated the long-term text-settings provided by our system as acceptable, and at least as good as a competing system.

In order to achieve a cross-modal mapping from syllables to onsets to melody notes, we made the simplifying assumption that each syllable is sung on one note. There is a clear way to improve this in the lyric-to-rhythm module by adding a syllable-state token to the Compound Word, indicating whether we are at the onset of a syllable, or the continuation of one. However, allowing a one-to-many syllable-to-note mapping would also complicate the automatic syllable alignment step, making the hand-corrected data even more precious.

We also found that POS tags were valuable text tokens; using them led to a boost in text-setting quality. Given this success, we ought to leverage more linguistic information, such as syllable stress and word frequency, as in [15, 16]. Music structure labels (e.g., verse and chorus) could also prove valuable. This is an under-explored area, but may become feasible with the introduction of more datasets, or with automatic labelling systems [43] to further augment existing data. if more datasets become available.

ABSTRACT

We propose a visual approach for interactive, AI-assisted composition that serves as a compromise between fully automatic and fully manual composition. Instead of generating a whole piece, the AI takes on the role of an assistant that generates short melodies for the composer to choose from and adapt. In an iterative process, the composer queries the AI for continuations or alternative fill-ins, chooses a suggestion, and adds it to the piece. As listening to many suggestions would take time, we explore different ways to visualize them, to allow the composer to focus on the most interesting-*looking* melodies. We also present the results of a qualitative evaluation with five composers.

1. INTRODUCTION

Composing music is a challenging task, especially for beginners. Complex music theory, different rules and patterns in a wide range of genres, missing experience, or even stagnating inspiration make it difficult to express intended ideas and emotions. These aspects can result in frustration and leave the composer unsatisfied or even unable to finish a piece. Artificial intelligence (AI) might potentially mitigate such situations by generating music that provides inspiration or even fits the composer's needs directly.

Current AI-driven approaches for music generation allow creating parts or whole pieces in audio [1] or symbolic form [2]. Although automatic composition can be useful, for example as background music in videos or games [3], it often lacks personality and structure [3, 4]. A fine-grained steering of the generation process, beyond parameters such as overall tempo and feel, is often not possible. Therefore, a piece that is fully generated by AI might not satisfy expectations [5]. Although AI-generated music can show potential creativity [6], the current state of AI music will most likely not replace human composers as a whole [5].

To address above problems, we propose a user-centered approach for AI-assisted composing. Here, users have more control, acting as a leading composer who always has the last word, while the AI serves as assistant that supports composers instead of replacing them [4, 5, 7]. When assisted with suggestions for continuations, fill-ins, and replacements, users can iteratively elaborate on these and make progress towards a personal creation. Composing step by step often yields better results than selecting from multiple completely generated ones and gives a greater feeling of satisfaction and authorship [8].

To support the communication between AI and human, we propose using interactive visualization. As it allows to quickly spot and filter the most interesting suggestions, visualization facilitates choice. This means users do not have to spend time sifting through heaps of less interesting suggestions and can spend their time more efficiently, for example by only listening to a few melodies per group of similar ones. Furthermore, visualization can improve understanding of how the underlying AI works [9], and allow for a more effective usage and better steering of the AI.

We make two primary contributions: (1) We designed four interactive visualizations to assist the user in choosing and investigating AI-generated suggestions. The first two represent a graph structure of suggestions [10–12], while the third displays larger numbers of melody samples, by encoding their similarities and characteristics. Our fourth visualization shows the correlation between melody samples. (2) We evaluated our approach through a qualitative study with five composers, who generally liked our approach and were curious in analyzing the AI and using visualizations to find interesting samples. Results show that our representations were unfamiliar to most participants, but made interaction with the AI more accessible.

Our supplemental material [1] contains a live version of our prototype, the full source code, and additional details.

2. RELATED WORK

Briot et al. [13] surveyed deep learning for music generation and compare objectives, data representations, architectures, and the output that consists of audio [1] or symbolic data [14]. They cover recurrent neural networks [2, 15], variational autoencoders [16–18], and generative adversarial networks [19, 20]. Other work [14, 21] shows combinations of above techniques for different tasks. Recently, transformers [22–24] showed promising results and there also exist agent-based or heuristic algorithms [25].

Figure 1. Overview of our design: (A) Piano roll to show/edit the composition. (B) Icicle plot and (C) node-link chart for tree structures. (D) Similarity-based scatterplot as overview of all samples. Color encodes the AI's temperature parameter.

A survey by Huang et al. [7] on usage and requirements of AI for music co-creation found that users desire control, authorship, and creative freedom and often create multiple samples to choose from. Our approach addresses these requirements and supports sample choice through visual overviews of samples and second-level continuations. We allow for fine-grained control and creative freedom by letting the user replace parts with fill-ins and edit individual notes. Suh et al. [26] found users to be more willing to take risks and try different styles when using AI, but also to be pushed to progress faster. Our approach uses AI as an assistant to provide similar benefits with more user control.

Magenta Studio [27] allows generating music with different tools but limited steering options. Our design uses similar options but allows generating many samples at once and gives full control over note selection and adaption. *Bach Doodle* [28] allows users to harmonize an input melody in the style of Bach via *CoCoNet* [29] and was later improved [30] in its usability for novice users. Our approach focuses on creating the melody itself, which could then later be harmonized through similar models. *SketchNet* [31] gives users control in music generation, allowing to roughly sketch melodies. For editing melodies, Tsuchiya et al. [32] proposed a non-notewise method. In contrast, we allow choosing and notewise editing suggestions before combining them into a composition and could integrate above work to make suggestions more relevant.

Steering interfaces (selecting from options part-by-part) are often preferred over radio options (selecting from longer options), as they allow for more control and efficacy, giving a stronger sense of authorship [8]. Following that idea, Huang [2] uses a tree structure of generated continuations for interactive composition. We use a similar idea, but additionally support cognition and control through visualization and more interaction.

There are many interactive tools that use AI to generate music [23, 33–35] or fill-in missing parts [36, 37] that provide various ways of control, but lack exploration of different choices and fine-grained editing. In contrast, we provide visual exploration techniques and options, such as single-note edits or overviews of many options at once.

Our visualizations make use of similarity metrics for melodies. Such metrics have been studied in prior work, for example recursive metrics [38] and edit distances [39] for symbolic melodic similarity. Instead of comparing complete pieces, we use our metrics to produce overviews of a collection of short melodies by visually sorting or positioning them by these metrics. Abstractly, we follow the idea of visual parameter analysis [40] by visualizing AI output for different parameters to get insights about their impact, which has not yet been explored systematically for semi-automatic music composition. For example, we use glyphs [41, 42] to show melody samples in a scatterplot, similar to music collections [43]. We also use tree visualisations such as icicle plots and node-link diagrams, which have been used for event sequences before [12], but have not yet been explored for a combination of music and AI.

3. DESIGN

With our approach, we target two primary user groups, namely amateur composers and developers/analysts of

[2] youtu.be/vnRrGCB04WE?t=1293

composer AI models. We focused on amateurs as a starting point, as we hypothesized that they could benefit most from a continuous interaction with a composing AI. In our approach, users query the AI for suggestions but make all decisions, keeping the composition personalized.

The AI analyst, on the other hand, is interested in investigating a composing AI's behaviour and the influence of different input melodies and parameters on output suggestions. Understanding this behaviour is crucial for the user's trust and leads to more efficient steering.

The main workflow of our approach looks as follows: Users start with recording or generating a seed melody. Based on it, they query the AI for multiple continuation suggestions with chosen parameters. We then visualize these samples to help users filter, listen to, select, and customize the most interesting continuations for a personal composition. Repeating these steps, or even creating multiple levels of continuations, results in a tree of melody samples, where a sample's children are the possible continuations for the remaining composition. Using the same steps to replace an existing part (fill-in) splits the composition node in the graph and adds the fill-in samples as nodes in between, resulting in a directed acyclic graph (Figure 2).

This approach is abstractly inspired by the idea of visual parameter space analysis [40], and also practically by the artist MJx Music. He used an AI to create an album by manually generating hundreds of samples, listening to all, selecting the most interesting, and combining them into songs [3]. In contrast to this brute-force workflow, we add visualization to provide similar flexibility but more usability, by showing overviews from which users then pick the most interesting samples to further investigate.

To make this general idea possible, we needed to investigate metrics and aggregations to be able to relate different samples to each other, as well as visualization designs which allow users to interact with the space of samples.

3.1 Metrics and Aggregations

We designed a range of metrics that help our visualizations arrange or summarize a collection of melody samples. A user might have some idea of prioritization when looking for samples with specific properties. Some of our visualizations therefore allow sorting by different aspects, such as the variance of interval sizes as a statistical metric to detect lively, varied, or monotone melodies. We can also sort by two metrics at once, with a scatterplot that uses each metric as one axis. As a starting point, we chose the following metrics: mean note duration, variance of interval sizes, similarity to composition, distinct pitches, range of pitches, temperature (AI parameter affecting randomness [4]), and number of noteshapes from composition. The latter indicates how often a shape of three consecutive notes (intervals between them) occur in the composition.

The similarity between samples can also be used for sorting, for example to focus on samples that are more similar to parts from the composition. Furthermore, pairwise similarities between all samples can be used to place them on a "map" where similar ones are closer to each other. We designed a rather simple similarity metric that takes both pitch and rhythm into account, and allows the user to choose a weight for controlling the impact of both.

Above metrics can also be used to compactly represent samples, by only visualizing the metrics instead of all notes, as we do in our glyphs and histograms.

Our example metrics are not necessarily complete or optimal, but serve as a starting point for further research. For some tasks, what is optimal can even be hard to define at all or be subjective, such as sorting by "happiness" or determining the degree of "similar feeling", possibly requiring users to fine tune or train metrics by themselves. Our main approach works with any kind of metric and could be easily extended in the future.

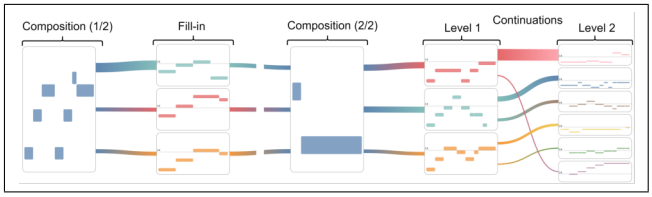

Figure 2. Node-link diagram with one fill-in and two levels of continuations. Colors help differentiate between melody samples. Here, nodes in the same level are sorted by variance of intervals descending, which is also encoded in the link width.

3.2 Visualizations

Piano Rolls as Note Representation: Piano rolls serve both as representation and editor for notes. We chose piano rolls over staff notation for multiple reasons: They are more easy to read for beginners, represent each pitch (MIDI note) in its own row, visually show rhythm and breaks through block size and gaps, and are better readable when small, as there are less fine details. The central view of our tool is a large piano roll at the top that shows all melody samples and the composition at all time (Figure 1A). In this view, we allow adjusting pitch, start, and duration of notes, as well as adding or deleting them.

Sample Relation Graphs: Users can create a tree structure of melody samples to see different continuation paths for a given melody. Listening to all paths takes time, so we want to make selection more efficient by extending and supporting the sequential listening process with a parallel visual approach. To this end, we visualize the tree structure and its melody samples together (Figure 2).

Displaying all samples in a single piano roll at once would lead to overlap and clutter. Therefore, we show the tree structure in an icicle plot, using most space to display piano rolls (Figure 1B). Children (continuations) of a sample are displayed on the right of its node, dividing its height equally. All piano rolls share a common timeline on the X-axis while the Y-axis is different for each. With different color encodings, users can differentiate between melodies or get additional information, for example about

[3] magenta.tensorflow.org/mj-hip-hop-ep
[4] magenta.tensorflow.org/performance-rnn

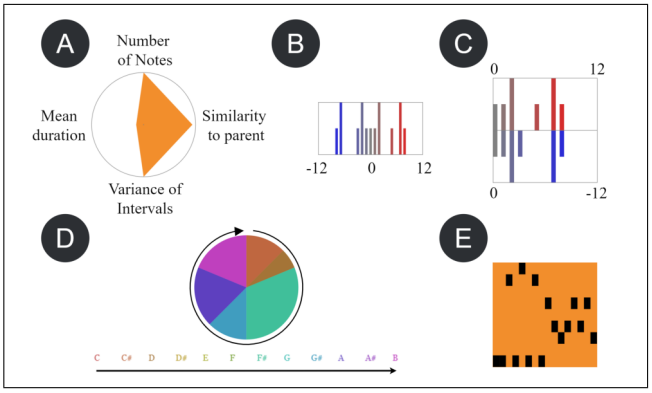

Figure 3. Comparison of our glyphs on the same data. (A) star glyph, (B, C) occurrences of intervals between consecutive notes, (D) chroma distribution, and (E) piano roll.

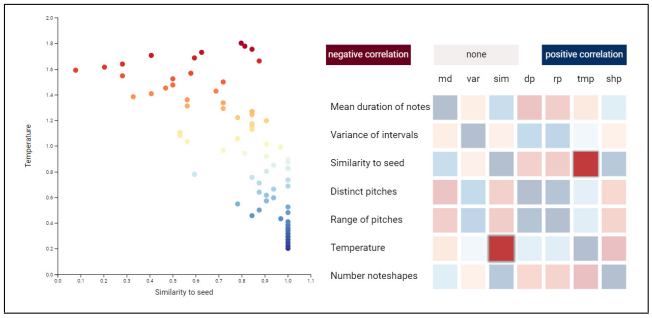

Figure 4. Negative correlation between temperature and similarity. Colors encode temperature (left) and correlation (right).

the parameters used to generate them. We allow listening to single samples or selecting a whole path or parts of it. Users can add a path to the composition and subsequently adjust notes manually or generate new continuations.

Sorting all melodies of the same tree level, which are alternatives for the same time span, could be useful when focusing on some priority. Since an icicle plot already encodes relations through position, sorting would break this encoding. Therefore, we added links between nodes to allow sorting melodies of each level while keeping relations visible, resulting in a node-link graph (Figure 2). Besides showing relationships, these links also encode the value of the selected sorting metric in their width.

Similarity-Based Layout and Glyphs: A composer can only use an AI efficiently if they roughly understand how it behaves. In our case, this means knowing which parameter values (e.g., temperature) to choose for an intended output. Since there is usually some uncertainty in the results, more than just a few samples are needed to draw conclusions.

Above visualizations do not scale to large numbers of samples, as small piano rolls are hard to read. While sorting and scrolling help, the overview gets lost. To provide an overview for hundreds of samples at once, we visualize them as dots in a scatterplot, placing similar once closer together via dimensionality reduction (Figure 1D).

Using a circular brush, users can select a neighborhood and take a look at its melodies, represented as piano rolls and statistical aggregations of all selected samples. To indicate the overall variety of the selection, we show two histograms for the occurrences of pitches and note durations.

Because selecting neighborhoods at random is inefficient, the user needs an impression of melodies directly inside the scatterplot. We therefore replaced the dots by glyphs, small symbols showing some kind of data, such as statistics or the melodic structure itself. Users can switch between these glyphs at any time to visually filter interesting melodies before looking at their neighbourhood in detail. As overlapping glyphs are unreadable, we apply gridification to produce a regular, occlusion-free layout.

We designed four types of glyphs to show different aspects of a melody (Figure 3): The first type shows multiple metrics in a *starglyph*. As default, four metrics are shown that convey both rhythm and melody: note count, mean note duration, variance of intervals between two notes, and similarity to notes in the current composition. Jumps between notes are often interesting for composers, for example when looking for a climax or a calm section after it, inspiring us to show the occurrences of intervals between two notes in a *histogram glyph*. Users can directly see when a melody mostly uses repeating notes and small changes or has larger jumps in it. The third type of glyph represents the tonality of melodies by a *pie chart of chroma occurrences*, i.e., one slice for each of the twelve notes. It helps selecting or investigating melodies based on contained notes and therefore tonality, as well as looking for outliers with unusual pitches. For example, a pie chart showing mostly C, E, and G likely fits into a C major composition. Because above glyphs represent metrics that can be hard to grasp for unfamiliar users, we added a fourth type that shows melodies as *small piano rolls*. With these glyphs, the rough contour of the melody is directly visible, so users can look for those matching their intention.

Correlation Analysis: An analyst can use the above scatterplot and glyphs to investigate sample metrics, but could also be interested in investigating correlation between metrics. We therefore provide a correlation matrix as overview of pairwise correlations between all metrics, which encodes Pearson correlation as color (Figure 4). We show negative, positive, and no correlation in red, blue, and white, so users can quickly filter interesting pairs. After choosing a pair of metrics by clicking, a 2D scatterplot shows all samples as points, positioned based on their metric values. One insight we made was a positive correlation between temperature and pitch range, so higher temperature values often lead the AI to generate more outlier notes.

Attribution: A common problem when co-creating with AI is authorship, as users are often hesitant to claim generated melodies as their own. To analyze this problem and provide a feeling for how much authorship a composer has, we added a coloring for the notes' attribution (Figure 5). We assign each note one of five attribution classes, covering the range between human- and AI-generated, and display the percentage of each class, to show composers how much and what they contributed to the composition.

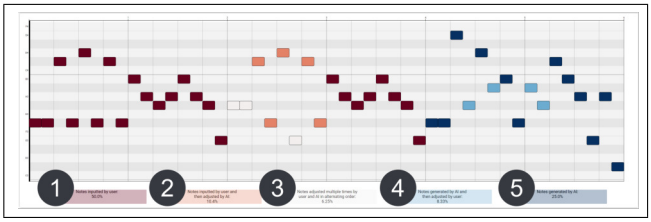

Figure 5. Color indicates the attribution of notes, from red (by user) to blue (by AI) along five steps: (1) completely human-created notes, (2) human-created but AI-adapted notes (fill-in), (3) notes changed by both parties multiple times, (4) AI-generated but user-updated notes, and (5) AI-generated, unedited notes.

3.3 Implementation

We implemented our prototype as a web app build with React, which allows publishing it as a website [1] . It works completely inside the browser with an AI model [5] made by Magenta [6] , which we chose due to easy access and usage, but other models from any framework or language can be hosted by others and integrated through plugins.

For our visualizations, we use D3 [44] for colormaps and scales, DruidJS [45] and MDS [46, 47] for computing dimensionality reduction layouts, and Hagrid [48] to avoid overlapping glyphs. Users can record melodies using MIDI [49] devices and export finished compositions as MIDI files for further processing with other tools.

4. EVALUATION

As music composition is a complex and time-consuming task without clear measures for efficiency and success, we chose a qualitative study design with five domain experts (P1 to P5). P1, P3, and P4 were pursuing a degree in composition for experimental music, P2 holds a degree in composition and studies performance, and P5 studied a music instrument major and composes occasionally. Although our approach primarily targets beginners, we chose experts, as they are more familiar with composition workflows. We therefore expected more detailed, thorough, and critical feedback from this group.

Our design brings potentially unfamiliar technology to participants, such as machine learning, visualization, and dimensionality reduction. To avoid them having to learn using our design, we conducted pair analytics [50], where domain experts and visualization designers jointly analyze data, while the designers serve as technical assistants.

We recorded screen and voice throughout the study with consent. The study concluded with a semi-structured interview to further inquire about general thoughts. On average, participants took 2.2 hours for the study. Due to space limits, we only discuss the main findings here, full details can be found in the supplemental material.

[5] MusicRNN, magenta.github.io/magenta-js/music/classes/
[6] github.com/magenta/magenta-js

Results: All participants started with recording and editing a short melody. They were interested in how the AI would react to their melodies, especially P3: *"I was curious, so I put in some short and some long notes"*. Next, they generated some continuations for their melody.

Participants found our icicle plot helpful *"when generating many samples, [this] can help [to] see more quickly which samples are interesting and which are not"* (P4). We found that the icicle plot led to a faster selection of samples by just looking at them: *"I can see that these [points to two samples] are very interesting"* (P5). Especially P4 and P5 liked this representation due to the miniature piano rolls that helped P5 find certain intervals in melodies.

Participants used the node-link diagram to sort samples, inspect them, and select continuations. They liked sorting by metrics: *"I think it's good to sort by intervals [... it is] essential when selecting a melody with specific characteristics"* (P1), and found it helpful to use different metrics: *"I can imagine for complex music and many samples [...] and having an rough idea, [sorting] can help using parameters"* (P4), *"[When] composing with dissonance [...] sorting by dissonance would help"* (P3).

While composing, P3 repeatedly asked where recently added samples began within the composition. Our attribution visualization showed the difference between notes added by the AI and edited notes, which helped P3: *"where was the last note? [switching to attribution] This visual is very comfortable"* (P3).

We were specifically interested in how participants would select samples to interact with them. They often had some idea for what they were looking for, such as setting a contrast (P1), wanting *"to hear the most randomness"* (P2), or variations and less randomness (P4), where our visualization helped: *"[This] is the only one that goes down"* (P5). Participants sometimes did not like samples (*"I liked the first part, but the second was not good"* (P2)) and edited them after adding to the composition (P5) or even discarded all to *"change something on my own"* (P3).

As we also wanted to evaluate AI analysis, participants then generated 50 to 80 continuations to analyze with our visualizations. P1 found all glyphs helpful and told us these could *"extend the intuitive analysis of composers [... and] lead to a different style"* in composing. The participants were *"not used to look at the data"* (P2, P3) and these kinds of visualizations, but most learned quickly and found the scatterplot *"very interesting as an analysis tool, even independent of the AI"* (P1). Especially P1 was very interested in all the analysis possibilities and mentioned that to their knowledge, the lack of analysis is a drawback to algorithmic composition that works with randomness: *"I did see that really rarely and this is a huge shortcoming [...] when composing with the computer"* (P1).

Surprisingly, P1 told us how their professor answered the question of *"how to select the best samples?"*: *"You could generate as often as you like and listen to all and decide while listening intuitively"*. P1 complained about this strategy: *"You would listen to all and have no overview"*. Our scatterplot provides such an overview (P1).

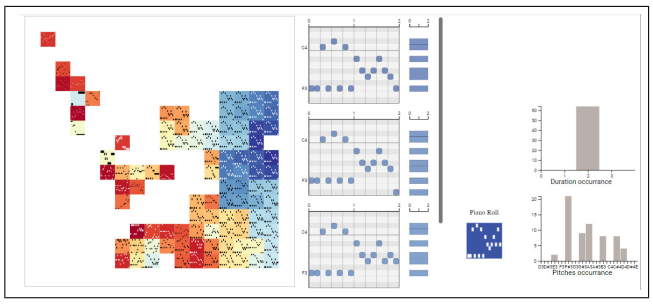

Figure 6. Similarity based scatterplot with piano roll glyphs colored by temperature (left). Selected samples are shown as piano rolls (center) and summarized as histograms (right).

We evaluated how users select neighborhoods in the scatterplot and found that the color (encoding temperature) impacted their decision. For example, P2 *"clicked there because of the color [...] ones with higher and lower temperature"* and P3 investigated *"how melodies vary"* based on temperature. Especially interesting to us was that P5 changed the similarity metric to rhythm only, to look for samples in a cluster with the original rhythm. P5 then clicked on an outlier sample: *"Why is this separate?"*.

The glyph representations were used by all participants. Piechart glyphs helped P3 select a melody sample, when they were looking for something calm that contrasts the composition. While analyzing, P5 searched for perfect fourths with the interval histogram glyphs, as their melody contained a lot of these. *"I am interested in finding melodies with perfect fourths [showing occurrences of interval glyph]. We can directly see [...] there is almost nothing"* (P5). Other participants used this glyph to select samples *"when I have a structure in mind [such as a rising line]"* (P1), which showed more positive intervals than negative, or to investigate the extreme melodies with many larger intervals. All participants used piano roll glyphs to compare melodic structures and find common pattern in clusters: *"I can see the same musical structure (melodic bows) [...] and further away it turns different"* (P1).

All participants found a relationship between temperature, shown through the color of piano rolls, and the structure (Figure 6): *"The blue ones have clearer structure while red ones are jumpier without that much connection"* (P1), *"I can see the randomness"* (P2). We found the piano roll to be more intuitive than other glyph types and therefore a good default, as it shows melodies directly: *"For me [the piano roll glyph] is very intuitive, I can directly imagine how they approximately could sound like"* (P4).

Especially P5 found that *"[correlation visualization] is fantastic [...]. This would make analysis much easier even without using the AI"*. After investigating some metric combinations, P5 surprised us by finding a pattern regarding similarity and temperature, where the correlation between an arbitrary metric and the similarity would always be the opposite to when combining the metric with temperature (Figure 4).

Our study concluded with short semi-structured interviews, summarized below. None of the participants preferred our approach over their current workflow – which we expected, as experts learned their workflow over years – but many could image using it for inspiration or certain tasks. All participants found the visualizations helpful for comparing, filtering, and selecting melody samples, especially for beginners, even when P2 had problems imaging the sound of a melody by its visuals. Most mentioned that it takes time to get used to the unfamiliar visualizations and metrics. Despite general scepticism against AI, all participants saw potential value in an AI-assisted approach.

5. LIMITATIONS

The sample relation visualizations do not scale for larger numbers of samples or levels, which could be addressed by not showing all samples at once but using scrolling or filtering. As alternative, the scatterplot can show many samples, but struggles with displaying similarities and complete glyphs. Using a gridified layout poses a trade-off between overlap and inexact positions.

Our example metrics and glyphs might not be optimal and miss some key characteristics. The current implementation is limited to monophonic melodies, but can be extended to polyphony through other AIs and metrics. Some glyphs only represent one aspect of music, but composers often need to consider multiple at once, such as pitch *and* time. For sorting, we only used statistical metrics of melodies, which are interesting for some experimental composers, but could be hard to interpret for beginners or other composers. These users would need more musical characteristics like mood, which is harder to calculate.

Another limitation of our approach is learnability, as users have to learn reading and interpreting a set of visual encodings. Based on our evaluation, we believe that regular users of our design can quickly get an intuition by looking at and listening to a range of samples.

6. CONCLUSION

As AI will likely not fully replace human composers in the foreseeable future [5], we advocate for an approach in which both, human and AI, cooperate. To this end, we propose a user-centered, interactive, and visual approach for iterative, AI-assisted music composition aimed at hobby musicians and experimental composers. We designed different visualizations as interface for interaction with generative models. Since these visualizations are AI-agnostic, a composer could use any kind of AI or general algorithm in combination with our approach.

In the future, we want to test different models [16, 22] to generate polyphonic music, harmonize melodies, extend metrics, and allow better steering. Analyzing the composition process could benefit from a history visualization that shows which notes were added or changed when and by whom. We further plan to explore aggregations and glyphs for more compact representations and extend our evaluation to more diverse composers, including beginners.

ABSTRACT

Various features – from low-level acoustics, to higher-level statistical regularities, to memory associations – contribute to the experience of musical enjoyment and pleasure. Recent work suggests that *musical surprisal*, that is, the unexpectedness of a musical event given its context, may directly predict listeners' experiences of pleasure and enjoyment during music listening. Understanding how surprisal shapes listeners' preferences for certain musical pieces has implications for music recommender systems, which are typically content- (both acoustic or semantic) or metadata-based. Here we test a recently developed computational algorithm, called the Dynamic-Regularity Extraction (D-REX) model, that uses Bayesian inference to predict the surprisal that humans experience while listening to music. We demonstrate that the brain tracks musical surprisal as modeled by D-REX by conducting a decoding analysis on the neural signal (collected through magnetoencephalography) of participants listening to music. Thus, we demonstrate the validity of a computational model of musical surprisal, which may remarkably inform the next generation of recommender systems. In addition, we present an open-source neural dataset which will be available for future research to foster approaches combining MIR with cognitive neuroscience, an approach we believe will be a key strategy in characterizing people's reactions to music.

1. INTRODUCTION

Musical surprisal, or, the relative expectations listeners have of ongoing musical events, is essential in understanding humans' engagement and experience with music [1]. Decades of theoretical and experimental work have defined the study of expectation and surprisal as cognitive processes, often in the context of language processing [2, 3]. Importantly, this line of inquiry has crucial implications for the study of music preference and pleasure [4, 5]. Recent studies have shown that the relationship between information-theoretic measures such as surprisal, entropy, or complexity, and enjoyment and pleasure may be described by an inverted U-shape curve (also referred to as the Wundt effect) where stimulus enjoyment is enhanced with an increase in complexity of the song. But as surprisal increases to higher levels, its effect becomes unpleasant [4, 6]. The perceptual measures (e.g. complexity, familiarity/novelty, surprisal) that have been shown to modulate musical preferences are referred to as *collative* variables [7–9]. Supposedly, when other high-level variables are controlled, collative variables explain a large portion of variance in listeners' musical preference [8, 10] following the aforementioned parabolic function. The "sweet spot" of this inverse U-shaped curve may shift left or right, with respect to surprisal measures, depending on factors such as personality, openness-to-experience, or genre preferences [9, 11]. While most music recommender systems rely on acoustic (extracted from a user's music library) and semantic features (derived from subjective behavioral ratings) to predict listeners' preferences, the use of cognitive measures such as music surprisal can remarkably improve their performance, especially because these are known to accurately predict musical pleasure. The results presented here suggest that cognitive neuroscience methods can be leveraged to elucidate new ways of extracting information from music and better predict user preferences.

Early theoretical work on bottom-up and top-down processes modulating expectations by Leonard Meyer and Eugene Narmour [12–14] brought about efforts to model musical prediction, evolving more concretely into explorations of musical tension [15, 16], entropy [17], and the neural bases of surprisal [18, 19]. Crucially, computational models may be tested against both subjective behavioral and objective neurophysiological measures in order to provide a deeper understanding of whether – and how precisely – information-theoretic measures of music inform the cognitive processes underlying music perception and enjoyment. The Information Dynamics of Music (IDyOM) model [20] generates variable-order Markov

Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

probability distributions for each note in a melodic sequence by extracting statistics from both a music corpora and a short-term musical context, thereby incorporating long-term (top-down) and short-term (bottom-up) musical regularities. The IDyOM model has been shown to predict behavioral and physiological markers of listeners' expectations [21–25] and has recently been related to brain activity, showing that melodic expectation is also directly encoded in the neural signal [26–31]. While IDyOM is a well-validated, efficient, and widely used computational model of musical surprisal, it operates only on symbolic (MIDI) data and requires a training set of stimuli (the long-term component of the model) to generate predictions.

To circumvent these shortcomings and explore the behavioral and neural response to continuous audio signals, we turn to a computational model of surprisal recently developed by Skerritt-Davis and Elhilali at Johns Hopkins, the Dynamic Regularity Extraction (D-REX) model [32, 33]. D-REX uses a Bayesian framework to generate predictions and was originally designed to evaluate prediction errors over time for stochastic sound sequences. This model is relevant to the MIR community, as it can be run on any continuous audio input, which broadens its usability for the analysis of large, diverse collections of music. Our previous behavioral results have validated D-REX as predictive of subjective ratings of surprisal, showing that surprisal as calculated by D-REX predicted subjective behavioral surprisal ratings for 80 music excerpts [34]. Given the important role that prediction plays in musical pleasure, enjoyment, and engagement [4, 6, 35], D-REX is used here to explore whether *the brain* tracks musical surprisal. Concretely, we go beyond subjective behavioral responses and test whether musical surprisal as calculated by D-REX is directly represented in an objective neurophysiological signal. Specifically, we present an experimental work in which we recorded brain activity using magnetoencephalography (MEG) while twenty participants listened to musical excerpts. We then relate the neural signal to the D-REX model output using a decoding algorithm to determine whether surprisal is represented at the brain level.

2. DATA COLLECTION AND PROCEDURE

Twenty participants with self-reported normal hearing completed the experiment (11 female, 24.8 $\pm$ 2.9 years of age). Participants were presented with 30 one-minute-long musical excerpts (described in Section 3.1) while their brain activity was recorded using MEG. Participants began each trial by clicking a button to start playing each musical excerpt. At the end of each excerpt, participants moved to the next stage where they provided ratings across five measures using a 4-point scale (1 lowest to 4 highest): pleasure, valence, recognition, familiarity, and surprisal.

MEG measures the magnetic fields generated by the electrical activity of neurons in the brain. Unlike electrical currents captured by EEG devices, magnetic activity can pass through the cortex and skull without distortion, resulting in higher spatial resolution [36]. Continuous MEG data was collected using a 157-channel axial gradiometer system at NYU, at a sampling rate of 1000Hz with an online low-pass filter of 200Hz. Prior to conducting the main analysis, MEG data underwent preprocessing, starting with the noise-reduction of the signal using the continuously adjusted least squares method (CALM) with the MEG160 software [37]. The data was then exported into MNE-Python [38] and bad channels (e.g., channels which saturated during the recording) were removed through visual inspection and interpolated using a weighted sum of signals from neighboring channels. An independent component analysis (ICA) was fitted on the data using FastICA in MNE-Python to isolate independent sources of noise contaminating the channels. Components corresponding to system noise, heartbeat, and eye-blinks were removed from the raw recording after inspection of the topography and time-course of magnetic activity for each component. Finally, epochs were extracted from one second before stimulus onset to stimulus offset, resulting in 61-second-long epochs. For an additional data quality check, we inspected each participant's auditory response to a set of randomized 1000Hz tones and 250Hz tones and observed a higher amplitude response to the higher tone, thus confirming satisfactory data quality.

3. STIMULI

The musical stimuli used here have been previously used to validate D-REX as a predictor of behavioral subjective ratings of surprisal using different genres of music (classical and elevator music) [34]. Classical stimuli were taken from a list of musical excerpts rated by 65 participants for pleasantness in a previous study [39]. The other music stimuli were selected from a range of sources, including songs from Muzak Orchestra's Stimulus Progression albums, as well as more contemporary elevator music compositions (see Supplementary Table S1 [1] for a list of stimuli). The most interesting minute (highest accumulated surprisal) of each piece was selected using a shifting window of 60s across D-REX's surprisal output, so that any results showing lower correlations with brain activity would not simply be due to choosing a particularly unsurprising minute of the piece (see [34]). All excerpts were normalized to 70dB using Praat and python's AudioSegment package, and the sound faded 3s in 3s out.

4. MODELING MUSICAL SURPRISE

4.1 Acoustic Features

D-REX takes as input a set of acoustic features, which can be extracted using any existing MIR techniques. In our case, we extracted features using the NSL Auditory-Cortical Matlab Toolbox developed by the Neural Systems Laboratory at the University of Maryland. The toolbox is an implementation of a cortical model of sound processing, and outputs an estimate of sound as it is represented

[1] Supplementary materials may be downloaded at `https://osf.io/dbm49/`.

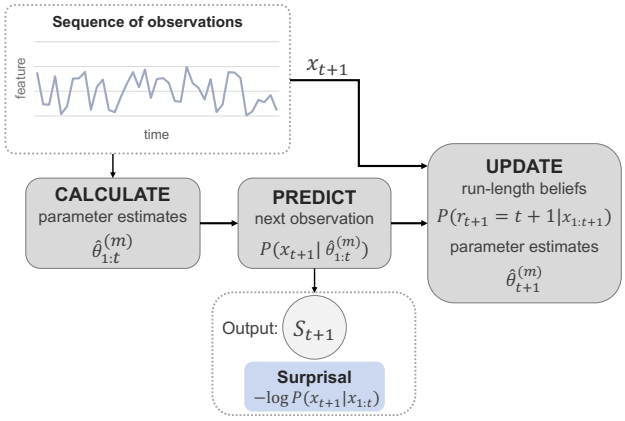

Figure 1. Simplified schematic of D-REX model. The model collects parameter estimates from run-lengths 0 until memory constraint m and generates a prediction for the next observation. At x_{t+1}, the model updates its run-length beliefs and parameter estimates. The output of the model used in the current project is surprisal S_{t+1}.

at various stages of the auditory pathway. We followed the same procedure as detailed in Huang and Elhilali [40], where each acoustic waveform was processed through log-spaced asymmetrical cochlear filters (from 255 Hz to 10.3 KHz). A cortical, or multi-resolution spectrotemporal representation was then generated for a 4-D output (scale-rate-time-frequency). *Rate* and *scale* refer to the two bandwidths (temporal and spectral, respectively) which characterize the filter making up the typical spectrotemporal receptive field of an auditory neuron [41]. *Time* and *frequency* refer to the dimensions of a sound's spectrogram. Fifteen features were extracted from the resulting auditory cortical representation, including average spectral energy, average rate energy, average scale energy, bandwidth, average bark loudness, pitch value, pitch salience (harmonicity), spectral brightness, spectral flatness, spectral irregularity, maximum rate (maximum of temporal variations along each frequency channel), maximum scale (maximum of the spread of spectral energy along the logarithmic frequency axis), centroid rate (centroid of temporal variations along each frequency channel), centroid scale (centroid of the spread of spectral energy along the logarithmic frequency axis), and centroid rate using absolute value of rate (see Supplementary Table S2 and [40] for a complete list of how features were extracted) [34, 40].

4.2 Surprisal Output: Dynamic Regularity Extraction (D-REX) Model

D-REX uses Bayesian sequential prediction with perceptual constraints, such as memory (m) and observation noise (n) to model the brain processes which govern expectation-realization over time in response to sound sequences (as depicted in Figure 1) [32, 33]. Memory m represents the working memory constraints of the listener, determining the maximum previous time points included in context hypotheses for the next time point. Observation noise n consists of adding independent Gaussian noise with zero-mean and a constant variance n^2 to the input. The model takes as input a continuous feature over time x_t extracted directly from the waveform as described in Section 4.1. From each feature, the model predicts the distribution for the next time point x_{t+1} given previous ones $x_{1:t}$. Concretely, previous context is estimated after collecting local statistics $\hat{\theta}$, which correspond to the sample mean and sample variance of the input. Predictions for future time-points are based on these statistical representations of previous events:

$$P(x_{t+1}, |x_{1:t}) = P(x_{t+1}|\hat{\theta}_t) \tag{1}$$

The model assumes the parameters θ can change at any time. A run represents the number of time points between change points of θ. Thus, the model generates multiple hypotheses by gathering statistics across runs and integrates over all possible run lengths (r_t) to predict the observation at the next time point:

$$P(x_{t+1}, |x_{1:t}) = \sum_{r_t} P(x_{t+1}|r_t, x_{t-r_t+1:t}) P(r_t|x_{1:t}) \tag{2}$$

The output of interest is surprisal, S_{t+1}, which refers to how well the new observation was predicted by the model. Specifically, it is the mismatch between the observation x_{t+1} and its predictive probability in bits:

$$S_{t+1} = -\log P(x_{t+1}|x_{1:t}) \tag{3}$$

As conveyed in Eqn (3), surprisal is inversely related to the event's probability: an event with low probability has high surprisal, an event with high probability has low surprisal, and an event with a probability of 1 has zero surprisal.

The D-REX model in this case takes a matrix of features (the 15 extracted features described in Section 4.1) and calculates surprisal as above *separately* across each feature vector. Then, D-REX combines all the outputs by getting the product of predictive probability (described in Eqn (3)) *across* features for a *summary measure* of joint surprisal. In our analysis, we use Surprisal to refer to *joint* surprisal, that is, the summary measure of surprisal across all 15 feature inputs (as in [34, 40]).

5. ANALYSIS

5.1 Decoding Method: Temporal Response Function

To decode acoustic (e.g., envelope) and cognitive (e.g., surprisal) features from the neural data, we used a Temporal Response Function (TRF) approach [42]. This decoding algorithm (`https://github.com/mickcrosse/mTRF-Toolbox`) describes the linear mapping of stimuli features onto a set of channels of neural activity. In this context, the input consists of the time-series collected at each MEG electrode n sampled at times $t = 1, ...T$. The assumption is made that the neural response at some time-point $r(t, n)$ can be described as the convolution of a specific stimulus feature $s(t)$ with a channel-specific kernel w_n, as described in Eqn (4):

$$r(t,n) = (s * w_n)(t) + \varepsilon(t,n) \quad (4)$$

where $\epsilon(t,n)$ is the residual noise at each channel that is not explained by the model. The kernel w_n, thus, is essentially a filter that describes the linear transformation of the stimulus feature into the neural response. Its weights are estimated for a specified range of time lags, τ, relative to the instantaneous occurrence of the stimulus feature $s(t)$, in order to capture the typical input-output activity of interest. In the context of auditory processing, the range of time lags over which to estimate $w(\tau,n)$ should be those used to capture the neural components of an auditory Event-Related Potential (ERP; e.g. -100-600 ms). Therefore, the weight at τ 100, for instance, describes how one unit of change in amplitude of a given input feature affects the neural response 100 ms later [43].

The weights $w(\tau,n)$ are estimated by minimizing the unexplained residual response $\epsilon(t,n)$, in this case by minimizing the difference (in terms of mean-squared error) between the actual neural response, $r(t,n)$, and the predicted $\hat{r}(t,n)$ response:

$$min\ \varepsilon(t,n) = \sum_t [r(t,n) - \hat{r}(t,n)]^2 \quad (5)$$

Concretely, this is achieved using ridge regression. This decoding method takes into account the high autocorrelation property of continuous stimuli such as music, thus avoiding the temporal smearing that would result from less sophisticated decoding approach, such as cross-correlation. We can interpret the continuous weights $w(n)$ for each τ as a *modeled-ERP*: a marker of the feature encoding into the neural data.

To summarize, the modeled-ERPs we will discuss describe the linear transformation of the stimulus feature into the neural response, and it can provide insights into the *dynamics* of the neural response to this specific feature [42]. As such, a modeled-ERP's shape may reveal cognitive processes usually observed through ERP analyses, such as the P1 and P2 components [43]. This method presents a useful alternative to averaging across segments of the neural response to derive ERP profiles from continuous signals, which is not precise nor informative enough. Speech envelope [44–46], phonemes [47, 48], semantics [49], and more recently, musical syntax [46] have been successfully decoded from brain data using TRF modeling [46–51].

5.2 Decoding Model Input

The decoding analysis was conducted twice using two different inputs: a purely acoustic signal (the first derivative of the amplitude envelope of the audio) and a cognitive signal (the surprisal D-REX output). The amplitude envelope of music carries modulations occurring in the 2-10 Hz range that capture the temporal patterns of critical rhythmic information [52]. Consistent results demonstrate a reliable cortical tracking of the music envelope [46, 53]. Therefore, we first conducted the decoding analysis using the envelope information, as a baseline for cortical tracking of low-level acoustical features [51, 53]. The broadband amplitude envelope was extracted using the Hilbert transform for each individual excerpt. The obtained signal was low-pass filtered at 30 Hz and down-sampled at 100 Hz. Then, the first derivative Envelope' was extracted (see Figure 2A), as it is well-known to enhance stimulus-neural response mapping when using linear system identification methods [54].

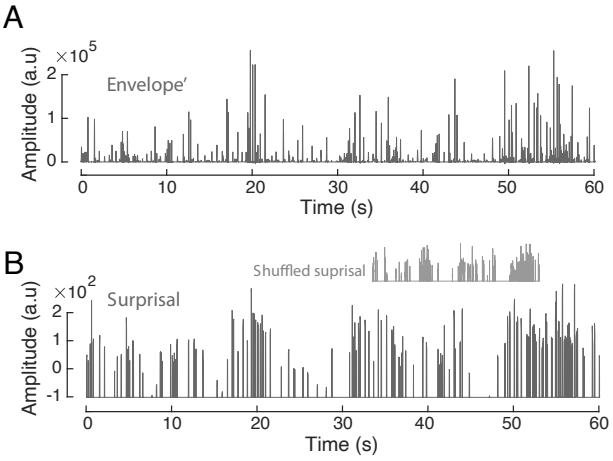

Figure 2. Example of decoding model input. **(A)** The first derivative of the envelope for one excerpt. **(B)** Surprisal as calculated using D-REX and indexed at each onset. Shuffled surprisal, shown in grey, is used for the null model.

The decoding analysis was then conducted using the Surprisal signal as input. Because the D-REX output is a smooth, continuous signal that does not constitute a good input for a TRF-based decoding method [42, 54], we used onset information to extract surprisal values associated with note onsets. From the Envelope', we extracted onset indexes by selecting indexes of amplitudes above a threshold determined individually for each excerpt. We then used the resulting onset vector to index Surprisal values (see Figure 2B), which resulted in a discrete, onset-based Surprisal signal.

5.3 Decoding Model Output

The modeled-ERP is estimated on a portion of the stimulus and neural data, and tested on an unseen part of the data through a leave-one-out cross-validation method. To evaluate the performance of the model in predicting neural data from stimulus features, a Pearson's correlation is then computed between the actual neural data (averaged across participants, which is typical for this type of experiment [51, 55]) and the data predicted by the convolution $s * w_n$. Thus, r-values are obtained for each channel and each musical piece and are then averaged across pieces to obtain one average r-value per channel. The distribution of these r-values is indicative of how well the particular feature used to obtain the modeled-ERP is encoded in the brain. For a visual representation of the flow of data processing, refer to Figure 3.

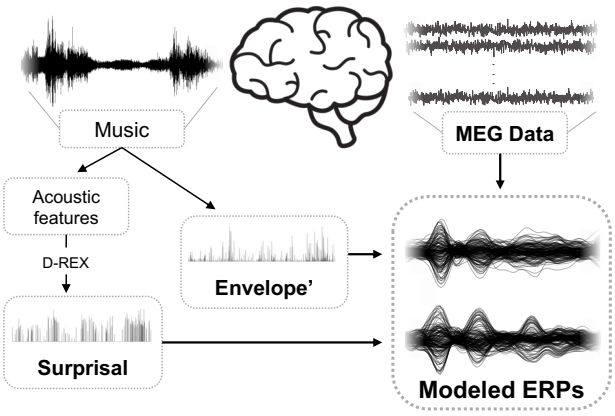

Figure 3. Diagram depicting the flow of the music to neural mapping described above.

6. RESULTS

The TRF decoding method capture the neural response to a feature (e.g. Envelope' or Surprisal) and informs us as to how well it is represented in the neural data. Here, this is evaluated by estimating a modeled-ERP that describes the mapping, at each channel, between a set of input features and the neural data. A correlation between predicted data obtained from the modeled-ERP and actual data is then computed as a marker of how well a feature is represented in the brain activity. Here we conducted two analyses to characterize the encoding of surprisal as modeled by D-REX in the neural data: we first tested the hypothesis that the encoding of surprisal was significantly different from its baseline, by computing a null model of Surprisal encoding and comparing the obtained r-value distribution between the null and the real model. Second, we sought to gain insight from the specific shape of the modeled-ERP by comparing it to the one obtained using the Envelope'.

6.1 Cortical Encoding of Surprisal

To properly baseline the encoding of features, the distribution of Pearson's correlation *r*-values obtained by decoding surprisal was tested against a distribution of r-values obtained by shuffling each song's surprisal and conducting the same decoding analysis on this shuffled surprisal. A significant enhancement of r-values obtained from the real model, as compared to the null one, would confirm that surprisal as predicted by D-REX is significantly encoded in the neural data. In practice, we examined the statistical difference between the Pearson's *r*-values for each MEG channel resulting from a real Surprisal model and its baseline. The real model was constructed using the Surprisal signal (plotted for one song in Figure 2B) as input to the TRF. The baseline model was obtained by shuffling the Surprisal values attributed to each onset over 100 permutations (one permutation is illustrated in Figure 2B).

For each electrode, we obtained an r-value by conducting a TRF analysis on the neural data averaged across participants, using either the real Suprisal input or a shuffled version of it (averaged over 100 permutations). We thus obtained one r-value for each channel and each musical piece, and the values obtained were consistent with previous reported musical stimuli encoding [46, 51]. We averaged these values across musical pieces and obtained two distributions of r-values (e.g. real and null model) for each channel, plotted in Figure 4D. They reveal that r-values obtained from the real model were higher, which was confirmed by a paired t-test where r-values for each MEG channel ($t(156) = 16.25; p < .001, d_s = 1.29$).

6.2 Higher-Level Processing

The second analysis consisted of examining the particular shape of modeled-ERPs obtained from the Envelope' and the Surprisal model, to gain insight into the differences in neural responses elicited by the two features. After averaging participants' neural data, the Envelope' and Surprisal modeled-ERPs were estimated for each individual MEG channel and each musical excerpt, and then averaged across musical excerpts. One modeled-ERP per MEG channel was thus obtained (see Figure 4A and 4B). As expected, both modeled-ERPs exhibit typical auditory responses at [50-100] ms and [150-200] ms [43]. However, the modeled-ERPs obtained from the Surprisal input exhibit an amplitude peak at around 350 ms. To statistically evaluate differences between the responses to the Envelope' and the Surprisal inputs, we first computed the absolute value of the difference Surprisal-Envelope' (z-scored). This difference signal is plotted in Figure 4C. The significant peaks were assessed over the entire signal ([-100-600] ms) using a series of t-tests that were conducted on each individual time sample, using the distribution of values over channels at each time point. The shaded grey areas on the *x*-axis indicate significance corrected for multiple comparisons (FDR correction, $p < .05$). This analysis revealed significant differences for the two main auditory components (at [50-100] ms and [150-200] ms). This may reflect the fact that the Surprisal signal was obtained by modulating values at note onsets, while the Envelope' model used a more continuous signal, yielding a more attenuated early modeled response. The third significant peak that occurs at around 350 ms indicates an enhanced neural response in the modeled-ERP obtained from the Surprisal. This response resembles a P3 response, a well-characterized, consistent, and reliable neurophysiological marker of syntactic processing in both the music [56, 57] and language [58] domains.

7. CONCLUSIONS

The central goal of the current project was to determine whether musical surprisal, a high-level, cognitive measure, enhances decoding performance of neural signal above and beyond what may be explained by acoustic features alone, thus showing that the human brain is tracking statistical regularities as modeled by D-REX. By validating D-REX, a computational model which simulates musical surprisal not from symbolic stimuli (e.g., MIDI) but directly from any audio file, we provide a valuable tool that can integrate perceptual and cognitive musical components relevant to

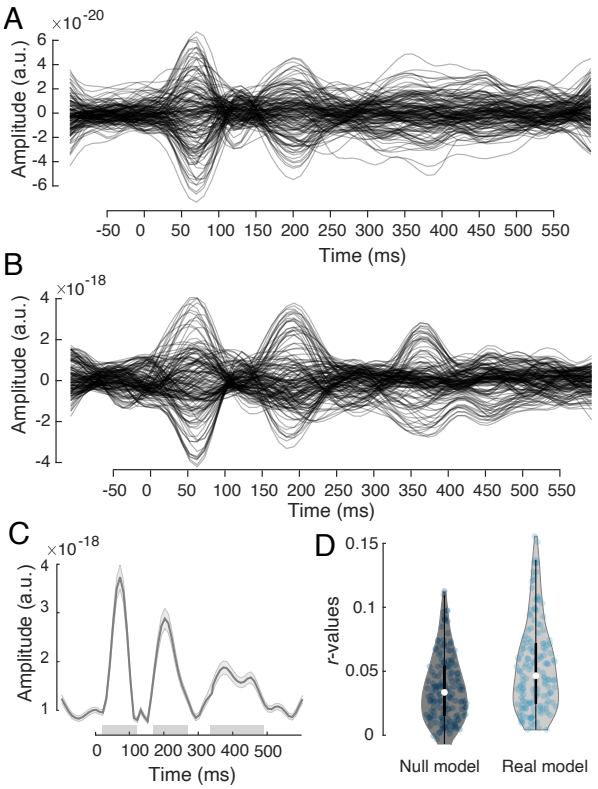

Figure 4. Results of decoding analysis. **(A)** The modeled-ERPs for each channel from the decoding model using Envelope' (the acoustic feature) as input. The weights for each channel are averaged across songs. **(B)** The modeled-ERPs for each channel from the decoding model using Surprisal (the cognitive feature) as input. **(C)** The absolute values of the Surprisal - Envelope' (z-scored) signals averaged across channels over time. Shaded areas around the curve indicate SEM over channels. Grey bars on the *x*-axis represent time windows during which a significant difference between the two averaged modeled-ERPs was found ($p < .005$, FDR-corrected). **(D)** Violin plots of *r*-value distributions for the real and baseline (i.e. shuffled) Surprisal models. Each dot corresponds to the *r*-value for one MEG channel.

recommender systems. Additionally, we provide an open-source database of neural data (twenty participants listening to 30 one minute long musical excerpts along with the audio files for these excerpts) with an excellent temporal resolution (at a sampling frequency of 1000 Hz) that can be used to further investigate the neural correlates of music processing. [2] In this paper, we used a decoding method to validate a Bayesian algorithm, D-REX, which models the continuous surprisal experienced by listeners during music listening. By describing a music-to-neural mapping between music stimuli and MEG data, we demonstrate that D-REX is an effective model to explain brain signals above and beyond mere acoustical features, capturing neural responses indicative of higher-level processing.

Our analysis also highlights a specific time window of auditory processing in the musical domain which is crucial to higher-level mechanisms involved in music listening. In the modeled-ERP derived from the Surprisal input (see Figure 4B), there is a significant peak around 350 ms, which undoubtedly evokes the P3 ERP [59, 60]. This ERP is implicated in syntax processing and context updating operations in both language [58] and music processing [56,57]. This further suggests that D-REX is capturing higher-level expectations generated by gathering statistics over time from acoustic information.

In the context of music listening, a recorded neural signal may be conceptualized as "a mid-level representation of the original music piece that has been heavily distorted by two consecutive black-box filters—the brain and the [MEG] equipment" [61]. However, while the brain does extract and represent the acoustic features contained in the musical excerpt, it also combines them to generate purely cognitive components, such as surprisal. In this experiment, we extract musical features and interface them with a cognitive model which abstracts beyond acoustic features into the psychological domain. Importantly, this cognitive model represents a measure which is one of the many factors predicting individual music preference and pleasure [4, 6]. Thus, we show that combining music information retrieval with cognitive neuroscience is an optimal way to measure people's responses to music.

8. FUTURE DIRECTIONS

8.1 Further Validation of D-REX Model

The current analysis was executed using *joint surprisal*, which is a summary measure across all 15 extracted acoustic features. Though our results show that D-REX joint surprisal is effectively encoded in the neural data recorded during music listening, it is possible that surprisal across specific features, such as pitch value or harmonicity, may be more relevant to cognitive aspects of music listening. Also, these representations may differ across participants. Thus, it is worth exploring across which dimensions surprisal is better represented. In addition, the present study used Western musical genres for listeners to validate D-REX, but future work may expand this exploration to non-Western genres.

8.2 Music Recommender Systems

This project presents a new line of inquiry for music recommender systems, which have typically been content-based (using extracted auditory features or subjective semantic ratings) or user-item/metadata-based [62]. Given the aforementioned inverse U-relationship between music surprisal and musical preferences, D-REX may be used to characterize individuals' musical corpora and, compiled with other variables, efficiently predict liking for new music. More broadly, we propose that harnessing cognitive neuroscience methods is potentially fruitful in improving and generating new methods for recommender systems by including cognitively relevant outcomes such as surprisal [4, 6].

ABSTRACT

We propose Beat Transformer, a novel Transformer encoder architecture for joint beat and downbeat tracking. Different from previous models that track beats solely based on the spectrogram of an audio mixture, our model deals with *demixed* spectrograms with multiple instrument channels. This is inspired by the fact that humans perceive metrical structures from richer musical contexts, such as chord progression and instrumentation. To this end, we develop a Transformer model with both time-wise attention and instrument-wise attention to capture deep-buried metrical cues. Moreover, our model adopts a novel *dilated self-attention* mechanism, which achieves powerful hierarchical modelling with only linear complexity. Experiments demonstrate a significant improvement in demixed beat tracking over the non-demixed version. Also, Beat Transformer achieves up to 4% point improvement in downbeat tracking accuracy over the TCN architectures. We further discover an interpretable attention pattern that mirrors our understanding of hierarchical metrical structures.

1. INTRODUCTION

Music audio beat and downbeat tracking, which aims to infer the very basic metrical structure of music, is a long-standing central topic in music information retrieval (MIR). A good beat estimation benefits various downstream MIR tasks, including transcription and structure analysis [1–5]. Moreover, beat tracking can be applied to human-computer interaction [6, 7], music therapy [8], and more scenes, as beats echo with human perceptual and motor sensitivity to musical rhythms.

We see significant progress in beat tracking with the development of deep neural networks. Current mainstream methods utilize temporal convolutional networks (TCNs) to extract frame-wise beat activations from an input spectrogram [9]. We further see successful efforts in boosting beat tracking performance, including phase-informed post-processing with dynamic Bayesian networks (DBNs) [10], multi-task learning for joint beat, downbeat and tempo estimation [11–13], and explicit beat phase modelling [14].

Recently, Transformer has demonstrated highly competitive performances over a range of MIR tasks [15–21]. In this paper, we propose Beat Transformer, a novel Transformer encoder architecture for joint beat and downbeat tracking. To better accommodate Transformer to our purpose, we introduce two extra inductive biases. Firstly, our model is constructed with *short-windowed dilated self-attention*. An exponentially increasing dilation rate enables our model to discern beats from non-beats in a hierarchical manner. With a fixed window size, our model maintains a linear complexity to the input sequence length.

Another inductive bias is *demixed beat tracking*. This strategy is inspired by the fact that human beat tracking is always accompanied by and enhanced by a deep understanding of the musical contexts. For example, the coordination of instruments enforces the progression of chords and bass notes, thus implying metrical accents, and such cues can be easily identified by human listeners. To capture this relation, we use Spleeter [22] to demix an input music piece into multiple instrument channels, and our model performs both *time-wise* and *instrument-wise* attention in alternate Transformer layers to excavate metrical cues.

We evaluate Beat Transformer on a wide range of beat- and downbeat-annotated datasets. Besides competing with state-of-the-art works, we present a thorough ablation study to illustrate the effectiveness of dilated self-attention and demixing. Moreover, our model learns highly interpretable representations. We demonstrate that our model can be interpreted as a learner over finite-state Markov chains, and we observe beat phase transition through visualization of the transition (attention) matrix.

In brief, the contributions of our paper are as follows:

- We propose Beat Transformer [1], a novel Transformer encoder architecture for joint beat and downbeat tracking in music audio.
- We devise dilated self-attention, which demonstrates powerful sequential modelling with linear complexity, potentially adaptable to more general MIR tasks.
- We make use of music demixing to complement and enhance beat tracking, shedding light on future MIR research towards universal music understanding.

2. RELATED WORKS

We review two topics related to our work: beat tracking, and Transformer. For beat tracking, we focus on its development with deep neural networks. For Transformer, we address its application in MIR. For more general review of both topics, we refer readers to [23] and [24], respectively.

2.1 Music Audio Beat Tracking

Beat tracking has been formulated as a two-stage sequential learning task. The first stage aims to determine the likelihood of beat presence, or beat activation, at each frame of an input spectrogram. The initial deep learning approach for this purpose was based on long short-term memory networks (LSTM) [25, 26]. To better pick up the beat sequence from raw model output, at the second stage, a dynamic Baysian network (DBN) is introduced to infer tempo and beat phase transition from beat activation [10].

The current mainstream methods substitute the LSTM with a TCN architecture [9, 12–15]. Specifically, the convolutional kernels have a dilation rate exponential to the depth of layer. This hierarchical structure facilitates the network to model various scales, functionally similar to pooling, but maintains the same input and output size [27]. Besides architecture, another breakthrough of beat tracking is the formulation of multi-task learning [11–15]. Specifically, beat, downbeat, and tempo are strongly correlated metrical features. Sharing model weights among all three sub-tasks helps each to reach better convergence.

A recent trend of beat tracking is to deal with *demixed* music sources. Chiu *et. al.* leverages demixed drum and non-drum streams to enhance model adaptability to different drum source conditions [28, 29]. In fact, humans can track beats while switching their attention among different instrument parts. Hence the coordination of instrumental sources can be explored for useful metrical information.

In our work, we inherit the fashion of multi-task learning and the use of DBN, while proposing a novel Transformer encoder architecture to replace TCN. We formalize *dilated self-attention* [30, 31] for efficient modeling of long metrical structures. Moreover, we seek to enhance beat tracking by introducing *instrumental attention* among drum, piano, bass, vocal, and other demixed sources.

2.2 Transformer in MIR

Transformer has established itself *de facto* state-of-the-art in natural language and symbolic music domain. Recently, it has also demonstrated outstanding performance over audio-based MIR tasks, including music transcription [17–19], music tagging [20, 21], and other analysis [16]. For these tasks, a Transformer model is trained over short spectrogram clips typically of 2-5 seconds as a compromise to the quadratic complexity computing self-attention.

Transformer is first applied to beat tracking by Hung *et. al.* [15] using SpecTNT blocks [16]. For each SpecTNT block, a spectral Transformer encoder first aggregates spectral information at each time step, and then a temporal encoder exchanges information in time and pays attention to beat and downbeat positions. Such a time-frequency design makes an effective use of spectral features and achieves the state-of-the-art performance.

Our work is also a Transformer-based architecture that strives to enhance beat tracking with richer musical contexts. Instead of aggregating spectral features as in [15], we resort to demixed instrumental attention as a more explicit inductive bias to exploring spectral information. Our design of dilated self-attention is also a crucial step to accommodate Transformer to beat tracking. With only linear complexity, our model handles full-length songs at a time.

3. METHOD

The core of our method is a Transformer encoder based on *1) dilated self-attention* (DSA), and *2) demixed instrumental attention*, to extract a framewise beat activation from input spectrograms. In this section, we first formalize DSA in Section 3.1. We then present our design of demixed beat tracking in Section 3.2. We further interpret our method with Markov chain properties in Section 3.3.

3.1 Dilated Self-Attention (DSA)

3.1.1 Background of Self-Attention (SA)

We first recall that, for vanilla Transformer layers, self-attention (SA) is computed via the scaled dot product:

$$\mathrm{Attention}(Q, K, V) = \mathrm{softmax}(\frac{QK^\top}{\sqrt{d_\mathrm{f}}})V, \qquad (1)$$

where $Q_{1:T}, K_{1:T}, V_{1:T} \in \mathbb{R}^{T\times d_\mathrm{f}}$ are query, key, and value sequences, each linearly mapped from input $x_{1:T}$. T is the sequence length, and d_f is the feature dimension.

The partial attention from position i to j is explicitly:

$$e_{ij} = \frac{Q_i K_j^\top}{\sqrt{d_\mathrm{f}}}, \qquad (2)$$

where $1 \leq i, j \leq T$. Such computation leads to quadratic complexity $\mathcal{O}(T^2)$ in terms of both time and space.

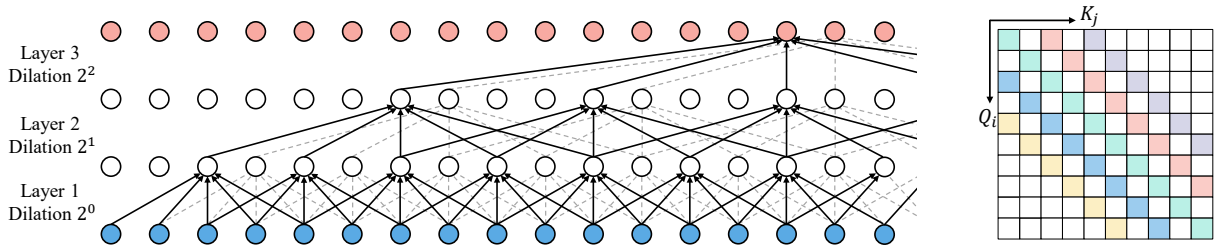
3.1.2 Dilated Self-Attention (DSA)

An illustration of DSA is shown in Figure 1. DSA is computed over a short window of size $l_\mathrm{win} = m + n + 1$, where m and n are the length of non-causal and causal components of the window (in Figure 1, $m = n = 2$). Each Transformer layer has a dilation rate $r \geqslant 1$, and r increases exponentially as the layer goes deeper.

Formally, given Q, K, and $V \in \mathbb{R}^{T\times d_\mathrm{f}}$, DSA first computes Q-K attention by:

$$e_{ik} = \frac{Q_i K_{i+rk}^\top}{\sqrt{d_\mathrm{f}}}, \qquad (3)$$

where $1 \leq i \leq T$ and $-m \leq k \leq n$. Specifically, $i + rk$ refers to the positions in $K_{1:T}$ that are attainable by Q_i under the dilated window of rate r. When $i + rk$ exceeds the sequence range $[1, T]$, we fill e_{ik} with $-\texttt{inf}$.



(a) Layer-wise view of dilated self-attention (Adapted from TCN structures [9, 27])

(b) Attention matrix view at layer 2

Figure 1: Illustration of dilated self-attention (with a non-causal short window of size 5) over a three-layer Transformer. Part (a) shows the hierarchical connectivity across layers, which shares the same pattern as TCN in [9]. Part (b) shows the attention matrix at layer 2, with colours indicating relative position. The white colour indicates unattainable positions.

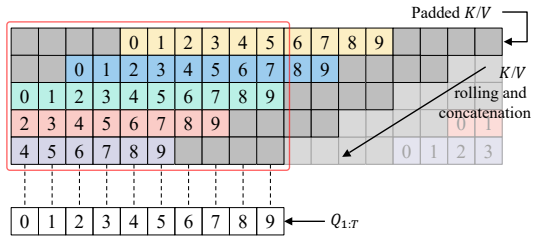


Figure 2: Illustration of efficient DSA implementation, with dilation rate $r = 2$ and window size $l_{\text{win}} = 5$.

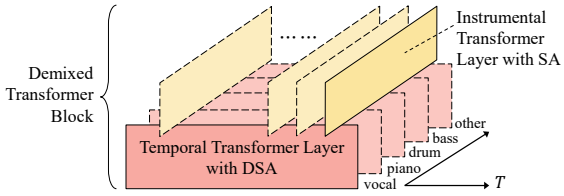

Figure 3: Demixed Transformer block. Two Transformer layers are stacked "orthogonally", each handling time-wise dilated self-attention and instrument-wise self-attention.

Then, the Q-K attention e_{ik} is normalized via softmax:

$$p_{ik} = \frac{\exp(e_{ik})}{\sum_{k=-m}^{n} \exp(e_{ik})} \tag{4}$$

The output of DSA is a sequence $z_{1:T}$, where z_i is the weighted average of V under the same dilated window:

$$z_i = \sum_{k=-m}^{n} p_{ik}(V_{i+rk}) \tag{5}$$

We apply DSA with exponentially increasing dilation rates and relative positional embedding (RPE) [32] to a stack of Transformer layers. Each layer consists of two sub-layers: DSA, and a position-wise feed-forward layer. We place residual connections across each sub-layer and perform layer normalization [33] before each sub-layer.

3.1.3 Memory Efficient Implementation of DSA

A straightforward implementation of DSA is to mask SA. Concretely, a square mask takes the same form as in Figure 1b, where all uncolored positions are filled with $-\texttt{inf}$, rendering a rather sparse attention matrix. This way, however, still requires quadratic complexity, because e_{ij} is explicitly computed for all masked positions.

Our implementation takes a "rolling" strategy to eliminate redundant computation. As in Figure 2, l_{win} copies of $K_{1:T}$ sequences are padded and rolled along the time axis, and then concatenated on a new axis. In this way, each Q_i sees K_j directly and only at $j = i + rk$ for $-m \le k \le n$, which is exactly the coverage of the dilated window.

Formally, given $K_{1:T} \in \mathbb{R}^{T \times d_{\text{f}}}$, dilation rate r, and window size l_{win}, the rolling strategy takes three steps:

1. Pad $K_{1:T}$ with $\lfloor \frac{l_{\text{win}}}{2} \rfloor \times r$ steps on both sides;
2. Make l_{win} copies of padded K. Starting from 0, each copy is cyclically rolled r more steps;
3. Concatenate each copy along a new axis and retrieve the first T steps. The output has shape $T \times l_{\text{win}} \times d_{\text{f}}$.

The same procedure applies to $V_{1:T}$ as well. In this way, computing DSA is essentially as simple as Equation (1). Here, instead of $Q, K, V \in \mathbb{R}^{T \times d_{\text{f}}}$, we have $Q \in \mathbb{R}^{T \times 1 \times d_{\text{f}}}$ and $K, V \in \mathbb{R}^{T \times l_{\text{win}} \times d_{\text{f}}}$, with T treated as a batch dimension. The computation complexity is $\mathcal{O}(T \times l_{\text{win}})$, while l_{win} is fixed and small enough to be left uncounted.

3.2 Demixed Beat Tracking

3.2.1 Demixed Transformer Block

We use Spleeter 5-stems model [22] to demix an input piece into spectrograms with $|C|$ instrument channels, where $C = \{\texttt{vocal}, \texttt{piano}, \texttt{drum}, \texttt{bass}, \texttt{other}\}$. As shown in Figure 3, we stack two Transformer layers to perform time-wise and instrument-wise attention in turn. Let the input at layer l be $x^l_{1:T,1:|C|} \in \mathbb{R}^{T \times |C| \times d_{\text{f}}}$, a *temporal* Transformer layer (TTL) first takes $x^l_{1:T,c}$ for $1 \le c \le |C|$:

$$x^{l+1}_{1:T,c} = \text{TTL}(x^l_{1:T,c}) \tag{6}$$

Then, an *instrumental* Transformer layer (ITL), on the *orthogonal* direction, takes $x^{l+1}_{t,1:|C|}$ for $1 \le t \le T$:

$$x^{l+2}_{t,1:|C|} = \text{ITL}(x^{l+1}_{t,1:|C|}) \tag{7}$$

A TTL followed by ITL forms a *demixed Transformer block*. TTL consists of DSA as described in Section 3.1.2.

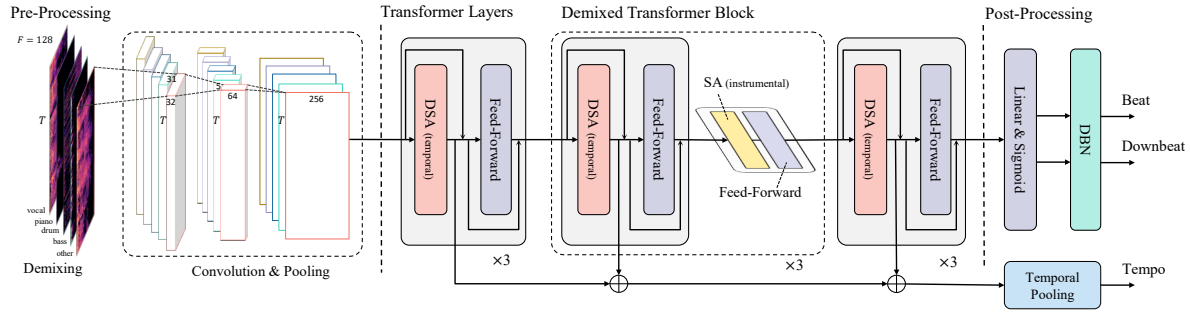

Figure 4: Beat Transformer architecture. For conciseness, layer normalization and dropout layers are not shown.

For ITL, we use vanilla SA because there is only 5 instrument channels. As instruments are not sequentially ordered, we do not add any positional encoding to ITL.

Through demixed Transformer blocks, our model can capture the rhythmic evolution of each instrument, as well as the harmonic coordination among all instruments.

3.2.2 Partial Demix Augmentation

Spleeter may produce empty channels when a certain instrument does not present. To avoid potential effects of such a situations, we develop a partial demix strategy for data augmentation. Partial demix creates new stems by summing up existing instrument channels of a default 5-stem demixed input sample. For example, an augmented data sample may have three channels corresponding to $C' = \{\texttt{vocal\&piano}, \texttt{drum}, \texttt{bass\&other}\}$.

In our case, we randomly sum up 2, 3, or 4 instrument channels of a 5-stem input with a probability 30%, 10%, and 10% during training. In this way, our model is encouraged to pay attention to *instrument-agnostic* musical contents and thus is less affected by empty channels where no valid music content is present. As our augmentation strategy also adds to the demix diversity and the data quantity, we believe it brings general benefits to training as well.

3.3 Markov Chain Interpretation

In Equation (4), we formulate the attention matrix of DSA as $P = [p_{ij}]_{1 \le i,j \le T}$, where $p_{ij} \ge 0$ if and only if $j = i + rk$ for $-m \le k \le n$. Here, r is the dilation rate, and m, n are components of the attention window. Moreover, P satisfies $\sum_{j=1}^{T} p_{ij} = 1$ for all i. Therefore, P can be regarded as the transition matrix of a finite-state Markov chain, where each state is a position of the input sequence.

For a stack of temporal Transformer layers (TTL), where DSA is employed, layer l essentially learns a unique one-step transition P^l, by which our model can attend to local neighbours covered by the attention window. Through L layers, our model makes an L-step transition, during which it attends to global positions hierarchically. The overall L-step transition matrix $P^{(L)}$ satisfies:

$$P^{(L)} = \prod_{l=1}^{L} P^l \tag{8}$$

Note that P^l itself is a rather sparse matrix (due to *short* attention window), while $P^{(L)}$ is densely connected. Its components $[p_{ij}^{(L)}]_{1 \le i,j \le T}$ represent the hierarchical attention weights across the whole L layers, which can tell us much richer attention patterns (more in Section 4.4).

3.4 Complete Architecture

A complete view of Beat Transformer is presented in Figure 4. The inputs are log-scaled spectrograms demixed by Spleeter, with $F = 128$ mel-bins and $|C| = 5$ instrument channels. Subject to Spleeter, our frame rate is 43.07 fps and the frequency range is up to 11 kHz. We then use three 2D convolutional layers, shared by each demixed channel, as a front-end feature extractor. The convolutional design is the same as in [13] except that we employ more filters to reach feature dimension $d_{\text{model}} = 256$.

Beat Transformer comprises 9 temporal Transformer layers (TTL) with DSA. Each TTL has 8 attention heads with window size $l_{\text{win}} = 5$, four of which have skewed window ranges, where $m = 0, 1, 3, 4$, respectively, and $n = 4 - m$. The dilation rate grows exponentially from 2^0 to 2^8, stretching to a receptive field of 47.51 seconds. Among the 9 TTLs, the middle three are expanded to demixed Transformer blocks by interleaving ITLs. We found it sufficient to perform instrumental attention only in the middle layers, which has a proper scale of 1-5 seconds. Each Transformer layer has 8 heads ($d_{\text{f}} = 32$) followed by a feed-forward layer with hidden dimension $d_{\text{ff}} = 1024$.

We sum up the instrument channels of the output of the last Transformer layer and obtain a frame-wise beat representation of shape $T \times d_{\text{model}}$. Following multi-task learning practice [11–14], we use a linear layer to map the representation to beat and downbeat activations respectively, and add a regularization branch predicting global tempo via "skip connections" [12]. We apply DBN in Madmom package [34] as the post-processor to pick up the beat and downbeat sequence from raw activations. For DBN parameters, we set $\texttt{observation\_lambda} = 6$, $\texttt{transition\_lambda} = 100$, and $\texttt{threshold} = 0.2$.

4. EXPERIMENTS

4.1 Datasets

We utilize a total of 7 datasets for model training and evaluation: *Ballroom* [35, 36], *Hainsworth* [37], *RWC Popular* [38], *Harmonix* [39], *Carnetic* [40], *SMC* [41],

Table 1: Testing results of beat and downbeat tracking under 8-fold cross-validation. GTZAN is unseen from training and held out for test only. Böck *et. al.* [13] on Harmonix is reproduced by [15], as indicated by the * symbol. We use underscore to denote best results comparing with our ablation models and use **boldface** to compare with state-of-the-art models.

and *GTZAN* [42, 43]. We acquire *Harmonix* in mel-spectrogram and invert each piece to audio using Griffin-Lim Algorithm [44, 45] with Librosa package [46]. Following convention, we leave *GTZAN* for testing only and use the other datasets in 8-fold cross validation [11–13].

4.2 Training

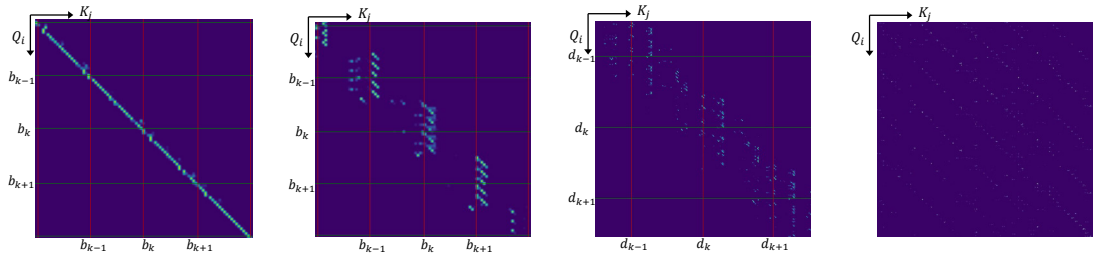
Our model is supervised in a multi-task learning fashion, where beat, downbeat, and tempo are predicted jointly [13]. Beat and downbeat annotations are each represented as a 1D binary sequence that indicates beat (1) and non-beat (0) states at each input frame. Following [13], we widen beat and downbeat states to ± 2 neighbours of annotated frames with weights 0.5 and 0.25. Following [12], we derive tempo target from beat annotation for the tempo prediction branch. We found the use of tempo branch generally beneficial to beat tracking, as it may serve as a regularization term that helps reaching better convergence.

For training, we combine the binary cross entropy loss over beat, downbeat, and tempo by weighing them equally. We use a batch size of 1 to train on whole sequences with different lengths. For excessively long songs, we split them into 3-minute (8k-frame) clips. We apply RAdam [47] plus Lookahead [48] optimizer with an initial learning rate of $1\mathrm{e}{-3}$, which is reduced by a factor of 5 whenever the validation loss gets stuck for 2 epochs before being capped at a minimum value of $1\mathrm{e}{-7}$. We use dropout [49] with rate 0.5 for the tempo branch and 0.1 for other parts of the network. We apply *partial demix augmentation* described in Section 3.2.2 as the only means of data augmentation. Our model has 9.29M trainable parameters and is trained with an RTX-A5000-24GB GPU. Each training fold generally takes 20 epochs (in 11 hours) to fully converge.

4.3 Evaluation

4.3.1 Baseline Methods

We first compare three ablation models to validate our module design. The first ablation model is *Ours* trained without partial demix augmentation (***Ours w/o Aug.***). The second model removes all ITL layers and tracks beat with a single channel of non-demixed mixture (***Ours w/o Demix***). The last model replaces each TTL layer with a TCN layer [13] of the same dilation rate (***TCN+Demix***). We imple-



(a) $P^{(1)}$ lower scale (b) $P^{(3)}$ beat scale (c) $P^{(5)}$ downbeat scale (d) $P^{(9)}$ higher scale

Figure 5: Visualization of temporal attention matrix based on the product rule in Equation (8) for L-step transition on a Markov chain. $L = 1, 3, 5$, and 9 from part (a) to (d), which model different hierarchies of the metrical structure.

ment TCN layers following [23] while setting the input and output shape to be the same as our model. The resulting model yields a comparable amount of 10.25M parameters and is trained without augmentation.

In addition, we compare our model with two recent works that have achieved state-of-the-art performance. Specifically, Böck *et al.* [13] is based on TCN architectures and Hung *et al.* [15] is based on SpecTNT.

4.3.2 Results and Discussion

In Table 1, we first observe *Ours w/o Aug.* yields generally better performance than *TCN+Demix*, especially on the unseen *GTZAN* dataset. As both models share a comparable amount of parameters, this result demonstrates the capability of Transformer (DSA) versus TCN (dilated convolution), which also corroborates with previous findings on Transformer's comparability to convolution on general tasks [50–52]. Considering that Transformer is notoriously data-inefficient to train, it is remarkable that our model is well-trained with limited data without augmentation. We owe this merit to DSA, which not only prevents redundant computation but also makes musical sense in terms of the hierarchical structure of music metrical modelling.

Comparing *Ours w/o Demix* to *Ours w/o Aug.*, while both models are highly competitive in beat tracking, the latter demonstrates more superiority in downbeat tracking. Downbeat tracking is generally more difficult than beat tracking because it is involved with deeper musical knowledge, such as chord and bass progression, behind the apparent spectrogram energy. In our model, the instrumental attention captures the instrumental coordination as hints to the harmonic cues that are orthogonal to the temporal axis, and thus acquires better metrical modelling.

Comparing *Ours w/o Aug.* to *Ours*, we observe a consistent improvement across datasets brought by partial demix augmentation, which indicates the general usefulness of this augmentation strategy to model training.

Compared to state-of-the-art models, our improvement in downbeat accuracy is more significant than that in beat accuracy. On the test-only *GTZAN* dataset, we obtain 4% point gain in *F-measure* over Böck *et al.* [13] in downbeat tracking. Compared to Hung *et al.* [15], which is also based on Transformer, our model can be more flexibly trained (owing to the efficient DSA mechanism) on a 24GB GPU in contrast to four 32GB GPUs reported in [15].

4.4 Attention Matrix Visualization

We visualize the attention matrix that our model learns by interpreting it as a *multi-step Markov transition matrix* as defined in Equation (8). Specifically, the L-step matrix is the product of L one-step matrices through L layers. Here we only consider TTLs with dilated self-attention, as ITLs work on an orthogonal axis. Figure 5 shows the attention matrix $P^{(L)}$ for $L = 1, 3, 5$, and 9 of the `drum` channel, inferred from the piece `hiphop.00090` chosen from *GTZAN*.

Figure 5a shows a one-step transition. Each position Q_i can only attend to its neighbours covered by the attention window. Still, we observe that beat positions (denoted by b_k) are likely to get more attention. In Figure 5b where we step to the beat scale, most attention spots are aligned with beats. Moreover, we observe that the attention at b_k is typically prolonged after Q_i leaves b_k, and is formed before Q_i reaches b_k for every k. This means that our model learns to transition its attention from the *offbeat* phase following the last beat to the *upbeat phase* preceding the next beat. Figure 5c further stretches the view to the downbeat scale, and we can see similar patterns aligned with downbeat positions (denoted by d_k). Finally, in Figure 5d, the attention reaches further positions and displays a structural pattern.

The above visualization demonstrates the inner logic that our model exploits for beat and downbeat tracking. We see that our model gathers information from both local and global scales with an organized hierarchy.

5. CONCLUSION

In conclusion, we contribute a novel Transformer architecture for audio beat and downbeat tracking. The main novelty lies first in our design of dilated self-attention, which brings down the computation complexity of Transformer from quadratic to linear level. In addition, we successfully enhance beat and downbeat tracking by utilizing off-the-shelf progress in music demixing. Our model not only captures deeper harmonic cues for better metrical inference but also discerns beat and downbeat in a visualizable hierarchical manner. Our model is efficient, interpretable, and potentially generalizable with highly competitive sequential modelling power. We hope our model encourages future MIR research toward universal music understanding.

ABSTRACT

We propose a system for rendering a symbolic piano performance with flexible musical expression. It is necessary to actively control musical expression for creating a new music performance that conveys various emotions or nuances. However, previous approaches were limited to following the composer's guidelines of musical expression or dealing with only a part of the musical attributes. We aim to disentangle the entire musical expression and structural attribute of piano performance using a conditional VAE framework. It stochastically generates expressive parameters from latent representations and given note structures. In addition, we employ self-supervised approaches that force the latent variables to represent target attributes. Finally, we leverage a two-step encoder and decoder that learn hierarchical dependency to enhance the naturalness of the output. Experimental results show that our system can stably generate performance parameters relevant to the given musical scores, learn disentangled representations, and control musical attributes independently of each other.

1. INTRODUCTION

Computational modeling of expressive music performance focuses on mimicking human behaviors that convey the music [1, 2]. For piano performance, one common task is to *render* an expressive performance from a quantized musical score. It aims to reproduce the loudness and timing of musical notes that fits to the given score. Most of the conventional studies have used musical scores of Western piano music that includes sufficient amount of guidelines for musical expressions [3–6]. Recent studies using deep learning methods have successfully rendered plausible piano performances that are comparable to those of professional pianists from the given Classical scores [7–9].

More recently, it has increased attention to *controlling* music performance by manipulating one or more *disentangled* representations from a generative model. These representations are sensitive to the variation of certain factors while invariant to other factors [10]. Maezawa *et al.* aimed to control a performer's interpretation through a conditional variational recurrent neural network (CVRNN) [11]. They intended to disentangle a time-variant representation of the personal interpretation. In the acoustic domain, Tan *et al.* proposed a generative model based on a Gaussian mixture variational autoencoder (GM-VAE) that separately controlled dynamics and articulations of the notes [12]. Their novelty lied in learning multiple representations of high-level attributes from the low-level spectrogram.

However, these studies have constrained musical creativity. Maezawa *et al.* controlled musical expression only through quantized features from the musical scores. Tan *et al.* did not consider controlling tempo or timing with a latent representation. These methods may have restricted any potential for rendering piano performances with flexible musical expression. Musical creativity can be expanded not only by composers but also by performers who can elastically choose various strategies to highlight multiple nuances or emotions [13–15]. Moreover, the music generation field can be also broadened if static music created by automatic composition systems can be easily colored with realistic and elastic expression [16].

Therefore, we attempt a new approach that renders piano performances with flexible musical expressions. We disregard a typical assumption from previous studies that a performer must follow a composer's intent [4, 17–19]. According to the literature, performers learn to identify or imitate "expressive models", or *explicit planning*, of existing piano performances [20]. We focus on this attribute, defining it as a higher-level *sketch* of the expressive attributes (i.e. dynamics, articulation, and tempo [21]) that the performer draws based on a personal interpretation of the musical piece [4, 11, 20]. We also assume that the remaining attribute represents common performing strategies that are connected to certain musical patterns, while these strategies slightly differ across performers [22, 23]. We call this attribute as a *structural attribute* that belongs to given note structures of a musical piece.

In this study, we propose a generative model that can

Lee, "Sketching the Expression: Flexible Rendering of Expressive Piano Performance with Self-Supervised Learning", in *Proc. of the 23rd Int. Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

flexibly control the entire musical expression, or the explicit planning, of symbolic piano performance [1]. Our system is based on a conditional variational autoencoder (CVAE) that is modified for sequential data [11, 24]. The system generates multiple parameters of piano performance from a note structure of a musical passage, using disentangled representations for the explicit planning and structural attribute.

We employ a self-supervised learning framework to force the latent representations to learn our target attributes [24–26]. In addition, we facilitate independent control of the three expressive attributes–dynamics, articulation, and tempo–by utilizing an existing method that aligns the latent code with a target attribute [27, 28]. Finally, we design a novel mechanism that intuitively models a polyphonic structure of piano performance. In particular, we insert intermediate steps for *chordwise* encoding and decoding of the piano performance to our encoder-decoder architecture, where a *chord* denotes a group of simultaneous notes.

Our approach has several contributions as follows: 1) Our system aims to control musical expression while maintaining any characteristics induced by a given musical structure; 2) We use self-supervised learning where new supervisory signals are involved in regularizing the latent representations effectively; 3) Our system aims to control multiple expressive attributes independently of each other; 4) Lastly, we leverage an intermediate step that projects a notewise representation into the chordwise in the middle of our system to intuitively model the polyphonic structure of piano performance.

2. PROPOSED METHODS

We aim to build a generative model that factorizes expressive piano performance as the explicit planning and structural attribute. The model is based on a conditional variational autoencoder (CVAE) that reproduces performance parameters based on a given musical structure.

2.1 Data Representation

We extract features that represent a human performance and the corresponding musical score, following the conventional studies [11, 19, 29].

Performance Features. We extract three features that represent the expressive attributes of each performed note, respectively: **MIDIVelocity** is a MIDI velocity value that ranges from 24 to 104. **IOIRatio** represents an instantaneous variation in tempo. We compute an inter-onset-interval (IOI) between the onset of a note and the mean onset of the *previous* chord for both a performed note and the corresponding score note. Then, a ratio of performed IOI to score IOI is calculated, clipped between 0.125 and 8, and converted into a logarithmic scale [4]. **Articulation** represents how much a note is shortened or lengthened compared to the instantaneous tempo. It is a ratio of a performed duration to an IOI value between the onset of a note and mean onset of the *next* chord [19]. It is clipped between 0.25 and 4 and converted into a logarithmic scale.

Score Features. The features for a musical score represent eight categorical attributes for how the notes are composed: **Pitch** is a MIDI index number that ranges from 21 to 108. **RelDuration** and **RelIOI** are 11-class attributes of a quantized duration and IOI between a note onset and a previous chord, respectively. They range from 1 to 11, and each class represents a multiple of a 16th note's length with respect to a given tempo [30, 31]. **IsTopVoice** is a binary attribute of whether the note is the uppermost voice. It is heuristically computed regarding pitches and durations of surrounding notes. **PositionInChord** and **NumInChord** are 11-class attributes of a positional index of a note within its chord and the total number of notes in that chord, respectively, that range from 1 to 11. An index 1 for PositionInChord denotes the most bottom position. **Staff** is a binary attribute of the staff of a note, either of the G clef or F clef. **IsDownbeat** is a binary attribute of whether a note is at a downbeat or not.

2.2 Modeling Musical Hierarchy

Inspired by previous studies [4, 8, 9, 32], we build a two-step encoder and decoder: An encoder models both notewise and chordwise dependencies of the inputs, and a decoder reconstructs the notewise dependency from the chordwise representation and the notewise condition. We denote a *chord* as a group of notes that are hit simultaneously, regardless of the staff, so that they sound together at an instant time [33]. Thus, learning the chordwise dependency is analogous to direct modeling of the temporal progression of the piano performance. Let $\mathcal{M} \in \mathbb{R}^{C\times N}$ be a matrix that aligns serialized notes to their polyphonic structure, where C and N are the number of chords and the number of notes, respectively. Within the encoder, the notewise representation is sequentially average-pooled by $\mathcal{M}$ with dynamic kernel sizes where each size represents the number of notes in each chord. We denote this operation as *N2C*. In this way, we can directly model chord-level dependency of the note-level expressive parameters [32]. In contrast, the decoder extends the chordwise representation from the encoder back to the notewise using the transposed alignment matrix $\mathcal{M}^T$, of which process we denote as *C2N*. Along this, the notewise embedding of the score features replenishes the notewise information for the output. Consequently, notes in the same chord *share* any information of their corresponding chord, while maintaining their differences by the conditional score features:

$$\text{N2C}(e) = \frac{\mathcal{M}\cdot e}{\sum_{n=1}^{N}\mathcal{M}_{n,1:C}}, \quad \text{C2N}(e) = \mathcal{M}^{\text{T}}\cdot e \qquad (1)$$

where e denotes a notewise or chordwise representation.

2.3 Overall Network Architecture

Our proposed network is generally based on the conditional VAE framework [34, 35]. Concretely, we use the sequential VAE that is modified for generation of sequential data [11,24,36]. Let $x = \{x_n\}_{n=1}^{N}$ be a sequence of the

[1] https://github.com/rsy1026/sketching_piano_expression

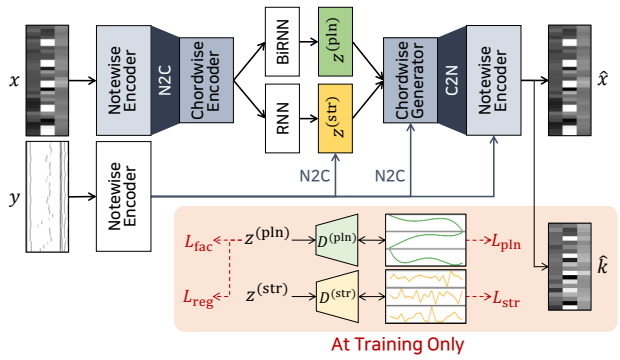

Figure 1: Overall architecture of the proposed system. The orange box includes the auxiliary tasks only for training.

performance features, and $y = \{y_n\}_{n=1}^{N}$ be a sequence of the conditional score features. Our network has two *chord-wise* latent variables $z^{(\text{pln})} = \{z_c^{(\text{pln})}\}_{c=1}^{C} \in \mathbb{R}^{C \times d^{(\text{pln})}}$ and $z^{(\text{str})} = \{z_c^{(\text{str})}\}_{c=1}^{C} \in \mathbb{R}^{C \times d^{(\text{str})}}$ that represent explicit planning and structural attribute, where $d^{(\text{pln})}$ and $d^{(\text{str})}$ are the sizes of $z^{(\text{pln})}$ and $z^{(\text{str})}$, respectively. Our network generates notewise performance parameters x from these latent variables and given score features y. The overall architecture of our proposed system is illustrated in Figure 1.

Generation. A probabilistic generator parameterized by θ produces the note-level performance parameters x from the two latent variables $z^{(\text{pln})}$ and $z^{(\text{str})}$ with the given condition y. We note that the latent variables are in chord-level. This decreases a computational cost and also enables intuitive modeling of polyphonic piano performance where each time step represents a stack of notes and the simultaneous notes share common characteristics [8]:

$$p_\theta(x, y, z^{(\text{pln})}, z^{(\text{str})}) = p_\theta(x|z^{(\text{pln})}, z^{(\text{str})}, y) \\ p_\theta(z^{(\text{pln})}) \prod_{c=1}^{C} p_\theta(z_c^{(\text{str})}|z_{<c}^{(\text{str})}, y_{\leq c}^{(\text{chd})}) \quad (2)$$

where $y^{(\text{chd})} = \text{N2C}(e_y)$ is the chordwise embedding, and e_y is the notewise embedding for y. We assume that the prior of $z_c^{(\text{pln})}$ is a standard normal distribution. In contrast, $z_c^{(\text{str})}$ is sampled from a sequential prior [24, 36, 37], conditioned on both previous latent variables and chordwise score features: $z_c^{(\text{str})} \sim \mathcal{N}(\mu^{(\text{prior})}, \text{diag}(\sigma^{(\text{prior})^2})$, where $[\mu^{(\text{prior})}, \sigma^{(\text{prior})}] = f^{(\text{prior})}(z_{<c}^{(\text{str})}, y_{\leq c}^{(\text{chd})})$, and $f^{(\text{prior})}$ is a unidirectional recurrent neural network. The latent representations and $y^{(\text{chd})}$ pass through the decoder as shown in Figure 1. During training, the model predicts the intermediate chordwise output that is computed as $\text{N2C}(x)$. This is to enhance reconstruction power of our system, propagating accurate information of chord-level attributes to the final decoder. The intermediate activation is then extended to the notewise through the C2N operation. The note-level parameters are generated autoregressively based on this activation and the notewise score feature. We use teacher forcing during training [38].

Inference. A probabilistic encoder parameterized by ϕ approximates the posterior distibutions of the latent representations $z^{(\text{pln})}$ and $z^{(\text{str})}$ from the performance input x and conditional score input y:

$$q_\phi(z^{(\text{pln})}, z^{(\text{str})}|x, y) = q_\phi(z^{(\text{pln})}|x^{(\text{chd})}) \\ \prod_{c=1}^{C} q_\phi(z_c^{(\text{str})}|x_{\leq c}^{(\text{chd})}, y_{\leq c}^{(\text{chd})}) \quad (3)$$

where $x^{(\text{chd})} = \text{N2C}(e_x)$ is the chordwise embedding, and e_x is the notewise embedding for x. The posterior distributions of $z_c^{(\text{pln})}$ and $z_c^{(\text{str})}$ are approximated by distribution parameters encoded by $f^{(\text{pln})}(x^{(\text{chd})})$ and $f^{(\text{str})}(x^{(\text{chd})}, y^{(\text{chd})})$, where $f^{(\text{pln})}$ and $f^{(\text{str})}$ are bidirectional and unidirectional recurrent neural networks, respectively. We note that $z^{(\text{pln})}$ is independent of the score features y. This allows a flexible transfer of the explicit planning among other musical pieces. On the other hand, $z^{(\text{str})}$ is constrained by y since the structural attributes are dependent on the note structure.

Training. We train the models p_θ and q_ϕ by approximating marginal distributions of the performance features x conditioned on the score features y. This requires to maximize negative evidence lower bound (ELBO) that includes regularization force by Kullback–Leibler divergence [34]:

$$\mathcal{L}_{\text{VAE}} = \mathbb{E}_{q_\phi(z^{(\text{pln})}, z^{(\text{str})}|x,y)} \left[\log p_\theta(x|z^{(\text{pln})}, z^{(\text{str})}, y)\right] \\ + \mathbb{E}_{q_\phi(z^{(\text{pln})}, z^{(\text{str})}|x,y)} \left[\log p_\theta(k|z^{(\text{pln})}, z^{(\text{str})}, y)\right] \\ - \text{KL}(q_\phi(z^{(\text{pln})}|x) \| p_\theta(z^{(\text{pln})})) \\ - \sum_{c=1}^{C} \text{KL}(q_\phi(z_c^{(\text{str})}|x_{\leq c}^{(\text{chd})}, y_{\leq c}^{(\text{chd})}) \| p_\theta(z_c^{(\text{str})}|z_{<c}^{(\text{str})}, y_{\leq c}^{(\text{chd})})) \quad (4)$$

where $k = \text{N2C}(x)$ is the chordwise performance features.

2.4 Regularizing the Latent Variables

We enhance disentanglement of the latent representations $z^{(\text{pln})}$ and $z^{(\text{str})}$ using four regularization tasks [24].

Prediction Tasks. We extract new supervisory signals for additional prediction tasks from the input data [24]. We define a signal of explicit planning $I^{(\text{pln})}$ as a set of smoothed contours of the expressive parameters. It is extracted as a polynomial function predicted from the chordwise performance parameters k. We also derive a signal of structural attribute as $I^{(\text{str})} = \text{sign}(k - I^{(\text{pln})})$ which represents normalized directions of the performance parameters. We train two discriminators $D^{(\text{pln})}$ and $D^{(\text{str})}$ that directly receive $z^{(\text{pln})}$ and $z^{(\text{str})}$, respectively. $D^{(\text{pln})}$ is composed of A sub-discriminators where each discriminator $D_a^{(\text{pln})}$ predicts a signal $I_a^{(\text{pln})}$ for each expressive attribute a from $z_a^{(\text{pln})} \in \mathbb{R}^{C \times (d^{(\text{pln})}/A)}$, where $z_a^{(\text{pln})}$ is a constituent part of $z^{(\text{pln})}$, and A is the number of expressive attributes. This setting is for a clear disentanglement among the expressive attributes. On the other hand, $D^{(\text{str})}$ predicts the signal $I^{(\text{str})}$ at once for all expressive attributes that belong to the same musical structure. All discriminators are jointly trained with the generative model, and the costs $\mathcal{L}_{\text{pln}}$ and $\mathcal{L}_{\text{str}}$ are minimized

as $\mathcal{L}_{\text{pln}} = \frac{1}{A}\sum_a \text{MSE}(D_a^{(\text{pln})}(z_a^{(\text{pln})}), I_a^{(\text{pln})})$ and $\mathcal{L}_{\text{str}} = \text{MSE}(D^{(\text{str})}(z^{(\text{str})}), I^{(\text{str})})$, respectively.

Factorizing Latent Variables. We further constrain a generator to guarantee that $z^{(\text{pln})}$ delivers correct information regardless of $z^{(\text{str})}$ [39]. During training, we sample a new output $\tilde{x}$ using $z^{(\text{pln})} \sim q_\phi(z^{(\text{pln})}|x)$ and $\tilde{z}^{(\text{str})} \sim p_\theta(z^{(\text{str})})$. Then, we re-infer $\tilde{z}^{(\text{pln})} \sim q_\phi(\tilde{z}^{(\text{pln})}|\tilde{x})$ to estimate the superversory signal $I^{(\text{pln})}$. This prediction loss is backpropagated only through the generator:

$$\mathcal{L}_{\text{fac}} = \frac{1}{A}\sum_a \text{MSE}(D_a^{(\text{pln})}(\tilde{z}_a^{(\text{pln})}), I_a^{(\text{pln})}) \quad (5)$$

Aligning Latent Variables with Factors. Finally, we enable the "sliding-fader" control of the expressive attributes [28]. To this end, we employ the regularization loss proposed by Pati *et al.* [27] that aligns specific dimensions of $z^{(\text{pln})}$ with the target expressive attributes. This method assumes that a latent representation can be disentangled through its monotonic relationship with a target attribute. Let d_i and d_j be a target dimension d of ith and jth latent representations, respectively, where $d \in z_a^{(\text{pln})}$, $i, j \in [1, M]$, and M is the size of a mini-batch. A distance matrix $\mathcal{D}_d$ is computed between d_i and d_j within a mini-batch, where $\mathcal{D}_d = d_i - d_j$. A similar distance matrix $\mathcal{D}_a$ is computed for the two target attribute values a_i and a_j. We minimize a MSE between $\mathcal{D}_d$ and $\mathcal{D}_a$ as follows:

$$\mathcal{L}_{\text{reg}} = \text{MSE}(\tanh(\mathcal{D}_d), \text{sign}(\mathcal{D}_a)) \quad (6)$$

2.5 Overall Objective

The overall objective of our proposed network aims to generate realistic performance features with properly disentangled representations for the intended factors:

$$\mathcal{L} = \mathcal{L}_{\text{VAE}} + \lambda_{\text{pln}}\mathcal{L}_{\text{pln}} + \lambda_{\text{str}}\mathcal{L}_{\text{str}} + \lambda_{\text{fac}}\mathcal{L}_{\text{fac}} + \lambda_{\text{reg}}\mathcal{L}_{\text{reg}} \quad (7)$$

where λ_{pln}, λ_{str}, λ_{fac}, and λ_{reg} are hyperparameters for balancing the importance of the loss terms.

3. EXPERIMENTAL SETUPS

3.1 Dataset and Implementation

We use Yamaha e-Competition Dataset [8] and Vienna 4x22 Piano Corpus [40]. From these datasets, we collect 356 performances of 34 pieces by Frédéric Chopin, which have been representative research subjects for analyzing the Western musical expression [6, 22, 41, 42]. We use 30 pieces (108,738 batches) for training and the rest for testing. To verify the generality of model performances, we also collect the external dataset from ASAP dataset [43]. We use 116 performances for 23 pieces by 10 composers who represent various eras of Western music. For subjective evaluation, we collect 42 songs of non-Classical songs from online source [2] which are less constrained to written expression than most Classical excerpts.

[2] http://www.ambrosepianotabs.com/page/library

We basically follow Jeong *et al.* [8] to compute the input features from the aligned pairs of performance and score data. We set MIDI velocities and Beat Per Minute (BPM) of all notes in the score data to be 64 and 120, respectively. We also remove any grace notes for simplicity and manually correct any errors. The performance features are further normalized into a range from -1 to 1 for training. We use an ADAM optimizer [44] with an initial learning rate of 1e-5, which is reduced by 5% every epoch during backpropagation. We empirically set λ_{pln}, λ_{str}, λ_{fac}, and λ_{reg} to be 1000, 100, 1, 10, respectively. We set a degree of the polynomial function computing $I^{(\text{pln})}$ as 4 through an ablation study described in the supplementary material.

3.2 Comparative Methods

To the best of our knowledge, there is no existing method that does not intentionally follow the written guidelines in the musical score. Therefore, we use variants of our proposed network as comparing methods that differ in model architecture: **Notewise** denotes the proposed model without the hierarchical learning. **CVAE** denotes a variant of Notewise where $z^{(\text{pln})}$ is substituted with the supervisory signal $I^{(\text{pln})}$. We also conduct an ablation study that investigates necessity of the four loss terms.

4. EVALUATION

We evaluate the proposed network in terms of both objective and subjective criteria.

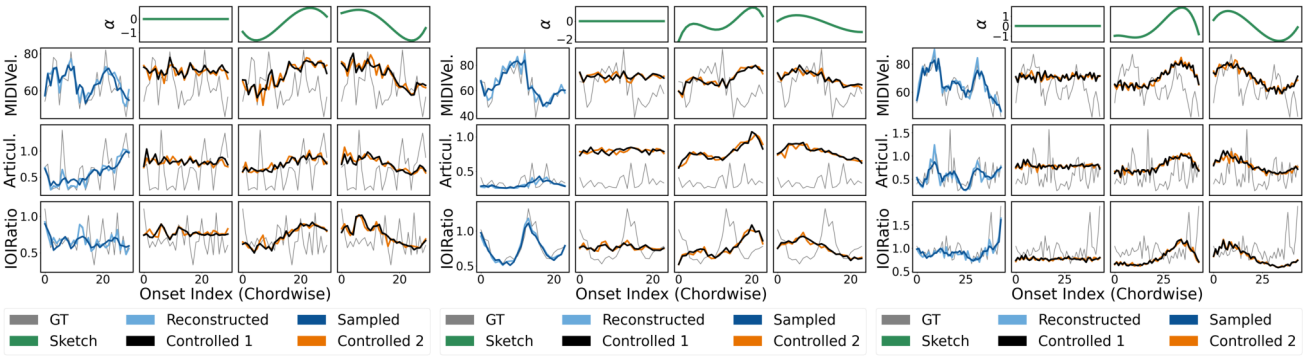
4.1 Generation Quality

We compute Pearson's correlation coefficients between the reconstructed or generated samples and human piano performances [6, 9, 11, 19]. We first measure the reconstruction quality of the test samples ("R_{recon}"). Then, we evaluate the samples generated from $\tilde{z}^{(\text{str})} \sim p_\theta(z^{(\text{str})})$ and either of : 1) $z^{(\text{pln})} \sim q_\phi(z^{(\text{pln})}|x)$ ("$\text{R}_{x|\text{pln}}$") and 2) $z_0^{(\text{pln})} \sim q_\phi(z_0^{(\text{pln})}|x_0)$ ("$\text{R}_{x|\text{pln}_0}$"), where x_0 is a zero matrix.

The results are shown in Table 1. Notewise shows the best scores in both datasets, and our method outperforms CVAE in R_{recon}. It indicates that our proposed architecture where a latent representation is used instead of a direct condition is generally good at reconstructing the human data. When using the randomly sampled $\tilde{z}^{(\text{str})}$, our method and the model without $\mathcal{L}_{\text{reg}}$ show stable scores compared to other baseline models. The model without $\mathcal{L}_{\text{reg}}$ also shows the highest scores in $\text{R}_{x|\text{pln}}$ for both datasets. It indicates that $\mathcal{L}_{\text{reg}}$ may contribute the least to generation power among other loss terms. CVAE and the model only with $\mathcal{L}^{(\text{pln})}$ also show high scores in $\text{R}_{x|\text{pln}_0}$. This may be due to the posterior collapse that makes the decoder depends mostly on the score condition [45], which is demonstrated in the supplementary material.

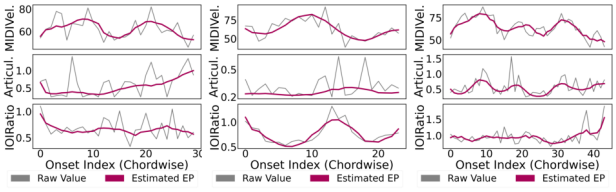
4.2 Disentangling Latent Representations

We verify whether the latent representations are well-disentangled by appropriate information [24]. To this



(a) (b) (c)

Figure 2: Qualitative samples for the proposed system. Light-blue, blue and gray lines denote the reconstructed results, sampled results from the inferred $z^{(\text{pln})}$, and their ground truths, respectively; black and orange lines denote the controlled results that are generated from different random $\tilde{z}^{(\text{str})}$; and green lines denote the "sketch" values, or α, that are inserted to $z^{(\text{pln})}$. The samples demonstrate three excerpts that are: (a) Haydn's Keyboard Sonata, Hob. XVI:39, 3rd movement, mm. 53-56; (b) Schubert's Impromptu, Op. 90, No. 4, mm. 149-152; and (c) Balakirev's Islamey, Op. 18, mm. 29-32.



(a) (b) (c)

Figure 3: Qualitative results for estimating the explicit planning from raw piano performances. Pink and gray lines denote the estimated contours and raw performance parameters, respectively. The results in (a), (b), and (c) are from the same excerpts for (a), (b), and (c) in Figure 2, respectively.

Table 1: Evaluation results for the generation quality. The higher score is the better.

end, each model infers the latent representations $z^{(\text{pln})}$ and $z^{(\text{str})}$ from the test sets. Each model also randomly samples $\tilde{z}^{(\text{str})}$ and infers $z_0^{(\text{pln})} \sim q_\phi(z^{(\text{pln})}|x_0)$. We use $z_0^{(\text{pln})}$ to measure the structural attribute, since $z_0^{(\text{pln})}$ represents a flat expression where the structural attribute can be solely exposed. Each model generates new outputs as $x^{(\text{pln})} \sim p_\theta(x^{(\text{pln})}|z^{(\text{pln})}, \tilde{z}^{(\text{str})}, y)$ and $x^{(\text{str})} \sim p_\theta(x^{(\text{str})}|z_0^{(\text{pln})}, z^{(\text{str})}, y)$. Then, we compute a new signal $\tilde{I}^{(\text{pln})}$ from $x^{(\text{pln})}$ using the polynomial regression. The MSE values are calculated as $\text{MSE}_\text{p} = \text{MSE}(\tilde{I}^{(\text{pln})}, I^{(\text{pln})})$ and $\text{MSE}_\text{s} = \text{MSE}(x^{(\text{str})}, k - I^{(\text{pln})})$.

Table 3: Evaluation results for the controllability of the expressive attributes. C, R, and L denotes consistency, restrictiveness, and linearity, respectively. Each score is the average score for the expressive attributes.

Table 2 shows that our method achieves the best scores in all metrics for both datasets. This confirms that our proposed system can learn the latent representations that reflect the intended attributes. Notewise and the model without $\mathcal{L}_{\text{reg}}$ also show the robust scores compared to other baseline models. It indicates that using the notewise modeling alone is still relevant for achieving appropriate representations. It also implies that $\mathcal{L}_{\text{reg}}$ may not contribute to the disentanglement as much as other loss terms.

4.3 Controllability of Expressive Attributes

We sample a new input $\bar{x}$ where entries of each feature are constant across time. Then, each model infers

Metric	Winning Rate (Human-likeness)		
Group	T	UT	Overall
Notewise	0.317(±0.223)	0.541(±0.316)	0.493(±0.309)
CVAE	**0.467(±0.356)**	0.477(±0.342)	0.475(±0.338)
Ours	0.417(±0.256)	**0.555(±0.256)**	**0.525(±0.258)**

Table 4: Evaluation results for the winning rate in terms of human-likeness. T, UT, and Overall denote musically trained, untrained, and all groups, respectively.

$\bar{z}^{(\text{pln})} \sim q_\phi(\bar{z}^{(\text{pln})}|\bar{x})$. We control each attribute by varying dimension values of $\bar{z}^{(\text{pln})}$ following Tan *et al.* [28] and examine the new samples generated from $\bar{z}^{(\text{pln})}$. We leverage the existing metrics to measure the controllability of each model [28]: *Consistency* ("C") measures consistency across samples in terms of their controlled attributes; *restrictiveness* ("R") measures how much the uncontrolled attributes maintain their flatness over time; and *linearity* ("L") measures how much the controlled attributes are correlated with the corresponding latent dimensions. We average over the three expressive attributes–dynamics, articulation, and tempo–into one score for each metric.

Table 3 demonstrates that our system shows the best scores in consistency and linearity in both internal and external datasets. This indicates that our proposed method can robustly control the latent representation $z^{(\text{pln})}$ in intended way. The model without $\mathcal{L}_{\text{reg}}$ outperforms our method in restrictiveness. It indicates that the uncontrolled attributes by this model are the least interfered by the controlled attribute. However, its scores on consistency and linearity are lower than ours. It confirms that $\mathcal{L}_{\text{reg}}$ promotes linear control of the target attributes.

4.4 Subjective Evaluation

We conduct a listening test to compare the proposed model architecture to Notewise and CVAE. We qualitatively evaluate the base quality of the samples that have flat expressions, so that quality judgments are independent of any preference of arbitrary explicit planning. We generate each sample using $z_0^{(\text{pln})}$. A listening test is composed of 30 trials where each participant chooses a more "human-like" sample out of the generated sample and its plain MIDI [9]. Both samples have the same length which is a maximum of 15 seconds, rendered with TiMidity++ [3] without any pedal effect. *Human-likeness* denotes how similar the sample is to an actual piano performance that commonly appears in popular music. A total of 28 participants are involved, and 6 participants are professionally trained in music.

The results are demonstrated in Table 4. We measure a *winning rate*, a rate of winning over the plain MIDI, and a *top-ranking rate*, a rate of being the highest rank among the three models in terms of winning rate. These metrics are further explained in the supplementary material. The results show that musically *trained* ("T") and *untrained* ("UT") groups show the different tendency of each other: in the trained group, CVAE shows the best winning rate, and our method gets the best top-ranking rate; in the untrained group, our method shows the highest winning rate, whereas Notewise is top-ranked most frequently. We note that our system reveals smaller variances than those of CVAE and Notewise of the musically trained and untrained groups in the winning rate, respectively. Moreover, our system receives the highest overall scores for both metrics. It indicates that our system can be stably perceived more human-like than the plain MIDI compared to other baseline models.

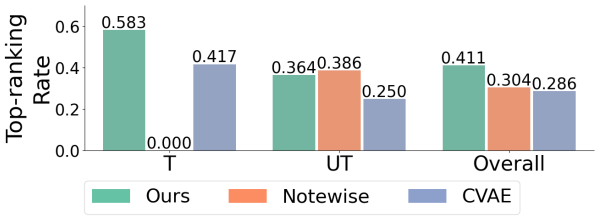

Figure 4: Evaluation results for the top-ranking rate. T, UT, and Overall denote musically trained, untrained, and all groups, respectively.

4.5 Qualitative Examples

Our system can render new piano performances from the scratch given a musical score. It can directly generate expressive parameters from the randomly sampled $\tilde{z}^{(\text{pln})} \sim p_\theta(z^{(\text{pln})})$ and $\tilde{z}^{(\text{str})} \sim p_\theta(z^{(\text{str})})$. We note that $\tilde{z}^{(\text{pln})}$ does not have temporal dependency: each $\tilde{z}_c^{(\text{pln})}$ is sampled independently of $\tilde{z}_{c-1}^{(\text{pln})}$. Hence, we need to insert specific values $\{\alpha^{(c)}\}_{c=1}^{C}$, which we call as "smooth sketches", into the target dimensions of $z^{(\text{pln})}$ if any temporal dependency of explicit planning is necessary. Figure 2 shows that the controlled parameters are greatly correlated with α, while their local characteristics follow those of the ground truth. In addition, the black and orange lines together demonstrate granular variety in the parameters induced by different $\tilde{z}^{(\text{str})}$ for the same musical structure. Moreover, Figure 3 shows that our system can estimate explicit planning from arbitrary human performances, indicating that our system can derive relevant information on explicit planning from the unseen data.

5. CONCLUSION

We propose a system that can render expressive piano performance with flexible control of musical expression. We attempt to achieve representations for the explicit planning and structural attribute through self-supervised learning objectives. We also leverage the two-step modeling of two hierarchical units for an intuitive generation. Experimental results confirm that our system shows stable generation quality, disentangles the target representations, and controls all expressive attributes independently of each other. Future work can be improving our system using a larger dataset for various genres and composers. We can also further compare our system with recent piano-rendering models [8] to investigate any connections between a performer's explicit planning and a composer's intent.

6. ACKNOWLEDGMENTS

We deeply appreciate Dasaem Jeong, Taegyun Kwon, and Juhan Nam for giving technical support to initiate this research. We also especially appreciate Hyeong-Seok Choi for providing critical feedback on the model architecture and evaluation. We greatly appreciate You Jin Choi and all of my colleagues who gave great help with respect to the listening test.

ABSTRACT

As music has become more available especially on music streaming platforms, people have started to have distinct preferences to fit to their varying listening situations, also known as context. Hence, there has been a growing interest in considering the user's situation when recommending music to users. Previous works have proposed user-aware autotaggers to infer situation-related tags from music content and user's global listening preferences. However, in a practical music retrieval system, the autotagger could be only used by assuming that the context class is explicitly provided by the user. In this work, for designing a fully automatised music retrieval system, we propose to disambiguate the user's listening information from their stream data. Namely, we propose a system which can generate a situational playlist for a user at a certain time 1) by leveraging user-aware music autotaggers, and 2) by automatically inferring the user's situation from stream data (e.g. device, network) and user's general profile information (e.g. age). Experiments show that such a context-aware personalized music retrieval system is feasible, but the performance decreases in the case of new users, new tracks or when the number of context classes increases.

1. INTRODUCTION

Since the invention of recorded music, people have been shifting from consuming music as a main activity in a live setting, to using music as a background activity as they go through the day. With the growing availability of music on streaming platforms, people developed distinct preferences for the varying listening situations, also known as context [1]. Consequently, there has been a growing interest in considering the user's situation when automatically recommending music to users.

Previous works have proposed user-aware autotaggers to infer situation-related tags from music content and user's global listening preferences [2]. However, in a practical music retrieval system, the autotagger could be only used by assuming that the context class is explicitly provided by the user. In this work, we perform a study to evaluate the feasibility of inferring the listening situation. The listening situation for our system is an activity, location, or time that is influencing the listener's preferences.

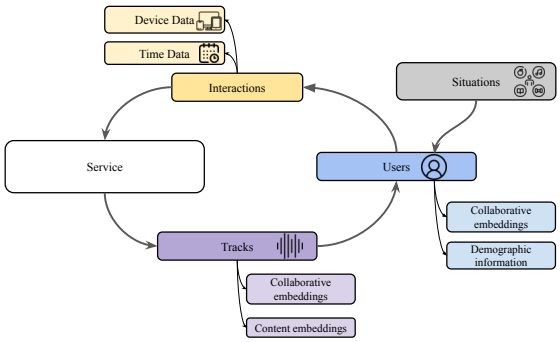

Figure 1. The available data to online music streaming services.

The process of music streaming from the perspective of our proposed approach can be found in Figure 1. We find that the music service is informed of the users, their track history, plus their past and current interactions with the service, i.e. the device and time data sent during an active session. However, the service is unaware of the influencing listening situation. Our goal is to utilize the available information for the service to infer the listening situation and the suitable tracks for the inferred situation. We propose an approach that infers the potential context from the user interactions in near real time, while the tagging of tracks with their potential listening situation happens in the background using autotaggers. Both systems are user-aware.

Our contributions in this paper are: 1) a large dataset of tracks, device data, and user embeddings labeled with their situational use through a rigorous labelling pipeline; 2) an extended evaluation of music autotaggers in predicting personalized situational tags in various scenarios; 3) a simple, yet effective model that ranks the potential listening situations for a given user based on the transmitted data from the device to the service.

2. RELATED WORK

Our proposed approach is related to two different problems: music autotagging with contextual tags, and instant

Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

prediction of the user's listening situation. Previous work has already showed that listening situation (i.e. context) has a strong influence on the user's preferences [1, 3–5]. Hence, context has become an important factor for reaching a personalized user experience [6].

On one hand, music content is highly complex and is often challenging to be analyzed and described in human readable terms. This missing link between the content of the music and a set of semantic descriptors is referred to as the "semantic gap" [7]. One common way, which is often used when searching for or organising music, is the intended listening situation [8]. Unlike most tags that depend solely on the music content, certain tags depend also on the user [9, 10]. There has been a recent work on predicting personalized situation-related tags from music content and user embeddings [2], which we adopt here too.

On the other hand, the listening situation, e.g. activity or location, can change frequently, which leads to changes in user preferences. Explicitly inferring the listening situation is a challenging task that has only been studied on a small scale [11]. We aim at addressing this missing link by performing an extensive study on predicting the listening situation using available device data. In order to employ the personalized autotagging approach in an actual real-world setting, it is also important to be able to predict when a specific listening situation is being experienced.

3. OBJECTIVE AND PROPOSED APPROACH

A *session* consists of a sequence of audio-tracks a a given user u is listening to over time t on a music streaming service in a continuous time span [1]. A session is therefore defined as a sequence of *streams* which are each a tuple (audio-track a, user u, device data $\mathbf{d}_u^{(t)}$).

A *situational (or contextual) session* is a session resulting from listening to tracks in a certain situation (or context) c such as "gym". However, in our case, in order to gather a ground-truth dataset, we consider that a situational session can also result from listening to a playlist that contains a context-related keyword in the title [2]. A situational (or contextual) session is defined as a sequence of tuples (audio-track a, user u, device data $\mathbf{d}_u^{(t)}$, situation c).

Our objectives is to propose for a given user u a session (sequence of audio-tracks a) that fits their current situation c. However, since we don't know its current situation c we estimate it based on its device data $\mathbf{d}_u^{(t)}$ (such as the time of the day, day of the week, or type of network connections).

3.1 Proposed approach

To do so, we first estimate for each pair audio-track/user (a, u) its situation $\hat{c}_{a,u}$. In other words, we estimate in which situation c the user u would intend to use the track a. This is done using an Audio+User based Situation Prediction (`auSP`) trained to estimate situation tags c given as input a pair (audio-track a, user u). This is done offline on the server side and stored in a database.

We then estimate in real-time (with a lightweight model on the client side) for a given user u and the transmitted data from its device to the service $\mathbf{d}_u^{(t)}$, its potential current situation $\hat{c}_{d,u}$. This is done using a Device+User based Situation Prediction (`duSP`) trained to estimate situation tags c given as input a pair (device-data $\mathbf{d}_u^{(t)}$, user u). `duSP` provides us with a list of the most likely situations $\hat{c}_{d,u}$ (ranked from the most to the less likely).

Finally, to create the situational playlist, we simply select the audio tracks a for which situation $\hat{c}_{a,u}$ matches the most-likely current situations of the user $\hat{c}_{d,u}$.

Figure 2 indicates the overall architecture.

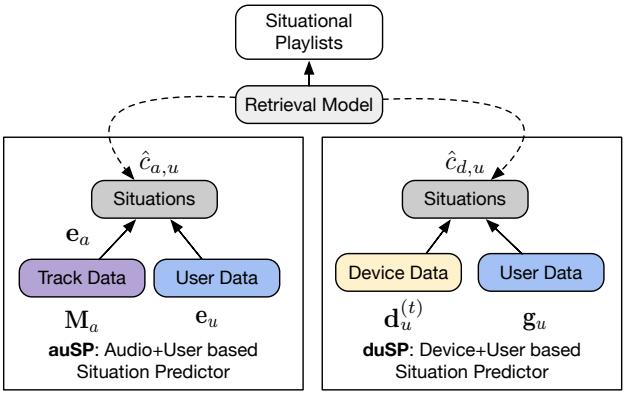

Figure 2. Overview of the system to generate a situational playlist. The left side (`auSP`) tags each track/user pair with a situational tag. The right side (`duSP`) ranks the potential situations for a device/user pair to be presented to the user.

3.2 Data description

We first describe what are exactly the data for the tracks a, the users u and the devices.

Track data $\mathbf{M}_a$. For each audio-track a, we retrieve its 30 s. snippet from the Deezer API. We represent a by its 96 Mel-bands $\times$ 646 frames matrix $\mathbf{M}_a$.

User data $\mathbf{e_u}$ and $\mathbf{g}_u$. Representing the users can be achieved through various versatile techniques. Consistent with our requirements (lightweight model and preserving privacy), we choose to represent the users using the basic data available during streaming. We use two different representations of the user that will be used for estimating $\hat{c}_{a,u}$ and $\hat{c}_{d,u}$ respectively.

For the `auSP` (estimation of $\hat{c}_{a,u}$) we use a user embedding $\mathbf{e_u}$. Similar to previous works on `auSP`, we used the users' listening history to derive user embeddings that encode their listening preferences. We compute these embeddings through matrix factorization of the user/track interactions matrix, leading to a 128-d embedding vector per user, which in commonly used to generate representations [13]. The constructed matrix uses all the tracks available in the catalogue to model the user preferences, i.e. it

[1] without any break longer than a pre-defined gap, defined here as 20 minutes as proposed by [5]

[2] The underlying assumption is that if the user started streaming a playlist with a certain title related to a situation (or context), most likely the intention of the user was to play something suitable for that situation (or context) [12].

Table 1. Summary of the notations

Symbol	Definition	Dimension
a	an audio track	
$\mathbf{M}_a$	Mel-spectrogram of a	$\mathbb{R}^{96\times646}$
$\mathbf{e}_a$	Embedding of a	$\mathbb{R}^{256}$
u	a user	
$\mathbf{e}_u$	Embedding of u	$\mathbb{R}^{128}$
$\mathbf{g}_u$	Demographics data of u	$\mathbb{R}^3$
$\mathbf{d}_u^{(t)}$	Device data of u at time t	$\mathbb{R}^8$
c	a situation (or context)	
s	a stream, a tuple $(a, u, \mathbf{d}_u^{(t)}, c)$	

is not computed exclusively with the tracks included in our dataset. The computed embeddings will be published with the dataset for reproducibility.

For the `duSP` (estimation of $\hat{c}_{d,u}$), we use the basic demographic data $\mathbf{g}_u$ of the user recorded during registration. This data is composed of: `|age,country,gender|`. While this data selection is prone to errors and short of fully representing the users, it is consistent with our requirements of using basic always-available data.

Device data $\mathbf{d}_u^{(t)}$. We collect only basic data sent by the device to the service and selected those that deemed relevant to the situation prediction. The data are: the time stamp (in local time), day of the week, device used and network used. Additionally, we extend the time/day data with circular representation of the time and day similar to the one used in [14]. The final feature vector representing device data is made of 8 features: `linear-time, linear-day, circular-time-X, circular-time-Y, circular-day-X, circular-day-Y, device-type, network-type`. The `device-type` can be: `mobile`, `desktop` (e.g. a laptop), or `tablet`. The `network-type` can be: `mobile` (a connection through cellular data), `wifi` (a WiFi connection), `LAN` (a connection through wired Ethernet), or `plane` (an offline stream from a device without a connection).

4. COLLECTING THE DATA

Pichl et al. and Ibrahim et al. proposed methods for labelling streaming sessions with a situational tag by leveraging playlist titles [2, 12]. Although sometimes prone to errors and false positives, playlist titles provide an appropriate proxy for labelling streams with tags [2, 12]. Users create playlists with a common theme according to their use [12]. One common theme of these playlists is the listening situation.

First, we collected a set of situational keywords used previously in the literature [1, 11, 15]. We extended these keywords by adding synonyms and hashtags that are frequently used on Twitter to refer to music listening. Afterwards, we retrieve from all public playlists from Deezer [3], an online music streaming service we were given access to, those playlists that include any of the keywords in their "stemmed" title. We then filtered out playlists that contained more than 100 tracks [4] or where a single artist or album represented more than 25% of the playlist, similar to [2].

From the extensive list of situational keywords and their corresponding playlists, we settled on three different subsets with an increasing number C of situational tags (4, 8, and 12): `work, gym, party, sleep | morning, run, night, dance | car, train, relax, club`.

These tags were selected by popularity [5]. We used these situations as independent tags without attempting to merge potentially similar activities and places (e.g. "party" and "dance"). Working with three situational tag sets (of increasing C) allowed us to observe how the system performs as the complexity of the problem increases.

We then focused on the users who actively listened to these playlists and retrieve the device data of those users while they were actively listening to the playlist. This resulted in a set of streams each described by an audio-track a, a user u, a playlist with a situational keyword c in the title, along with the device data $\mathbf{d}_u^{(t)}$ sent during this stream. Note that an audio-track/user/device triplet have a joint tag, none of them are tagged individually.

To ensure high quality data, we selected the month of August 2019 for inspection, because this period had more stable use patterns, before the Covid-19 pandemic. We had access to data from two locations: France and Brazil. These two locations were provided because they have the most active users in Deezer, while being in two distinctive time zones and seasons. This allowed us to perform our study on diverse data with different sources and patterns. We release the dataset [6] along with the code [7].

4.1 Dataset Analysis

As a sanity check on the collected data, we plot the distribution of the situations c across the different device-data. Figure 3 shows the ratio of the used `network-type` to connect to the service across situations c. We observe variations that correspond to what is expected from each situation, i.e. outdoors vs. indoors. However, we also find certain networks that do not match the expectations, e.g. LAN connections in a car situation, which represents noise in the dataset that can be a continuation of already existing sessions that moved indoors. Figure 4 represents the used `device-type` across situations c. We notice that most users overwhelmingly use mobile device in most cases, with small variations that also match expectations of indoor and outdoor situations. Finally, Figure 5 shows the distribution of all situations for each hour of the day. Similarly, we find predictable patterns for each situation ranging from night-related situation in the early hours that gradually progress as the time passes. These patterns support

the hypothesis of using playlist titles as proxy for inferring the actual listening situation.

5. DETAILED MODELS DESCRIPTION

5.1 Audio+User based Situation Prediction (`auSP`)

The `auSP` estimates the probability of each situation $c \in \{1 \dots C\}$ given a pair (track a represented by $\mathbf{M}_a$, user u represented by e_u): $P(c|\mathbf{M}_a, \mathbf{e_u})$. It is implemented as a Deep Neural Network $\hat{c}_{a,u} = f_\theta(\mathbf{M}_a, \mathbf{e}_u)$ with softmax output and trainable parameters θ. To train it we use the set of training streams represented as tuples $(\mathbf{M}_a, \mathbf{e}_u, c)$ We train it by minimizing the categorical cross-entropy $\mathcal{L}(\hat{\mathbf{c}}_{a,u}, \mathbf{c}, \theta)$ where $\hat{\mathbf{c}}_{a,u}$ is the estimated probability and $\mathbf{c}$ the one-hot-encoded ground-truth.

Practical implementation. The **audio input**, $\mathbf{M}_a$, is passed to a batch normalization layer then to 4 layers each made of a convolutional (CNN) and a Max-pooling operation. The CNNs have various numbers of filters (32, 64, 128, 256) but each with the same size (3x3). They are each followed by a ReLU. All Max-poolings are (2x2). The flattened output of the last CNN layer is passed to a fully connected (FC) layer with 256 units followed by a ReLU. The output of the audio branch $\mathbf{e}_a$ is a 256-d audio embedding vector $\mathbf{e_a}$. The **user input**, $\mathbf{e}_u$, is processed through 2 FC layers each with a ReLU. This output is then concatenated with $\mathbf{e}_a$ and passed to a FC layer with ReLU activation, and a dropout (with 0.3 ratio) for regularization. The final layer is made of C output units with a Softmax activation function, where C is the number of situations to be predicted. We train the model until convergence by minimizing the categorical cross entropy, optimized with Adam [16] and a learning rate initialized to 0.1 with an exponential decay every 1000 iterations.

5.2 Device+User based Situation Prediction (`duSP`)

The `duSP` estimates the probability of each situation $c \in \{1 \dots C\}$ given a pair (device-data d represented by $\mathbf{d}_u^{(t)}$, user u represented by $\mathbf{g}_u$): $P(c|\mathbf{d}_u^{(t)}, \mathbf{g}_u)$. It is implemented as a function $f_\gamma(\mathbf{d}_u^{(t)}, \mathbf{g_u})$ with Softmax output and trainable parameters γ. To train it we use the set of training streams represented as tuples $(\mathbf{g}_u, \mathbf{d}_u^{(t)}, c)$

Practical implementation. In choosing a real-time "light" `duSP` model, we prioritize the computational complexity requirements over accuracy. The low dimensional input features (11-d = 8 device features + 3 demographic features) already provide a strong case for the investigated models. For our implementation, we experimented with different classifiers: Decision Trees, K-Nearest Neighbors, and eXtreme Gradient Boosting (XGBoost) [17]. While all gave comparable results, we chose XGBoost for its consistent performance across splits and different evaluation scenarios. Similar to the autotagger model, the output predictions depend on the number C of situations in the dataset.

6. EVALUATION

We evaluate here the performance of our system which aims at proposing for a given user u a session (sequence of audio-tracks a) that fits their current situation c. For this, we first evaluate the performance of the two branches of our system (`auSP` and `duSP`) to correctly estimate the situation c. We evaluate this using various numbers of situations: $C \in \{4, 8, 12\}$. To evaluate the `auSP`, we use the common AUC (Area Under Roc Curve) and Accuracy performance measures. To evaluate the `duSP`, we use the Accuracy but also the Accuracy@K. This measures the capability of `duSP` to include the correct situation in the top K predictions. We then evaluate the global system by measuring the overlap of correct predictions between the `auSP` and `duSP` branches. This accuracy can be interpreted as the ratio of existing streams that would have occurred in these sessions if the playlists were generated with this system instead.

6.1 Scenario

We approach the evaluation of this system from two different perspectives: 1) evaluating the system on its capability of learning and generalizing, 2) evaluating the proposed system in a stable use-case with frequent users/tracks.

We simulate these scenarios through a different split criteria for the test-set. Let the full set of streams in our collected dataset S, where each stream s has a user u and a track a. We will be referring to the training-set as S_{train}, the test-set as S_{test}, the set of unique users in training and

testing as U_{train} and U_{test} respectively, and similarly the unique audio-tracks in the splits as A_{train} and A_{test}.

To evaluate the system intelligence and fit to the data, we restrict the evaluation splits to include either: 1) new users (cold-user case): $S_{test} = \{s|u \notin U_{train}, a \in A_{train}\}$, 2) new tracks (cold-track case): $S_{test} = \{s|u \in U_{train}, a \notin A_{train}\}$. We exclude the specific case of both new tracks and new users because splitting the data with only new user/track pairs in the testset is difficult and rare to find. Additionally, recommending a new track to a new user is not a common nor practical scenario to use for evaluating a system.

To evaluate how the system would perform in a regular use-case (warm case): $S_{test} = \{s|u \in U_{train}, a \in A_{train}, s \notin S_{train}\}$. The regular use-case does not restrict the system to neither new users nor tracks. However, the test-set contains exclusively new streams, i.e. (user/track) pairs, not present in the training-set. The evaluation of this regular use-case is relatively complex and includes several entwined evaluation criteria. The goal is to compare the overlap of generated sessions with groundtruth sessions.

6.1.1 auSP Evaluation

The results for the auSP can be found in Table 2.

As shown, the model can reach satisfying performance relative to the evaluation scenario. In terms of AUC, the model's fit for both new users and tracks in the cold user/track splits is not significantly impaired compared to the warm case. The performance decreases evidently as the problem gets harder with more situations C to tag, though in some cases it increases given the increase of dataset size from additional situations. In terms of accuracy, the model's performance in the intended use-case, i.e. warm case, is satisfying (Accuracy above 70). That is to say, the system can correctly tag around two thirds of the user/track listen streams with their correct situational use, when it has seen the user or the track before, but not jointly.

Note that this accuracy was computed by selecting the most probable situation from the predictions. While the high values of AUC (above 0.94) suggest a threshold optimization is needed for each class, in real use-case we do not necessarily need a threshold. The prediction probability could be used directly to retrieve tracks, e.g. by ranking tracks with the prediction probabilities and include top ranked tracks in the generated sessions. However, this max-probability threshold is needed for further evaluations with the situation predictor and with the sequential retrieval model.

Additionally, Figure 6 represents the confusion matrix obtained in the $C = 12$ and warm case.

6.1.2 duSP Evaluation

The results for the duSP can be found in Table 3. We find that predicting the situation for new users becomes noticeably harder. In the case of C=12 situations, the system was able to correctly predict the situation for only 25% of the streams. However, when the system is allowed to make multiple guesses (Accuracy@3), the accuracy evidently increases. In the case where the user is to make the last decision, the system is able to include the correct situation in the top 3 suggestions 96%, 80%, and 68% in the cases of C =4, 8, and 12 situations respectively. The choice of K, when evaluating with accuracy@K, can be obviously changed, and the performance will increase as K increases. We choose to display the results for K=3 since 3 is around the number of visible items in the carousels displayed by most streaming services on the suggestions screen on mobile devices.

Additionally, Figure 7 shows the confusion matrix obtained in the C=12 situations and warm case. We observe that the confusion is mostly coherent with the statistic shown earlier of the distribution of situations with the device data. Situations that are likely to originate with similar device data are harder to discriminate than the rest. For example, we observe a cluster of night-related situations including night, sleep, and relax situations. Similarly, outdoors situation are also often confused together. Discriminating those situations is hindered by the limited data available. However, the convenience of recommending top k situations provides as easy solution to further discriminate between these similar situations.

Table 2. Results of the auSP evaluated with AUC and Accuracy in the three evaluation protocol splits (cold-user, cold-track, and warm case) and the three subsets of situations (4, 8, and 12). The results are shown as mean(std.).

C	AUC		
	Cold User	Cold Track	Warm
4	0.889 (.009)	0.873 (.013)	0.959 (.013)
8	0.815 (.005)	0.866 (.007)	0.945 (.007)
12	0.852 (.004)	0.824 (.012)	0.941 (.012)
C	Accuracy		
	Cold User	Cold Track	Warm
4	69.72 (1.07)	63.77 (2.33)	83.75 (2.33)
8	47.56 (0.53)	52.44 (2.31)	70.81 (1.45)
12	52.68 (1.25)	37.61 (3.47)	69.14 (3.79)

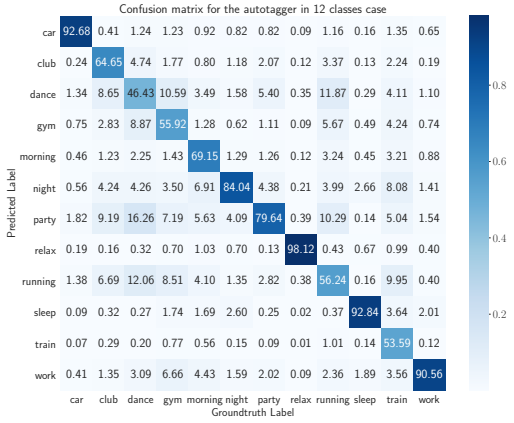

Figure 6. Confusion Matrix of the auSP in the case C=12 and warm case

Table 3. Results of the duSP evaluated with Accuracy and Accuracy@3 in the three evaluation protocol splits (cold-user, cold-track, and warm case) and the three subsets of situations (4, 8, and 12). The results are shown as mean(std.).

C	Accuracy		Accuracy @3	
	Cold User	Warm	Cold User	Warm
4	47.46 (0.98)	66.96 (0.39)	90.51 (0.31)	96.3 (0.1)
8	30.95 (0.89)	49.23 (0.16)	64.11 (1.42)	79.62 (0.13)
12	25.00 (0.29)	39.92 (0.13)	52.04 (0.61)	67.62 (0.21)

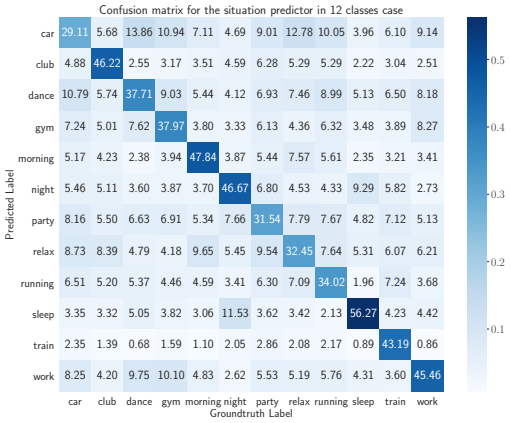

Figure 7. Confusion Matrix of the duSP with C=12 and warm case

Finally, to evaluate the challenge in classifying situations from multiple sources, we compare between the evaluation results in each location (France, Brazil) separately. We compare between two different cases: 1) a model trained globally on the data from both locations but tested locally, 2) a model trained locally on each location independently and tested on the corresponding location. Table 4 shows the results for this evaluation setting. We find that training the models locally slightly improves the results, but not significantly. This suggests that using a single unique model for all locations gives comparable results to using multiple local models. We also observe a clear distinction in the accuracy between the two locations, where Brazil scores higher than France in all cases. This is due to the larger number of users in our dataset who are in France, i.e. there are more users with more distinct patterns in the France case.

Table 4. Evaluation results of the globally and locally trained models for each of the two locations in our dataset, France and Brazil, evaluated with accuracy at each subset of situations in the warm case. The results are shown as mean(std.).

C	France		Brazil	
	Global	Local	Global	Local
4	53.4 (0.2)	55.1 (0.2)	59.2 (0.2)	61.7 (0.2)
8	35.8 (0.1)	36.8 (0.1)	45.9 (0.1)	48.2 (0.1)
12	27.6 (0.1)	28.2 (0.1)	39.6 (0.2)	41.8 (0.1)

Table 5. The joint evaluation results of the auSP and duSP and their overlapping predictions evaluated with Accuracy in the three evaluation protocol splits (cold-user, cold-track, and warm case) and the three subsets of situations (4, 8, and 12). The results are shown as mean(std.).

Model	Cold Users	Cold Tracks	Warm Case
	4 Situations		
auSP	69.73 (1.07)	63.78 (2.33)	83.75 (2.33)
duSP	47.46 (0.98)	66.81 (0.35)	67.20 (0.26)
Overlap	36.22 (1.27)	44.60 (1.01)	**58.92** (1.71)
	8 Situations		
auSP	47.56 (0.53)	52.44 (2.31)	70.81 (1.45)
duSP	30.95 (0.89)	49.13 (0.24)	49.35 (0.19)
Overlap	17.77 (0.49)	28.94 (1.24)	39.52 (1.27)
	12 Situations		
auSP	52.68 (1.25)	37.61 (3.47)	69.14 (3.79)
duSP	25.00 (0.29)	39.05 (0.31)	39.19 (0.14)
Overlap	16.19 (0.32)	18.75 (1.63)	31.26 (1.30)

6.1.3 Joint Evaluation

The results for the joint system can be found in Table 5. As we can see, each variable in our evaluation influences the performance of the system. The most influential parameter is the number C of potential situations. As the complexity increases, we find the accuracy of the model decreasing: from 58% in the case C=4 with no new users or tracks to 16% in the case C=12 with cold scenarios. Additionally, we find the expected variation in performance between the cold cases and the warm case of intended use. We observe how the drop in the performance of the auSP and duSP, on new users/tracks, negatively affects the joint system performance.

However, in the harder evaluation case of generating a situational playlists with only 1 guess allowed out of C=12, the proposed system would have been able to include at least a third of the actual listened tracks (31.26%) in those playlists, while pushing them to the user at the exact listened time.

7. CONCLUSION

In this study, we address the problem of the unobserved listening situation which influences the users' preferences. We proposed a two-branch framework to predict when a situation is being experienced based on the device data, while simultaneously autotagging the music tracks with their intended listening situation in a personalized manner. Through the proposed approach, users could access a set of predicted potential situations. These situations are also associated with a set of tracks "likely" to be listened to by the user. This likelihood is estimated using an autotagger trained on predicting the situational use of tracks, given a specific user and his/her listening history. We evaluated each of our system's blocks individually and combined. The evaluation results indicated that the system is capable of learning personalized patterns for users, which can be employed to provide contextual music recommendation.

ABSTRACT

This paper proposes a model that generates a drum track in the audio domain to play along to a user-provided drum-free recording. Specifically, using paired data of drumless tracks and the corresponding human-made drum tracks, we train a Transformer model to improvise the drum part of an unseen drumless recording. We combine two approaches to encode the input audio. First, we train a vector-quantized variational autoencoder (VQ-VAE) to represent the input audio with discrete codes, which can then be readily used in a Transformer. Second, using an audio-domain beat tracking model, we compute beat-related features of the input audio and use them as embeddings in the Transformer. Instead of generating the drum track directly as waveforms, we use a separate VQ-VAE to encode the mel-spectrogram of a drum track into another set of discrete codes, and train the Transformer to predict the sequence of drum-related discrete codes. The output codes are then converted to a mel-spectrogram with a decoder, and then to the waveform with a vocoder. We report both objective and subjective evaluations of variants of the proposed model, demonstrating that the model with beat information generates drum accompaniment that is rhythmically and stylistically consistent with the input audio.

1. INTRODUCTION

Deep generative models for musical audio generation have witnessed great progress in recent years [1–8]. While models for generating symbolic music such as MIDI [9–12] or musical scores [13] focus primarily on the *composition* of musical content, an audio-domain music generation model deals with *sounds* and thereby has extra complexities related to timbre and audio quality. For example, while a model for generating symbolic guitar tabs can simply consider a guitar tab as a sequence of notes [11], a model that generates audio recordings of guitar needs to determine not only the underlying sequence of notes but also the way to render (synthesize) the notes into sounds. Due to the complexities involved, research on deep generative models for musical audio begins with the simpler task of synthesizing individual musical notes [1–3], dispensing the need to consider the composition of notes. Follow-up research [4–6] extends the capability to generating musical passages of a single instrument. The Jukebox model [7] proposed by OpenAI greatly advances the state-of-the-art by being able to, quoting their sentence, "generate high-fidelity and diverse songs with coherence up to multiple minutes." Being trained on a massive collection of audio recordings with the corresponding lyrics but not the symbolic transcriptions of music, Jukebox generates multi-instrument music as raw waveforms directly without an explicit model of the underlying sequence of notes.

This work aims to improve upon Jukebox in two aspects. First, the backbone of Jukebox is a hundred-layer Transformer [14, 15] with billions of parameters that are trained with 1.2 million songs on hundreds of NVIDIA V100 GPUs for weeks at OpenAI, which is hard to reproduce elsewhere. Inspired by a recent Jukebox-like model for singing voice generation called KaraSinger [8], we instead build a light-weight model with only 25 million parameters by working on Mel-spectrograms instead of raw waveforms. Our model is trained with only 457 recordings on a single GeForce GTX 1080 Ti GPU for 2 days.

Second, and more importantly, instead of a fully autonomous model that makes a song from scratch with various instruments, we aim to build a model that can work cooperatively with human, allowing the human partner to come up with the musical audio of *some* instruments as input to the model, and generating in return the musical audio of *some other* instruments to accompany and to complement the user input, completing the song together. Such a model can potentially contribute to human-AI co-creation in songwriting [16] and enable new applications.

In technical terms, our work enhances the controllability of the model by allowing its generation to be steered on a user-provided audio track. It can be viewed as an interesting sequence-to-sequence problem where the model creates a "target sequence" of music that is to be played along to the input "source sequence." Besides requirement on audio quality, the coordination between the source and target sequences in terms of musical aspects such as style, rhythm, and harmony is also of central importance.

We note that, for controllability and the intelligibility of the generated singing, both Jukebox [7] and KaraSinger [8] have a lyrics encoder that allows their generation to be steered on textual lyrics. While being technically similar,

Yang, "JukeDrummer: Conditional Beat-aware Audio-Domain Drum Accompaniment Generation via Transformer VQ-VAE", in *Proc. of the 23rd Int. Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

our *accompaniment generation* task ("audio-to-audio") is different from the lyric-conditioned generation task ("text-to-audio") in that the latter does not need to deal with the coordination between two audio recordings.

Specifically, we consider a *drum accompaniment generation* problem in our implementation, using a "drumless" recording as the input and generating as the output a drum track that involves the use of an entire drum kit. We use this as an example task to investigate the audio-domain accompaniment generation problem out of the following reasons. First, datasets used in musical source separation [17] usually consist of an isolated drum stem along with stems corresponding to other instruments. We can therefore easily merge the other stems to create paired data of drumless tracks and drum tracks as training data of our model. (In musical terms, drumless, or "Minus Drums" songs are recordings where the drum part has been taken out, which corresponds nicely to our scenario.) Second, we suppose a drum accompaniment generation model can easily find applications in songwriting [18], as it allows a user (who may not be familiar with drum playing or beat making) to focus on the other non-drum tracks. Third, audio-domain drum accompaniment generation poses interesting challenges as the model needs to determine not only the *drum patterns* but also the *drum sounds* that are supposed to be, respectively, rhythmically and stylistically consistent with the input. Moreover, the generated drum track is expected to follow a steady tempo, which is a basic requirement for a human drummer. We call our model the "JukeDrummer."

As depicted in Figure 1, the proposed model architecture contains an "audio encoder" (instead of the original text encoder [7, 8]) named the *drumless VQ encoder* that takes a drum-free audio as input. Besides, we experiment with different ways to capitalize an audio-domain beat and downbeat tracking model proposed recently [19] in a novel *beat-aware module* that extracts *beat-related information* from the input audio, so that the language model for generation (i.e., the Transformer) is better informed of the rhythmic properties of the input. The specific model [19] was trained on drumless recordings as well, befitting our task. We extract features from different levels, including low-level tracker embeddings, mid-level activation peaks, and high-level beat/downbeat positions, and investigate which one benefits the generation model the most.

Our contribution is four-fold. First, to our best knowledge, this work represents the first attempt to drum accompaniment generation of a full drum kit given drum-free mixed audio. Second, we develop a light-weight audio-to-audio Jukebox variant that takes an input audio of up to 24 seconds as conditioning and generates accompanying music in the domain of Mel-spectrograms (Section 3). Third, we experiment with different beat-related conditions in the context of audio generation (Section 4). Finally, we report objective and subjective evaluations demonstrating the effectiveness of the proposed model (Sections 6 & 7). [1] .

[1] We share our code and checkpoint at: `https://github.com/legoodmanner/jukedrummer`. Moreover, we provide audio examples at the following demo page: `https://legoodmanner.github.io/jukedrummer-demo/`

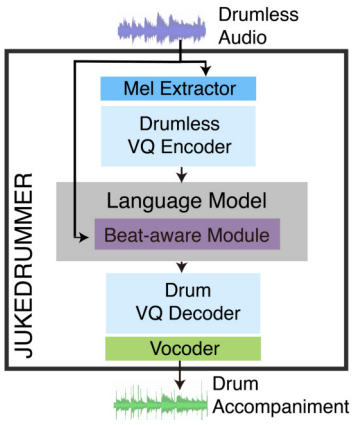

Figure 1: Diagram of the proposed JukeDrummer model for the inference stage. The training stage involves learning additional Drum VQ Encoder and Drumless VQ Decoder (see Figure 2) that are not used at inference time.

2. BACKGROUND

2.1 Related Work on Drum Generation

Conditional drum accompaniment generation has been studied in the literature, but only in the symbolic domain [20, 21], to the best of our knowledge. Dahale *et al.* [20] used a Transformer encoder to generate an accompanying symbolic drum pattern of 12 bars given a four-track, melodic MIDI passage. Makris *et al.* [21] adopted instead a sequence-to-sequence architecture with a bi-directional long short-term memory (BLSTM) encoder extracting information from the melodic input and a Transformer decoder generating the drum track for up to 16 bars in MIDI format. While symbolic-domain music generation has its own challenges, it differs greatly from the audio-domain counterpart studied in this paper, for it is not about generating sounds that can be readily listened to by human.

Related tasks that have been attempted in the literature with deep learning include symbolic-domain generation of a monophonic drum track (i.e., kick drum only) of multiple bars [4], symbolic-domain drum pattern generation [22–25], symbolic-domain drum track generation as part of a multi-track MIDI [26–29], audio-domain one-shot drum hit generation [30–34], audio-domain generation of drum sounds of an entire drum kit of a single bar [35], and audio-domain drum loop generation [36]. Jukebox [7] generates a mixture of sounds that include drums, but not an isolated drum track. By design, Jukebox does not take any input audio as a condition and generate accompaniments.

2.2 The Original Jukebox model

The main architecture of Jukebox [7] is composed of two components: a multi-scale vector-quantized variational autoencoder (VQ-VAE) [37–41] and an autoregressive Transformer decoder [14, 15]. The **VQ-VAE** is for converting a continuous-valued raw audio waveform into a sequence of so-called discrete *VQ codes*, while the **Transformer** establishes a language model (LM) of the VQ codes capable of generating new code sequences.

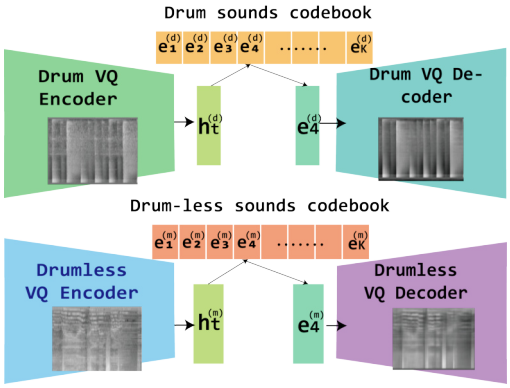

Figure 2: We use separate VQ-VAEs for the drumless and drum tracks, both operating on the Mel-spectrograms.

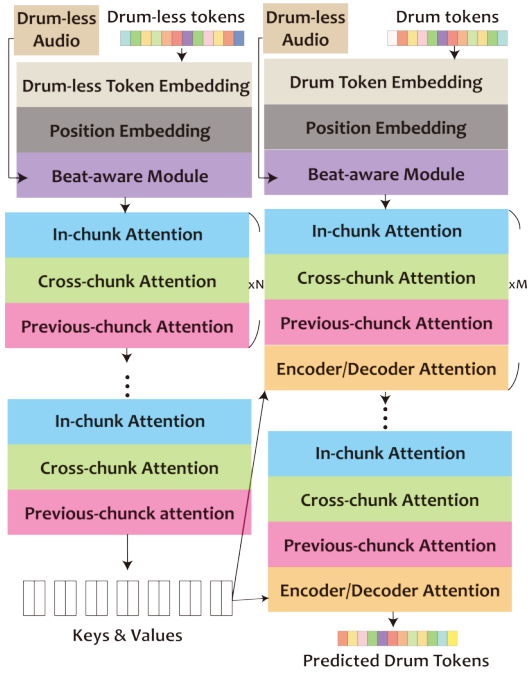

Figure 3: Details of our Transformer encoder/decoder.

Specifically, VQ-VAE consists of an encoder and a decoder, referred to as the VQ-VAE encoder $\mathcal{E}$ and VQ-VAE decoder $\mathcal{D}$ below, respectively. Given an audio waveform $\mathbf{x} \in \mathbb{R}^{1\times N}$, where N denotes the number of audio samples (e.g., N = 1,058,400 for a 24-second audio clip sampled at 44.1 kHz), the VQ-VAE encoder would convert $\mathbf{x}$ into a sequence of latent vectors $\{\mathbf{h}_t \in \mathbb{R}^D, t = 1, ..., T\}$, where the sequence length T is proportional to N, and the VQ-VAE decoder would have to reconstruct $\mathbf{x}$ from the "vector-quantized" version of the latent vectors, denoting as $\{\mathbf{h}'_t \in \mathbb{R}^D, t = 1, ..., T\}$, that is obtained by finding the nearest prototype vector $\mathbf{h}'_t = \mathbf{e}_z$ of each $\mathbf{h}_t$ in a codebook of prototype vectors $\{\mathbf{e}_k \in \mathbb{R}^D, k = 1, ..., K\}$, where K is the size of the codebook. Each prototype vector can be regarded as a cluster centroid in the latent space as a result of K-means clustering. The VQVAE encoder/decoder and the codebook are jointed learned by minimizing the reconstruction loss $\|\mathbf{x}_t - \mathcal{D}(\mathbf{h}'_t)\|_2^2$, and the commitment loss of the clustering $\|\mathcal{E}(\mathbf{x}_t) - sg(\mathbf{e}_z)\|_2^2$, where $\mathbf{x}_t$ denotes a slice of $\mathbf{x}$, $sg(.)$ the stop-gradient operation, and $\mathbf{h}_t = \mathcal{E}(\mathbf{x}_t)$.

Once the VQ-VAE is trained, the $\mathbf{x}$ can be viewed as a sequence of "IDs" $\{z_t \in \mathbb{Z}_{1:K}, t = 1, ..., T\}$, each corresponding to the index of the element of the codebook that is used to represent each slice of $\mathbf{x}$. The Transformer can then be trained on such sequences of IDs to learn the underlying language, or "composition rules," of the audio codes. Once trained, the transformer can be used to generate a novel sequence of codes, which can then be converted into an audio waveform by the VQVAE decoder.

As the waveforms are extremely long, Jukebox actually uses a "multi-scale" VQ-VAE that converts a waveform into three levels of codes, and accordingly three Transformers for building the LM at each level [7]. KaraSinger works on Mel-spectrograms but also uses multi-scale VQ-VAE [8]. We simplify their architecture by working on Mel-spectrograms with only one level of codes instead of multiple levels, as introduced below.

3. PROPOSED METHODS

In our task, we are given pairs of audio waveforms, namely a drumless stem $\mathbf{x}^{\mathrm{m}}$ and a drum stem $\mathbf{x}^{\mathrm{d}}$. Our goal is to train a model that can generate $\mathbf{x}^{\mathrm{d}}_*$ given an unseen $\mathbf{x}^{\mathrm{m}}_*$ from the test set. To achieve so, we propose several extensions of the Jukebox model. While we focus on drum accompaniment generation only, the same methodology may apply equally well to other conditional generation tasks.

Two VQ-VAEs. As illustrated in Figure 2, we build separate VQ-VAEs for $\mathbf{x}^{\mathrm{m}}$ and $\mathbf{x}^{\mathrm{d}}$ using drumless stems and drum stems respectively. Once trained, the drumless VQ-VAE encoder and the drum VQ-VAE encoder would convert $\mathbf{x}^{\mathrm{m}}$ and $\mathbf{x}^{\mathrm{d}}$ into $\{z^{\mathrm{m}}_t \in \mathbb{Z}_{1:K^{\mathrm{m}}}, t = 1, ..., T\}$ and $\{z^{\mathrm{d}}_t \in \mathbb{Z}_{1:K^{\mathrm{d}}}, t = 1, ..., T\}$ separately. Assuming that the drumless tracks are more diverse, we suggest use a larger codebook size for the drumless sounds codebook than the drum sounds codebook, namely $K^{\mathrm{m}} \geq K^{\mathrm{d}}$.

Mel VQ-VAE & Vocoder. To reduce computational cost, we build VQ-VAEs that take Mel-spectrograms as the input and target output. Specifically, we use the convolutional blocks of UNAGAN [5] to build a pair of VQ-VAE encoder and VQ-VAE decoder that has symmetric architectures (one downsampling and the other upsampling). We omit the details of UNAGAN due to space limit. Our Transformer accordingly learns the LM for codes of the Mel-spectrograms. Once a novel sequence of (drum) codes is generated by the Transformer, we use our (drum) VQ-VAE decoder to convert the codes into a Mel-spectrogram, and then use a neural *vocoder* [42] to convert the Mel-spectrogram into the corresponding waveform. While the latent vector $\mathbf{h}_t$ (and accordingly z_t) corresponds to a slice of waveform in the original Jukebox, here the latent vectors $\mathbf{h}^{\mathrm{m}}_t$ and $\mathbf{h}^{\mathrm{d}}_t$ (and z^{m}_t, z^{d}_t) both correspond to a fixed number of L frames of the short-time Fourier Transform (STFT) while computing the Mel-spectrograms.

Seq2seq Transformer. While the Jukebox model uses a Transformer decoder to model the sequences $\{z_t, t = 1, ..., T\}$ corresponding to mixtures of sounds, in our case we need a dedicated Transformer encoder to take the se-

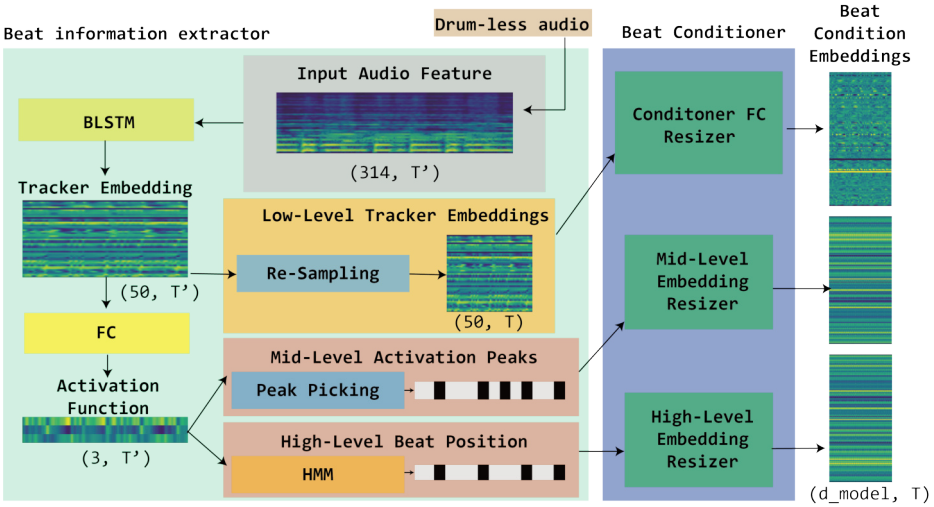

Figure 4: Details of the proposed beat-aware module that extracts beat condition embeddings from the drumless audio.

quence $\{z_t^{\mathrm{m}}, t = 1, ..., T\}$ corresponding to a drumless audio as the input, and a Transformer decoder to generate the sequence $\{z_t^{\mathrm{d}}, t = 1, ..., T\}$ corresponding to the accompanying drum audio as the output, leading to a sequence-to-sequence (seq2seq) architecture. Following Jukebox, we use the attention mechanism of the Scalable Transformer [15] in our Transformer encoder/decoder. As depicted in Figure 3, to determine its output z_i^{d} at each i, our Transformer decoder uses factorized "in-chunk," "cross-chunk" and "previous-chunk" attention layers to attend to the drum codes it generates previously, namely $z_{<i}^{\mathrm{d}} = \{z_t^{\mathrm{d}}, t = 1, ..., i-1\}$, to maintain the coherence of its output. A "chunk" here is a slice of the corresponding sequence. Moreover, the Transformer decoder uses "encoder/decoder attention" to attend to the final layer of the Transformer encoder to get contextual information from the drumless code sequence $\{z_t^{\mathrm{m}}, t = 1, ..., T\}$. To better synchronize the input and output, position embeddings are used. We refer readers to [7, 15] for details.

Beat-Aware Module. Figure 3 also shows that we use a novel "beat-aware module" (after the position embedding) in both Transformer encoder and decoder. We note that the code z_t^{m} is trained to provide essential information needed to reconstruct the drumless audio $\mathbf{x}_t^{\mathrm{m}}$, so the information carried by z_t might be *mixed*, covering different musical aspects including timbre, style, rhythm, etc. To supply the Transformer with *clear* rhythm-related information of $\mathbf{x}^{\mathrm{m}}$, we might need such a dedicated beat-aware module.

As depicted in Figure 4, the beat-aware module consists two sub-modules, the "beat information extractor" and the "beat conditioner." The former extracts beat-related information per frame from $\mathbf{x}^{\mathrm{m}}$ using an existing beat/downbeat tracker [19], while the latter incorporates that beat-related information for each t as a beat condition embedding $\mathbf{c}_t^{\mathrm{m}} \in \mathbb{R}^{d_{\mathrm{model}}}$ that has the same length d_{model} as the token embedding of the Transformers, and adds together the beat condition embedding and token embedding per t to serve as the input to the subsequent attention layers.

Despite that deep learning-based beat/downbeat trackers such as those proposed by Böck *et al.* [43–45] have achieved excellent performance for mainstream pop, rock or dance music, their performance and behaviors are influenced by the sound source composition (i.e., drum/non-drum sounds) of their training data [19, 46]. Considering that our input music is drumless, which is quite different from the music that existing common beat/downbeat trackers [44, 45] are trained with and trained for, we use in our beat information extractor the "non-drum tracker" developed by Chiu *et al.* [19] exclusively for drumless stems. In Section 4, we describe three ways to extract different levels of beat information feature from the non-drum tracker.

4. BEAT CONDITION EMBEDDING

As shown on the left of Figure 4, following the common design [44], the beat/downbeat tracker [19] uses BLSTM layers to get 50-dimensional "tracker embeddings" from $\mathbf{x}^{\mathrm{m}}$, and then uses fully-connected (FC) layers to compute 3-dimensional "activation functions" indicating the likelihood of observing a beat, downbeat, or non-beat at each frame. Finally, either a simple peak-picking or a hidden Markov model (HMM)-based algorithm [44] can be used to finalize the beat and downbeat time positions from the activation functions. We accordingly investigate extracting features from different stages of this processing pipeline.

Low-level (tracker) embeddings. We simply use the high-dimensional tracker embeddings, resampling it temporally, pooling them every L frames, and converting each of them to the desired length d_{model} with an FC.

High-level beat/downbeat positions. From the beat and downbeat time positions estimated by HMM, a frame can be labeled as either a beat, downbeat, or non-beat. We learn three d_{model}-dimensional embedding vectors corresponding to each case, and represent every L frames with one of the three vectors according to the frame labels.

Mid-level activation peaks. As the beat/downbeat positions are sparse over time, we consider a "denser" version by simply picking the peak positions of the activation func-

tions by `scipy.signal.find_peaks` [47] and similarly learning embedding vectors that are assigned to the frames according to whether a frame corresponds to a peak or not. Such a peak might represent a musical onset.

5. EXPERIMENT SETUP

Multi-track datasets for research on musical source separation [17] usually host recordings that each consists of an isolated drum stem along with stems corresponding to other instruments. We can simply take the drum stem as the target drum track, and the summation of the remaining stems as the input drumless track. In our implementation, we used the multi-track recordings from three datasets. MUSDB18 [17] contains 150 recordings, each of which has four stems corresponding to vocal, drums, bass, and "others." It is commonly used in source separation. MedleyDB [48] contains 196 multi-track recordings, each of which includes a drum stem along with many other stems. MixingSecret [49] has 257 multi-track recordings with various instruments, all including drums. We removed the 46 duplicate recordings between MUSDB18 and MedleyDB and the 100 duplicate recordings between MUSDB18 and MixingSerect, leading to 457 recordings to be used in our work. We randomly split the recordings into 80%, 10%, 10% as the training set, validation set (for parameter tuning), and testing set (for objective and subjective evaluation) at the "recording-level," ensuring that a recording does not appear in different splits.

All the recordings are sampled at 44.1 kHz and the stems are all monaural. Following Jukebox [7], we used 24-second audio clips in our work. We sliced each recording (and accordingly the stems) to 23.8-second audio clips with 50% temporal overlaps (as $2^{20}/44100 = 23.8$), and discarded the clips that do not contain any drum sounds. We then computed the Mel-spectrograms of each clip with PyTorch v1.7.1 with a Hann window of 1,024 samples for STFT, a hop size of 256 samples and 80 Mel-filter banks.

To evaluate the performance of the proposed JukeDrummer and validate the effectiveness of model components, we adopted the following variants in our experiments. [2]

- `seq2seq+beat (low)`: given a drumless clip $\mathbf{x}^{\mathrm{m}}$, we computed the drumless codes $\{z_t^{\mathrm{m}}\}$ and the low-level beat/downbeat tracker embeddings $\{\mathbf{c}_t^{\mathrm{m}}\}$ as the model input, to predict the drum codes $\{z_t^{\mathrm{d}}\}$ that eventually lead to the generated drum clip $\mathbf{x}^{\mathrm{d}}$, using the proposed seq2seq Transformer.
- `seq2seq+beat (mid)`: using the beat condition embeddings computed from the mid-level activation peaks (see Section 4) for $\{\mathbf{c}_t^{\mathrm{m}}\}$ instead.
- `seq2seq+beat (high)`: using the beat condition embeddings from the high-level beat/downbeat positions as $\{\mathbf{c}_t^{\mathrm{m}}\}$ instead.
- `seq2seq w/o beat`: to study the usefulness of the beat conditioning, we predicted $\{z_t^{\mathrm{d}}\}$ from $\{z_t^{\mathrm{m}}\}$, not using any beat-related conditions at all.
- `decoder+beat (low)`: to study the usefulness of the drumless codes $\{z_t^{\mathrm{m}}\}$, we used only the low-level beat condition embeddings $\{\mathbf{c}_t^{\mathrm{m}}\}$ as input to predict $\{z_t^{\mathrm{d}}\}$, via a Transformer decoder-only architecture (i.e., not seq2seq Transformer).
- `decoder w/o beat`: this is the baseline drummer that "plays its own," generating $\{z_t^{\mathrm{d}}\}$ autoregressively via a Transformer decoder without taking any information (neither $\{z_t^{\mathrm{m}}\}$ nor $\{\mathbf{c}_t^{\mathrm{m}}\}$) from the drumless clip $\mathbf{x}^{\mathrm{m}}$ it is supposed to play along to.

While the Mel-spectrogram for a clip in our case has 4,096 frames, the VQ-VAE encoder downsamples it to a sequence of $T = 1{,}024$ latent vectors, namely each corresponding to $L = 4$ frames. For VQ-VAE, we set the codebook size of drumless sounds $K^{\mathrm{m}} = 1{,}024$ and that of drums $K^{\mathrm{d}} = 32$ (so $K^{\mathrm{m}} \gg K^{\mathrm{d}}$), and the dimension of the latent vectors $D = 64$. The VQ-VAE encoders/decoders for both drumless and drums all have two layers. For those models employing a seq2seq LM, the Transformer encoder has 9 layers and the Transformer decoder has 20 layers. [3]

At inference time, we used the drum VQ decoder to convert the drum codes $\{z_t^{\mathrm{d}}\}$ to a Mel-spectrogram, which is then turned into the waveform of the drum clip $\mathbf{x}^{\mathrm{d}}$ by a HiFi-GAN V1 vocoder [42]. We trained the vocoder from scratch with audio of drum sounds from our dataset for 2.5 days, and then, inspired by [50, 51], fine-tuned it on the reconstructed Mel-spectrograms of the Drum VQ decoder.

6. OBJECTIVE EVALUATION

As audio-domain drum accompaniment generation is new, we propose customized metrics. Specifically, we use the "drum tracker" trained exclusively for drum stems by Chiu *et al.* [19], which follows exactly the same pipeline as the non-drum tracker (cf. Figure 4), to extract rhythmic features at three different levels for the ground-truth and generated drum sounds for the test split. We then compare the rhythmic features of the ground-truth and the generated in such three levels, using the mean square error for the low-level tracker embeddings (**TrackEmb-MSE**), cross entropy for the mid-level activation functions (**Act-Entropy**), and the F-measure for beat/downbeat estimation (**B/DB-F1**). The last one, computed by `mir_eval` [52], uses the beat positions of the ground-truth drums as the reference and those of the generated drums as the estimated beats. These metrics evaluates only the *rhythmic consistency* between the generated drums and the drumless audio (using its human-made drum track as a proxy), not other aspects such as stylistic consistency and audio quality, which will be evaluated subjectively in Section 7.

[2] A reviewer suggested that we should have compared our model with other accompaniment generation models that operate in the symbolic domain such as [20] and [21], saying that we can use existing audio samples or drum synthesis models to render their output to audio. However, the problem is that such a symbolic-domain accompaniment generation model also requires its input to be a MIDI file rather than audio.

[3] We used Adam as our optimizer with a learning rate of 0.0003 for both VQ-VAE and Transformer LM. We trained our LM with a batch size of 16, input feature dimension $d_{\text{model}} = 512$, two heads for multi-head attention, and the chunk size for factorized attention being 16. For those employing a decoder-only architecture, the number of layers of the Transformer decoder reduces to 15 because 5 of the layers corresponding to the "encoder/decoder attention" are removed.

Model	Objective metrics			Subjective MOS ($\in [1, 5]$)

Table 1: Results of objective and subjective evaluation of variants of the proposed JukeDrummer model. The metrics are (from left to right): beat/downbeat tracking embedding MSE, beat/downbeat activation entropy, beat/downbeat F1, $\mathbf{R}^{m/d}$ (rhythmic consistency), $\mathbf{S}^{m/d}$ (stylistic consistency), $\mathbf{Q}^{d}$ (audio quality), $\mathbf{R}^{d}$ (rhythmic stability), $\mathbf{O}^{d}$ (overall). ↓/↑: the lower/higher the better; best two results (among the six model variants) per column highlighted in bold.

Result shown in the middle of Table 1 clearly shows that the models with low-level beat information achieve lower MSE, cross entropy, and higher F1, suggesting the usefulness of the low-level beat information for rhythmic consistency. The mid-level and high-level ones seem less effective (possibly because they are relatively monotonic), so we did not evaluate them further in Section 7. The objective scores also suggest that the Transformer encoder does not contribute much to rhythmic consistency.

7. SUBJECTIVE EVALUATION

With an online study, we solicited 22 anonymous volunteers to rate the result for 3 out of 15 random drumless tracks (each 23.8 seconds) from the test split. Each time, a volunteer listened to a drumless tracks ($\mathbf{x}_*^{m}$) first, and then (in random orders) the mixture (i.e., $\mathbf{x}_*^{m} + \mathbf{x}_*^{d}$) containing drum samples generated by four different models, plus the real human-made one (to set a high anchor). The volunteer then rated them in the following aspects on a 5-point Likert scale: **rhythmic consistency** between the drumless input and generated drums; **stylistic consistency** concerning the timbre and arrangement of the drumless input and generated drums; **audio quality** and **rhythmic stability** (whether the drummer follows a steady tempo) of the generated drum; and **overall** perceptual impression.

The mean opinion scores (MOS) in Table 1 show that `seq2seq+beat (low)` consistently outperforms the others, validating the effectiveness of using both the drumless codes and beat conditions. `decoder+beat (low)` performs consistently the second best, outperforming the two models without beat information significantly in three aspects according to paired t-test (p-value < 0.05), validating again the importance of the beat-aware module. Complementing Section 6, the MOS result suggests that the beat conditions seem more important than the drumless codes, though the best result is obtained with both.

Figure 5 further demonstrates that, given the same input, our model can generate multiple accompaniments with diversity in both beat and timbre. Diversity is an interesting aspect that is hard to evaluate, but it is desirable as there is no single golden drum accompaniment for a song. This may also explain why the F1 scores in Table 1 seem low.

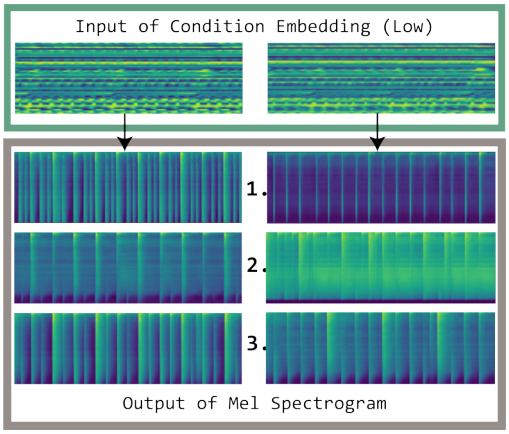

Figure 5: Two sets of three different generated samples by the same model given the same beat condition embedding.

Verbal feedbacks from the subjects confirm that our best model generates drum accompaniment that is rhythmically and stylistically consistent with the input, especially for band music or music with heavy use of bass. However, the model still has limits. At times the model generates total silence, though it can be avoided by sampling the LM again. The model may struggle to change its tempo going through different sections of a song. Moreover, the generation might be out-of-sync with the input in the beginning few seconds, until the model gets sufficient context. Please visit the demo page for various examples.

8. CONCLUSION

We have presented JukeDrummer, a novel audio-to-audio extension of OpenAI's JukeBox model capable of adding the drum part of a drumfree recording in the audio domain. To our knowledge, this represents the first attempt to audio-domain generation conditioned on drumless mixed audio. With objective and subjective evaluations, we validated the effectiveness of the customized VQ-VAE plus the seq2seq Transformer design, and the proposed beat-aware module. Among the beat conditions, we found that the low-level embeddings work the best. Future work can be done to further improve the language model (LM), and to extend our work to other audio-to-audio generation tasks.

ABSTRACT

Music contains hierarchical structures beyond beats and measures. While hierarchical structure annotations are helpful for music information retrieval and computer musicology, such annotations are scarce in current digital music databases. In this paper, we explore a data-driven approach to automatically extract hierarchical metrical structures from scores. We propose a new model with a Temporal Convolutional Network-Conditional Random Field (TCN-CRF) architecture. Given a symbolic music score, our model takes in an arbitrary number of voices in a beat-quantized form, and predicts a 4-level hierarchical metrical structure from downbeat-level to section-level. We also annotate a dataset using RWC-POP MIDI files to facilitate training and evaluation. We show by experiments that the proposed method performs better than the rule-based approach under different orchestration settings. We also perform some simple musicological analysis on the model predictions. All demos, datasets and pre-trained models are publicly available on Github [1] .

1. INTRODUCTION

Music contains rich structures at different levels, and the structure annotations play an important role in music understanding [1, 2] and generation [3, 4]. Progress has been made in music structure analysis on certain levels, like beat tracking [5–7], downbeat detection [8–11] and part segmentation [12–15]. These levels of structures are often inter-connected with each other, and can be described in a hierarchical way. For example, a part may contain several sections, each containing several measures. Measures can be further decomposed into beats.

Several views of hierarchical music structures are formally discussed in the Generative Theory of Tonal Music (GTTM) [16], including the grouping structure, the metrical structure, the time-span tree, and the prolongational tree, each focusing on different music properties (i.e., the grouping structure focuses more on melodic grouping while the metrical structure focuses on rhythmic patterns). Among these structures, we choose the metrical structure as the topic for two reasons: (1) For polyphonic music, the metrical structures of different voices are usually compatible, building up a common song-level metrical structure. This property makes data annotation easier and provides opportunities for self-supervision; (2) Some low-level metrical structures (e.g., beats and downbeats) are already annotated in music scores and most MIDI datasets, which can be a helpful source of supervision. In this paper, we will focus our analysis on pop songs, which often contain a well-defined hierarchy of metrical structures [17].

Figure 1. The hierarchical metrical structure of the beginning of RWC-POP No. 001. Only the main melody is shown. Despite the pick-up bar, these 4 measures are grouped into 2 hypermeasures of length 2, which are further grouped into 1 hypermeasure of length 4.

Our main goal is to infer the high-level metrical structures given low-level ones like beats and downbeats. The hierarchy of the metrical structure is created by recursively grouping lower metrical units into upper ones (see Figure 1 for an example). We call the grouping of measures (or other larger metrical units) a *hypermeasure*, and the number of units that form the group as its *hypermeter* [18, 19]. While some properties of beats and measures can be generalized to upper-level metrical structures, there are still many differences to take into account. Similar to the meter, the hypermeter of each layer tends to stay the same to maintain a regular rhythmic pulse, but it is not uncommon to see hypermeter changes in a piece, as shown in Figure 4. Such changes occur more often than low-level meter changes since listeners are less sensitive to long-term rhythmic regularity. Another major difference is that the decision of upper-level metrical structures requires a longer context in the time domain compared to downbeat or beat tracking.

To resolve these issues, we design a new model that contains a Temporal Convolutional Network (TCN) front-end for metrical level prediction and a Conditional Random Field (CRF) decoder for joint metrical structure decoding. We design the transition of CRF hidden states to allow hypermeter changes with some penalties. To han-

Xia, "Learning Hierarchical Metrical Structure Beyond Measures", in *Proc. of the 23rd Int. Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

dle polyphony, the model takes an arbitrary number of voices/tracks as input, and predicts a confidence score for each track. The final prediction is a weighted average of the results from all tracks. We annotated 70 songs from the RWC-POP dataset and used them for model training and evaluation. We conduct experiments under different orchestration setups with results shown in section 4.4.

2. RELATED WORK

2.1 Downbeat and Meter Tracking

Downbeat tracking for raw audio is a well-studied task with many promising results. Krebs et al. [8] use particle filters to find the downbeats, yielding a 2-level metrical structure. Durand et al. [9] use an ensemble of convolutional networks to locate downbeats robustly. Fuentes et al. [10] use skip-chain CRF and deep learning to track downbeats, noting that longer-term musical contexts can better inform downbeat tracking. The reader is referred to Gouyon and Dixon's review [11] for non-symbolic low-level metrical analyzers before 2005.

Notably, locating the beats and downbeats for symbolic music is not a trivial task. Kostek et al. [20] apply neural networks and rough sets to a polyphonic symbolic piece and classify whether each note is accented or not, yielding a 2-level metrical structure (beat and downbeat). Chuang and Su [21] use various RNNs to classify each timestep in a piano roll into non-beat, beat, or downbeat.

Another related task is time signature detection. Benoit [22] uses symbolic-level auto-correlation to obtain a 4-level metrical structure, and ultimately extracts the meter. More auto-correlative methods [23, 24] share a similar logic, since note onsets usually display periodicity in every measure. More recently, inner metric analysis was also used to infer the time signature by Haas et al. [25].

2.2 Music Segmentation

The task of music segmentation is to infer musically meaningful section or part boundaries from the music content. Audio-based music segmentation is usually achieved by detecting similarity or repetition of the audio spectral features. McFee and Ellis [13] evaluate inter-time frame similarity and use spectral clustering to obtain a multi-level segmentation of music. Salamon et al. [14] and McCallum [15] replace traditional features with pre-trained deep embeddings to estimate timbre and harmonic similarity. Tralie and McFee [26] fuse multiple similarity metrics for better prediction results. Ullrich et al. [27] train fully supervised CNN on a segment-annotated dataset to detect segment boundaries. See Dannenberg and Goto's review [28] and the 2010 SOTA report by Paulus et al. [29] to learn more about audio-based music segmentations.

Segmentation of symbolic music relies more on domain knowledge of music composition. Van der Werf and Hendriks [30] restate GTTM grouping rules in terms of Optimality Theory (OT) and design a Prolog program to find an optimal parse for short monophonic pieces. Dai et al. [31] identify phrases as units of melodic repetition by minimizing the Structural Description Length (SDL) for the entire piece, and then extract a 2-layer hierarchy.

2.3 Hierarchical Structure Analysis

The Generative Theory of Tonal Music (GTTM) [16] discusses several views of the hierarchical music structures, but GTTM does not describe how to realize an analyzer computationally. Various efforts have been made to mechanize GTTM. For example, Jones et al. [32] use a rule-based expert system to obtain a 6-level metrical structure for monophonic pieces, satisfying all GTTM's well-formedness rules while following Povel's grid theory [33]. Rosenthal's Machine Rhythm [34] ventures into the polyphonic domain and uses rule-based methods to extract a 3-level rhythmic annotation for MIDI input. Temperley and Sleator [35] use a preference-rule approach and dynamic programming to obtain the optimal parse. Hamanaka et al. [36] propose the Automatic Time-span Tree Analyzer (ATTA) for structural analysis of 8-bar monophonic scores. Temperley [37] use Bayesian reasoning to jointly analyze metrical, harmonic, and stream structures. Wojcik and Kostek [18] use rule-based methods to retrieve hypermetric rhythm from only the melody.

Machine learning models are also used for hierarchical structure analysis. Hamanaka et al. propose Deep-GTTM [38, 39] which is a fully automatic analyzer that uses a neural network to predict the applicability of GTTM rules for each note, yielding a 5-level metrical structure for 8-bar monophonic scores.

There are some issues when applying previous works to large polyphonic MIDI databases. Most systems work only for monophonic music or music with limited polyphony. Also, they often work in a short context, usually up to 8 bars.

3. METHODOLOGY

3.1 Problem Setting

We first formally define the metrical structure prediction task for this paper. Assume we have a music score with T voices (or tracks, in the sense of MIDI files) $\mathbf{m}_1, ..., \mathbf{m}_T$. We also have a list of pre-annotated downbeats $d_1, ..., d_N$ for the music. The aim is to assign hierarchical metrical labels $l_i \in \{0, 1, ..., L\}$ to each downbeat d_i where L is the total number of layers we want to build beyond measures. Each label serves as the level of the metrical boundary at d_i. $l_i = l$ means d_i serves as a metrical boundary of all levels for the first l levels beyond measures. Specially, $l_i = 0$ means d_i serves only as a measure boundary but not any metrical boundary beyond measures.

If we use GTTM's metrical structure notation, we can use (l_i+1) dots to represent a metrical boundary level of l_i. For the example in figure 1, the first 4 measures (excluding the pickup measure) would have labels $l_1 = 2, l_2 = 0, l_3 = 1, l_4 = 0$.

We can also introduce the following notations.

Hypermeasures: A hypermeasure of level l is an interval

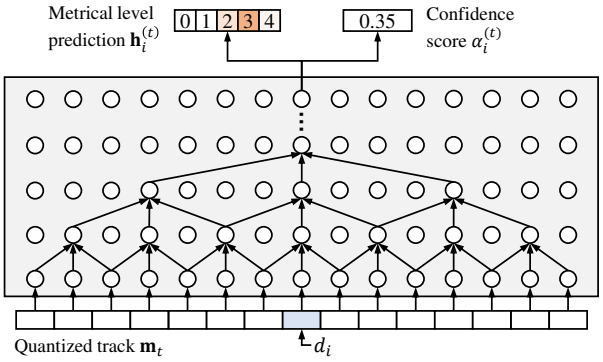

Figure 2. The architecture of the neural network.

between two downbeats d_i and d_j where $l_i \geq l, l_j \geq l$ and $l_k < l$ for all $k = i+1...j-1$. In other words, any $l_k \geq l$ serves as a separator of a level-l hypermeasure. Specially, level-0 hypermeasures are just measures.

Hypermeters: A hypermeter is the generalization of meters by counting how many level-$(l-1)$ hypermeasures are in a level-l hypermeasure. Since a binary structure is the most commonly used [19, 40], we assume a general hypermeter of 2 in all levels, with a few exceptions that cause *binary irregularity*.

3.2 Temporal Convolutional Network

Temporal Convolutional Networks (TCNs) have been proven an effective model for beat, downbeat, and tempo tracking [7, 41, 42]. We believe it is useful for general metrical structure analysis for its unique property we will mention below. We mainly reference [43] for the design of the TCN, but we made it non-causal similar to [7]. Each TCN block contains 8 sequential layers. The first 4 layers are a dilated convolutional layer with kernel size 3 and 256 channels, a batch normalization layer, a Rectified Linear Unit (ReLU) activation layer, and a dropout layer. The next 4 layers repeat this configuration. There is also a residual component that adds a linear transformation of the input to the block output, allowing shortcut connections.

Our model uses 6 TCN blocks sequentially. Each block multiplies the dilation by 2, starting from 1 at block 1, resulting in an exponentially growing context range for each layer. This allows the model to capture long-term context and more importantly, integrate prior knowledge about binary metrical structure into the network. The model input contains the piano roll and the onset roll of a track quantized into a 16th note level. Under a 4/4 meter, the dilations of the convolutional layers in each block are therefore 1/4 beat, 1/2 beat, 1 beat, 2 beats, 1 measure and 2 measures, respectively. This encourages the convolutional layers to capture more musically meaningful context for binary metrical structures.

For each track $\mathbf{m}_t$ in a song, we first feed them into the TCN blocks to get the features for each time step, and then discard the time steps that do not correspond to any downbeat. We use linear layers to project the features into a metrical level prediction $\mathbf{h}_i^{(t)}$ and a confidence score $\alpha_i^{(t)}$.

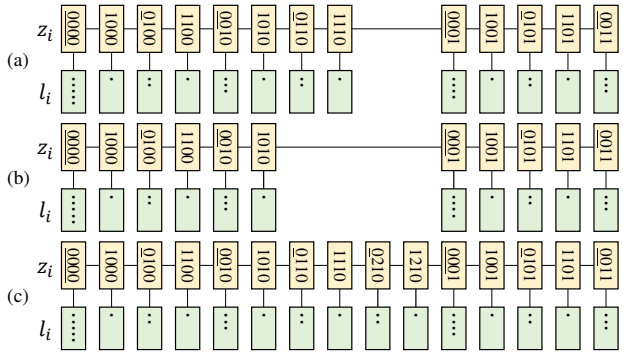

Figure 3. Examples of the CRF hidden variables z_i (shown as a L-digit number $z_i^{(1)}...z_i^{(L)}$) and the corresponding metrical boundary levels l_i when $L = 4$. (a) Binary regularity is satisfied. (b) A level-1 hypermeasure is deleted from (a). (c) A level-1 hypermeasure is inserted into (a). Both (b) and (c) are examples of binary irregularity.

Each prediction $\mathbf{h}_i^{(t)}$ is a vector of size $(L+1)$ for the labels $0...L$. The final prediction of l_i is the weighted average of all predictions $\mathbf{h}_i^{(t)}$ on the same time step weighted by their confidence scores:

$$a_i^{(t)} := \exp \alpha_i^{(t)} / \sum_{t'} \exp \alpha_i^{(t')} \quad (1)$$

$$\mathbf{p}_i := \sum_t a_i^{(t)} \text{Softmax}(\mathbf{h}_i^{(t)}) \quad (2)$$

3.3 Conditional Random Fields

Conditional Random Fields (CRFs) have been widely used in downbeat tracking [10, 44] to enforce the regularity of the decoded downbeat patterns. Inspired by this, we also use a structured prediction method for decoding. The major differences are that this model needs to predict a hierarchy of $L = 4$ layers of metrical structures jointly.

The state space of hierarchical metrical structure can be complex and ambiguous. To make it simple, we restrict our model to accept a hypermeter of 1, 2 or 3 on any level. In the sense of transformational grammar, a level-l hypermeter of 1 can be constructed by deleting some level-$(l-1)$ hypermeasures from a deep structure with binary regularity, and a hypermeter of 3 can be constructed by inserting some level-$(l-1)$ hypermeasures (see figure 3 for an example). A hypermeter of 4 or more is not allowed and needs to be decomposed into multiple metrical levels (e.g., $4 = 2 + 2$).

We design the linear CRF with a joint state space $z_i = (z_i^{(1)}, ..., z_i^{(L)})$ where each $z_i^{(l)} \in \{0, 1, 2\}$ corresponds to the current hypermeasure position at level l, i.e., the number of complete level-$(l-1)$ hypermeasures in this level-l hypermeasure up to the current time step. It can be seen as a generalization of the beat position in [10]. A state $z_i^{(1...l)} = 0 \wedge z_i^{(l+1)} \neq 0$ denotes a metrical boundary level $l_i = l$. Specially, the highest-level metrical boundary $l_i = L$ is associated and only associated with the state $(0, ..., 0)$, and the lowest-level metrical boundary $l_i = 0$ is associated with any z_i where $z_i^{(1)} \neq 0$. See figure 3 for some concrete examples.

We manually design the transition potential function to encode the belief of binary regularity on each level. We define the transition potential matrix of a single level as

$$\mathbf{A}^{(l)} = \begin{bmatrix} \exp\big(-w_{\text{del}}^{(l)}\big) & 1 & 0 \\ 1 & 0 & \exp\big(-w_{\text{ins}}^{(l)}\big) \\ 1 & 0 & 0 \end{bmatrix} \quad (3)$$

where $A_{ij}^{(l)}$ denotes the potential of transition from hypermeasure position i to position j on level l. $w_{\text{del}}^{(l)} > 0, w_{\text{ins}}^{(l)} > 0$ are hyperparameters that controls the penalty of a level-l hypermeasure deletion and insertion respectively. Intuitively, an alternating state sequence like $0, 1, 0, 1$ on a single level satisfies binary regularity and will not be penalized. Binary irregularity by inserting (e.g., $0, 1, 2, 0, 1$) or deleting (e.g., $0, 0, 1$) states are penalized.

In a hierarchical metrical transition to a level-l metrical boundary, the hypermeasure positions of level $1...(l+1)$ are updated, and the ones above level-$(l+1)$ keep the same. Therefore, the joint transition potential is defined as

$$\phi(z_{i-1}, z_i) = \prod_{l=1}^{L} \begin{cases} A_{z_{i-1}^{(l)} z_i^{(l)}} & l \leq l_i + 1 \\ \mathbb{I}[z_{i-1}^{(l)} = z_i^{(l)}] & l > l_i + 1 \end{cases} \quad (4)$$

where l_i denotes the corresponding metrical boundary level of z_i, and $\mathbb{I}[b]$ is the indicator function that returns 1 if b is true and 0 if b is false.

The emission potential function is designed as $\psi(z_i, \mathbf{p}_i) = p_{il_i}$ where p_{il_i} is the l_i-th entry of $\mathbf{p}_i$. We use Viterbi decoding to decode the optimal hidden states $z_{1..d}$ given the observations $\mathbf{p}_{1...N}$:

$$\hat{\mathbf{z}} = \arg\max_{\mathbf{z}} \psi(z_1, \mathbf{p}_1) \prod_{i=2}^{N} \phi(z_{i-1}, z_i) \psi(z_i, \mathbf{p}_i) \quad (5)$$

4. EXPERIMENTS

4.1 Datasets

The main dataset we use in model training and evaluation is the RWC-POP dataset. It contains 100 songs with aligned MIDI files. The MIDI files have beat and downbeat annotations that are mostly correct [2]. We manually annotated the 4-layer song-level metrical structure for 70 songs. We use 50 songs for training, 10 for validation, and 10 for testing. We acknowledge the ambiguity in data annotation which potentially causes bias by annotator subjectivity [45], so we publicized the annotation data and methods to facilitate discussion and future research.

All samples are quantized into 16th-note units. The binary piano roll and onset roll are extracted for each track. During training, a random 512-unit (32 measures) segment is chosen from each song, resulting in a 512×256 feature matrix (128 MIDI pitches for piano roll and 128 MIDI pitches for onset roll) for each track. To prevent overfitting, we perform label-preserving data augmentation including random pitch shift augmentation of -12 to +12 semitones and a microtiming shift up to an 8th note on the training set. The drum track does not use pitch shift augmentation and does not share the same parameter with pitched instruments for the first convolutional layer.

[2] 2 out of 70 songs have minor beat/downbeat annotation issues.

4.2 Model Training

For model training, we use a mini-batch of 16. We use the Adam optimizer [46] on the cross-entropy classification loss with a learning rate 0.0001 for 100 epochs. In one epoch, we go through each augmented version of each song for 5 times. For each song, we randomly select 2 tracks and try to predict the song-level metrical structure given the weighted average of their predictions. We also apply dropout with a probability 0.5 after each convolutional layer to further suppress overfitting.

4.3 Baseline Models

While there are some existing rule-based hierarchical metrical structure analyzers [32,39,47] in previous works, they mostly focus on low-level (e.g., beat & downbeat) boundary features like note transitions, durations and local rhythmic patterns. Those features are not effective enough for metrical structures above the measure level. We here build our baseline model using the methodology from [48]. For each metrical level, we calculate the similarity matrix of piano rolls on different granularity and estimate their novelty score as observations. We use a CRF decoder as mentioned above with a different set of hyper-parameters tuned for the baseline model.

To assess the necessity of introducing metrical irregularity, We also introduce another hypothetical baseline model called the *oracle* model. The oracle model is not allowed to predict any hypermeter changes (i.e., it always assumes binary regularity) but it always performs the best possible prediction (i.e., maximal F1 score) for each level. This hypothetical model serves as an upper bound for any model that does not allow binary irregularity.

4.4 Results

Table 1 shows the performance of each model on the test split of RWC-POP songs. To perform a more systematic evaluation, we also created two difficult versions of each test song: (1) **no drums**: the drum track(s) are removed from the original song and each model is required to predict the same metrical structure without referring to any drum clues; (2) **mel. only**: all tracks except the melody track are removed. Each model is required to predict the structure by purely referring to the main melody track.

From the results, we can see that our proposed model performs better than the rule-based counterpart on all metrical levels. Since most test songs have more than 10 MIDI tracks, they provide sufficient metrical hints to both the proposed model and the rule-based model even if the drum track is removed. When we only have the melody track, both the proposed model and the rule-based model's performances are not satisfactory even on the first level beyond measure. Still, the data-driven approach shows improved performance compared to the rule-based system.

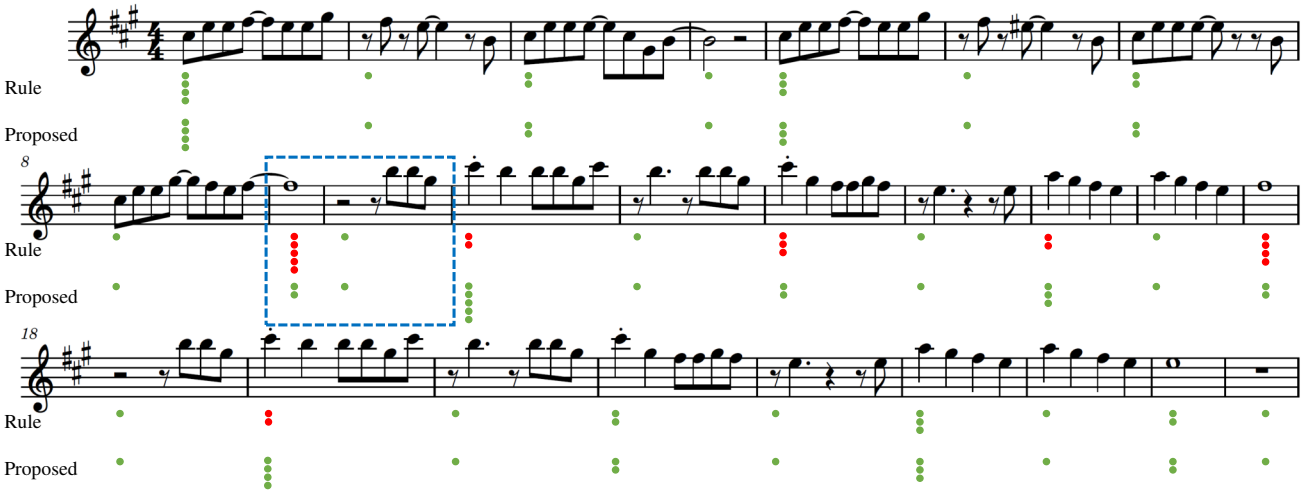

Figure 4. A case study with song RWC-POP No. 008 from the test split. The song is multi-track but we only show the main melody here. The metrical structure of the song does not satisfy binary regularity because of the 2-bar extensions in the pre-chorus (marked by a dashed blue box), causing hypermeter changes. The prediction of the proposed method aligns well with the reference. The errors in the rule-based prediction are marked in red (better viewed in color).

Model	Level 1	Level 2	Level 3	Level 4
Proposed	0.9848 ±0.0215	**0.9559 ±0.0386**	**0.8880 ±0.0889**	**0.6849 ±0.1900**
Proposed w/o CRF	0.9338 ±0.0390	0.8528 ±0.0937	0.7971 ±0.1276	0.6646 ±0.0844
Rule	0.9228 ±0.0698	0.8425 ±0.1195	0.7485 ±0.1536	0.5185 ±0.2656
Oracle	0.9427 ±0.1120	0.7782 ±0.2076	0.5188 ±0.1751	0.4225 ±0.1234
Proposed (no drums)	**0.9868 ±0.0174**	0.9519 ±0.0346	0.8803 ±0.1023	0.6611 ±0.2170
Rule (no drums)	0.9312 ±0.0660	0.8107 ±0.1568	0.7055 ±0.2008	0.4823 ±0.2239
Proposed (mel. only)	0.7413 ±0.2139	0.6253 ±0.2448	0.5551 ±0.2536	0.3808 ±0.2399
Rule (mel. only)	0.6606 ±0.1451	0.4395 ±0.1522	0.3142 ±0.1211	0.1863 ±0.1310

Table 1. Evaluated F1 scores on the test split of the RWC-POP dataset.

We observe that the proposed model is better at capturing irregular metrical structures than the rule-based approach. Figure 4 shows a cherry-picked example where binary irregularity can be found. Both the proposed model and the rule-based baseline can detect such irregularity but only the proposed model correctly tells the exact position of the hypermetrical change.

There is also a tendency for the performance to drop rapidly from lower to higher levels. We believe there are 2 main reasons. First, the higher levels have fewer positive samples, making it hard for the model to learn its semantic characteristics. Second, metrical structures on higher levels are often more ambiguous than lower ones even for human listeners. Sometimes, the highest level (level 4) needs to decide how to group parts together (e.g., verse + pre-chorus or pre-chorus + chorus). Different decisions are sometimes all acceptable.

4.4.1 Out of Distribution Evaluation

We also want to know whether the proposed model can be applied to MIDI files with very different orchestration setups. Such experiments are hard to perform because of the lack of ground truth annotations. We here perform a small-scale experiment on the POP909 [49] dataset. We select the first 5 songs in the dataset ordered by index and manually annotate the metrical structure [3]. POP909 is a dataset of Chinese pop songs rearranged for piano performance. Each song only has 3 tracks, i.e., a vocal track and two piano tracks, making it harder compared to RWC-POP. The results are shown in table 2.

From the results, we can see the performance degrades even when all 3 tracks are present. By case inspection, we find that the proposed model has generally satisfactory performance on 3 out of 5 songs on lower layers. However, there is one complex song [4] with multiple metrical and hypermeter changes that make all the approaches fail. Also, due to the lack of rhythmic clues (e.g., drums), a deeper understanding of the syntax and semantics of melody and chords might be required to perform musically meaningful segmentation, which we assume our model can hardly acquire on a small training set of 50 pop songs.

4.5 Confidence Score Analysis

To perform a statistical analysis of the model behavior and provide a musicological view of the model prediction, we perform model inferences on a large selection of the Lakh MIDI dataset [50]. To ensure enough accuracy of model prediction, we only select a part of the Lakh MIDI dataset

[3] We are aware that POP909's downbeat annotations are sometimes inaccurate and we manually fixed them.

[4] POP909 No. 005: *I Believe* by Van Fan.

Model	Level 1	Level 2	Level 3	Level 4
Proposed	**0.9084 ±0.0896**	**0.8742 ±0.1101**	**0.6470 ±0.2174**	0.4930 ±0.3132
Rule	0.6818 ±0.1855	0.6625 ±0.1550	0.5163 ±0.1195	0.3446 ±0.1856
Oracle	0.8527 ±0.1735	0.7348 ±0.2763	0.5883 ±0.2493	**0.5767 ±0.2474**
Proposed (mel. only)	0.6742 ±0.2962	0.6542 ±0.2737	0.5685 ±0.2403	0.4797 ±0.2053
Rule (mel. only)	0.6062 ±0.1034	0.3933 ±0.0275	0.2642 ±0.0546	0.1551 ±0.0305

Table 2. Evaluated F1 scores on the first 5 songs in the POP909 dataset. Mel. only denotes that the melody track is used. Otherwise, all 3 tracks (melody, bridge and piano) are used.

that has a similar orchestration compared to RWC-POP. We filter the MIDI files according to the following criteria: (1) it contains at least 6 MIDI tracks, including 1 drum track and 1 track whose name contains strings "melody" or "vocal"; (2) if multiple MIDI files' identified audio sources are the same, at most one MIDI file is kept. A filtered dataset of 3,739 MIDI files is collected.

We here evaluate the relevance of instruments and the model's predicted confidence score. Notice that the instrument program number is not a part of the model input, so the only difference comes from the rhythmic properties of their scores. We collect the unnormalized confidence scores $\alpha^{(t)}$ for each track $\mathbf{m}_t$ of different instruments, and calculate their means and standard derivations. Specially, we regard all melody tracks (identified by their names) as a new instrument and ignore its original MIDI program number. Also, we remove all tracks with too many measure-level rests (more than 1/3 of the whole song) since they trivially result in low confidence scores.

Table 3 shows the results of confidence score analysis. We can see that drums are the strongest clue for metrical structures. The melody track and many melodic instruments (e.g., guitars) also serve as useful clues. On the other hand, instruments that produce slow accompaniments (e.g., string ensemble and pads) are less preferred.

4.5.1 Drum Track Analysis

As another experiment of musicological analysis, we perform an experiment on the relation between drum notes and the metrical structure level. For simplicity, we only collect samples that a certain drum event happens exactly on the downbeat, and we collect the corresponding metrical boundary level of that downbeat. The results are shown in Table 4. While the occurrence of many drum events does not significantly change the distribution of the metrical boundary level, the crash cymbal and splash cymbal are certainly useful clues to a high-level metrical boundary. This aligns with people's perception of them since these cymbals are usually associated with a strong burst of energy, serving as an important rhythmic hint.

Track/Instrument	Confidence
Melody	1.78 ± 1.22
Drum	3.61 ± 2.58
Acoustic Grand Piano	0.35 ± 1.69
Electric Guitar (jazz)	0.75 ± 1.55
Acoustic Bass	0.33 ± 1.66
String Ensemble	0.11± 1.70
Pad (warm)	-0.86 ± 1.78

Table 3. A selected view of the means and standard derivations of the confidence score for different tracks/instruments. The melody track is identified by its name instead of the MIDI instrument. The drum track is identified by its MIDI channel number (No. 10).

Drums (%)	L-0	L-1	L-2	L-3	L-4
Any	50.00	24.71	12.06	6.21	7.02
Bass Drum	48.66	25.10	12.46	6.47	7.30
Acoustic Snare	52.27	23.28	11.19	6.27	7.00
Closed Hi Hat	51.32	25.14	11.91	5.54	6.11
Open Hi Hat	51.90	25.07	11.33	5.38	6.32
Crash Cymbal	20.97	19.13	18.58	18.94	22.38
Ride Cymbal	51.41	25.03	11.57	5.61	6.39
Splash Cymbal	34.80	22.30	16.00	12.90	14.01

Table 4. A selected view of the frequency of different drum instruments (on a downbeat) associated with different levels of metrical boundaries. L-n means level-n metrical boundary.

5. CONCLUSION AND FUTURE WORK

In this paper, we propose a data-driven approach for hierarchical metrical structure analysis of symbolic music. Our model adopts a TCN-CRF architecture and accepts an arbitrary number of voices as input. Experiments on MIDI datasets show that our model performs better than rule-based methods under different orchestration settings.

The model performance is still not satisfactory, especially for high-level metrical structures and music with very different orchestration. We assume the performance would be better if more data were annotated, but there are also other possible directions for data-driven methods. First, self-supervised or semi-supervised methods might be a helpful complement to the lack of labeled datasets. For example, a consistency loss can be used to evaluate the prediction between different voices in the same music piece. Different data augmentation strategies might also be helpful. Second, it might be useful to utilize datasets of related tasks (e.g., section labels) as a source of weak supervision. Related tasks can also be used for multi-task learning.

Other potential future works include improving the automatic analysis system of other hierarchical structures, e.g., the grouping structures. The application of hierarchical structure analysis in the audio domain is also worth exploring.

ABSTRACT

The extraction of harmonic information from musical audio is fundamental for several music information retrieval tasks. In this paper, we propose novel harmonic audio features based on the perceptually-inspired tonal interval vector space, computed as the Fourier transform of chroma vectors. Our contribution includes mid-level features for musical dissonance, chromaticity, dyadicity, triadicity, diminished quality, diatonicity, and wholetoneness. Moreover, we quantify the perceptual relationship between short- and long-term harmonic structures, tonal dispersion, harmonic changes, and complexity. Beyond the computation on fixed-size windows, we propose a context-sensitive harmonic segmentation approach. We assess the robustness of the new harmonic features in style classification tasks regarding classical music periods and composers. Our results align with, slightly outperforming, existing features and suggest that other musical properties than those in state-of-the-art literature are partially captured. We discuss the features regarding their musical interpretation and compare the different feature groups regarding their effectiveness for discriminating classical music periods and composers.

1. INTRODUCTION

Over the last decades, music consumption has shifted from physical media to streaming services comprising large digital collections [1]. Methods for organizing these collections are fundamental for user navigation, browsing, and retrieval. In this context, a significant effort has been devoted to the automatic classification of musical audio signals into style or genre categories within Musical Information Retrieval (MIR) [2–4]. While the traditional approach to such tasks is based on hand-crafted features and classical machine learning, end-to-end deep-learning approaches have led to major improvements [4]. Nevertheless, strategies based on hand-crafted *mid-level* features are still of relevance since they allow interpretable and controllable systems that focus on specific aspects of the music.

Weiß, "Mid-level Harmonic Audio Features for Musical Style Classification", in *Proc. of the 23rd Int. Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

Existing approaches for style classification mostly rely on timbral or rhythmic mid-level features, which appear suitable for discriminating top-level genres such as pop, rock, jazz, and classical music [2, 5, 6] or sub-genres of popular music [7, 8]. However, such features are less suitable for discriminating sub-genres or historical periods within Western classical music—consider, e. g., the co-existence of solo piano music composed over several centuries [9]. To address this challenge, harmonic features have shown promising results [10–13]. Yet, existing harmonic audio features exhibit two main limitations. First, many of these features focus on low-level and short-term properties, which do not explicitly capture the horizontal or long-term structure of harmony, known to be relevant to style classification. Second, these features do not explicitly consider perceptual qualities, such as the degree of dissonance or the perceptual relationship of sonorities.

To account for the two limitations identified above, we consider in this paper a set of harmonic features based on the Tonal Interval Vector (TIV) space proposed in [14]. Multi-level pitch is mapped into a 6-dimensional complex space whose distances capture perceptual relationships between sonorities. We make the following four main contributions. (1) We consider the TIVs proposed in [14] for style classification. (2) On the TIV space, we advance a set of novel harmonic features for capturing long-term hierarchical harmonic relationships. (3) Moreover, we propose a structural audio segmentation based on harmonic changes and compare this approach to a fixed-window segmentation. (4) To assess the newly proposed harmonic features, we perform experiments for style classification of Western classical music, considering historical periods (eras) and composers as sub-genre taxonomies.

The paper is structured as follows. Section 2 discusses related work on the harmonic description of musical audio and style classification. Section 3 presents novel harmonic features based on the TIV space. Section 4 presents our experimental results using TIV features for style classification compared to the state-of-the-art. Finally, Section 5 presents the conclusions and future work.

2. RELATED WORK

The harmonic description of musical audio typically adopts chroma vectors to represent the energy of pitch-class content and to design higher-level harmonic features. Several methods have been proposed for the extraction of

chroma vectors [15–18]. The Non-Negative Least Squares (NNLS) chroma reduces the impact of overtones and has shown to be one of the most robust chroma vector representations for audio transcription [17].

For describing harmonic properties based on chroma vectors, Weiß et al. proposed a set of template-based chord and interval features [10] as well as tonal complexity features [11] for style period and composer classification within Western classical music. Most of these features are transposition-invariant and therefore do not depend on the key of the piece. These two sets of features are detailed in Sections 2.1 and 2.2. Furthermore, mid-level features for capturing chord transitions over time using Hidden Markov Models were proposed in [13].

2.1 Template-based Features

Motivated by the study on stylistic features from pitch-class sets by Honingh and Bod [19, 20], Weiß et al. [10] propose a set of template-based features (denoted as $\mathbf{F}$) studying the likelihood of a given complementary interval or triad type in a chroma vector $\mathbf{c} = (c_0, c_1, ..., c_{11}) \in \mathbb{R}^{12}$. For example, the likelihood of a perfect fourth/fifth interval, F_{IC5}, results from multiplying c_0 by c_5. To make these features transposition-invariant, the authors sum all cyclic shifts of the same interval in a given chroma vector $\mathbf{c}$. This calculation is simplified by applying a binary template $\mathbf{I}$ according to the desired type of interval or triad. A perfect fourth/fifth interval template is $\mathbf{I} = (1, 0, 0, 0, 0, 0, 0, 1, 0, 0, 0, 0)^\top$.

2.2 Tonal Complexity Features

Tonal Complexity features (denoted as $\mathbf{G}$) aim to capture musical attributes such as the amount of tonal variation in musical content. In [11], a total of seven complexity features are defined. For example, G_{CompEntr} represents the Shannon entropy of a chroma vector while $G_{\mathrm{CompFifth}}$ describes the spread of a chroma vector over the circle of fifths. Please refer to [11] for a thorough mathematical definition and musical interpretation of these features.

2.3 Tonal Interval Vectors

TIVs represent multi-level pitch in a geometrical space where vector distances relate to their perceived proximity [14]. The perceptual basis of the TIV space addresses three common limitations in preceding tonal pitch spaces [21–24]. First, it allows the representation and comparison of pitch at multiple time scales, namely individual pitches, chords, and keys. Second, prior knowledge of the key center is not required when measuring pitch distances. Third, it provides an indicator of consonance, lacking in related spaces. Moreover, distances between TIVs capture musical properties such as voice leading and shared interval content. Similar to the approach used in [25], the 6-dimensional complex TIV $\mathbf{T} \in \mathbb{C}^6$ is computed as the Discrete Fourier Transform (DFT) to a chroma vector $\mathbf{c} \in \mathbb{R}^N$

k	IC	Harmonic Quality	Intervals	w_k
1	IC1	Chromaticity	m2/M7	3
2	IC6	Dyadicity	Tritone	8
3	IC4	Triadicity	M3/m6	11.5
4	IC3	Diminished Quality	m3/M6	15
5	IC5	Diatonicity	P4/P5	14.5
6	IC2	Wholetoneness	M2/m7	7.5

Table 1. Harmonic quality and interval category associated with each TIV coefficient magnitude $\frac{\|T_k\|}{w_k}$.

as follows:

$$T_k = w_k \sum_{n=0}^{N-1} \bar{c}_n e^{-\frac{j2\pi kn}{N}}, \quad 1 \leq k \leq 6, \\ \text{with} \quad \bar{c}_n = \frac{c_n}{\sum_{n=0}^{N-1} c_n} \quad , \tag{1}$$

where $N = 12$ is the dimension of the chroma vector. We set $1 \leq k \leq 6$ due to the properties of the DFT by which the remaining coefficients are symmetric. $\mathbf{w} = (3, 8, 11.5, 15, 14.5, 7.5)$ are weights adjusting the contribution of each dimension T_k to improve the perceptual basis of the space in representing musical audio. They adjust the contribution of each coefficient T_k and promote the importance of the most relevant intervals within tonal music, such as fourths/fifths and major and minor thirds/sixths. These weights are derived from empirical dissonance ratings of complementary intervals and triads (major/minor, sus4, augmented, diminished). The adoption of the weights $\mathbf{w}$ have shown to capture perceptual distances between musical audio sonorities irrespective of timbral differences to a greater degree than chroma vectors or an unweighted DFT space [26].

2.4 TIV Basic Features

We now describe a group of features directly computed from TIVs, referred to as TIV Basic (denoted as $\mathbf{B}$). Musical interpretations are attributed to the magnitude $\|T_k\|/w_k$ of each of the six coefficients, evaluating the intervallic content of pitch configurations and its associated harmonic quality (see Table 1). For example, $k = 5$ corresponds to the $B_{\mathrm{Diatonicity}}$ feature. We establish a correspondence between each coefficient magnitude and the six complementary interval categories defined in Western music theory [20].

A TIV's indicator of consonance is computed as its magnitude (vector length) normalized to the norm of the weight vector $\mathbf{w}$, such that:

$$B_{\mathrm{Dissonance}} = 1 - \|\mathbf{T}\|/\|\mathbf{w}\| \quad . \tag{2}$$

3. FEATURE DESIGN IN THE TONAL INTERVAL SPACE

Aiming to take full advantage of the properties of TIVs, we now propose novel mid-level harmonic audio features that consider the harmonic structure and long-term hierarchical dependencies between audio segments.

3.1 TIV Complexity Features

Our first feature group, denoted as **Q**, captures aspects of tonal complexity and consonance, somehow mirroring the features presented in Section 2.2.

3.1.1 Distance Between Audio Segments

Distances between TIVs relate to their perceived similarity such that small distances equate to perceptually similar sonorities. To this end, Euclidean and cosine distance metrics between TIVs, which measure different perceptual characteristics of the signal, have been considered in the literature [14, 27].

The cosine distance θ measures the phase difference between two TIVs, capturing pitch class distances that roughly correspond to voice leading parsimony. Smaller values indicate a higher number of shared pitch classes.

The Euclidean distance metric d captures the phase φ_k and magnitude $\|T_k\|$ differences between TIVs. In addition to measuring the number of shared pitch classes between TIVs, it also accounts for shared interval content.

To exploit the musical properties of these two distance metrics, we propose new features that measure the perceptual distance between consecutive musical audio segments. Given the TIV $\mathbf{T}_n = (T_{0,n}, \ldots, T_{5,n})$ of the n-th segment, the Euclidean (d) and cosine (θ) distances between two consecutive segments is defined as:

$$\begin{aligned} Q_{\text{EucDist}} &= s_n^{\text{euc}} = d\{\mathbf{T}_n, \mathbf{T}_{n+1}\}, \\ Q_{\text{CosDist}} &= s_n^{\text{cos}} = \theta\{\mathbf{T}_n, \mathbf{T}_{n+1}\} \end{aligned} \tag{3}$$

The metrics can be applied at multiple hierarchies (or time scales) by adopting musical audio segments of different sizes. While short segments capture chord changes, larger segments can capture the overall tonal structure (e.g., key modulations).

3.1.2 Tonal Dispersion

The tonal dispersion of the n-th audio segment n is defined as the distance of its respective TIV to the tonal center $\overline{\mathbf{T}}$:

$$\begin{aligned} Q_{\text{EucTonalDisp}} &= u_n^{\text{euc}} = d\{\mathbf{T}_n, \overline{\mathbf{T}}\}, \\ Q_{\text{CosTonalDisp}} &= u_n^{\text{cos}} = \theta\{\mathbf{T}_n, \overline{\mathbf{T}}\} \end{aligned} \tag{4}$$

The tonal center of a piece corresponds to the TIV of the pitch-class distribution averaged across its entire duration. The tonal dispersion indicates how much the harmonic content of a given segment deviates from the tonal center $\overline{\mathbf{T}}$ and can indicate the degree of modulations across the piece or the segments with non-diatonic pitch classes (i.e., further away from the tonal center). This feature can help discriminate later classical musical periods that typically have larger tonal dispersion [28]. To compute the distance of a given segment n from the tonal center, we adopt both the Euclidean and cosine distance metrics to capture the different harmonic aspects mentioned in Section 3.1.1.

3.1.3 TIV Entropy

Related literature has been adopting Shannon entropy to capture the harmonic complexity within musical style [11, 29]. Amiot [30] recently proposed the computation of harmonic complexity from symbolic pitch-class distributions as the Shannon entropy of its Fourier coefficients. Following [30], we propose a TIV entropy feature to capture harmonic complexity from musical audio. The TIV entropy is high for random pitch-class distributions and low for pitch-class distributions that exhibit some degree of organization (i.e., periodicity or sparseness). We define the TIV entropy feature as the entropy of the normalized coefficient magnitudes of a TIV $\mathbf{T}$:

$$Q_{\text{TIVEntropy}} = \sum_{k=1}^{6} -p_k \log p_k, \quad p_k = \frac{\|T_k\|}{\sum_{j=1}^{6} \|T_j\|} \tag{5}$$

While entropy has been shown to capture different stylistic attributes depending on the time scale under analysis [29], we demonstrate in Table 2 the TIV entropy of various pitch-class sets. Lower TIV entropy (i.e., denoting greater organization) includes fairly common pitch-class distributions such as diatonic scales, triads, and tetrads. Higher TIV entropy denotes musical structures with less common adoption in the tonal music lexica, such as the chromatic set and its many subsets.

Pitch class set	TIV Entropy
Octatonic scale	0.3551
Diminished seventh chord	0.3552
Whole tone scale	0.5268
Diatonic scale	1.2444
Pentatonic scale	1.2972
Harmonic minor scale	1.4927
Minor seventh chord	1.5542
Single note	1.6767
Chromatic scale	1.6906

Table 2. TIV entropy of several pitch-class sets. For details on the elements of each set please refer to [30].

3.2 Harmonic Rhythm Features

Harmonic rhythm is the rate at which the chords change in a musical piece. It can provide a prominent indicator to distinguish style periods. For example, a fast harmonic rhythm is a characteristic of the Baroque period [31] in comparison with the large-scale structures of a Romantic symphony. To this end, we advance new features (denoted as **R**) that study the rate and magnitude of harmonic changes based on the Harmonic Change Detection Function (HCDF) proposed in [32]. The value ξ_n of the HCDF at frame n is defined as the rate of change between the TIVs $\mathbf{T}_{n-1}$ and $\mathbf{T}_{n+1}$ after Gaussian smoothing and is computed using the Euclidean distance.

Let us now consider Ξ_m as the set of frame indices of the peaks of the HCDF, considering all local maxima as peaks. We define the inter-peak interval feature as the difference between the frame numbers of consecutive peaks of the HCDF:

$$R_{\text{HCDFPeakInterval}} = \Delta_m = \Xi_{m+1} - \Xi_m \tag{6}$$

As an additional feature, we consider the magnitude of the peaks, $R_{\text{HCDFPeakMag}}$, given by ξ_Y, with $Y = \Xi_m$, which captures the degree of the harmonic changes.

3.3 Temporal Resolution of Tonal Interval Vectors

We detail two segmentation strategies for the feature extraction process: multiple fixed-size segment resolutions (Section 3.3.1) and variable-size segments resulting from the analysis of harmonic changes (Section 3.3.2).

3.3.1 Fixed-size Segmentation with Multiple Resolutions

Fixed-size segments with equal duration are adopted at multiple time scales or resolutions to capture the piece's different harmonic or tonal dimensions. Following [10–12], we consider four time resolutions in our work: 100ms, 500ms, 10s, and global (i.e., the entire piece or excerpt under analysis). Smaller time scales (e.g., 100ms and 500ms) capture finer musical elements such as individual notes, intervals, and chords. Larger time scales (e.g., 10s and global) capture higher harmonic structures at the level of structural parts or the overall piece, enhancing the harmonic changes in the large-scale tonal structure of the composition (such as key and modulations) and the harmonic trajectories of the horizontal structure (such as chord progressions).

3.3.2 Harmonic Structural Segmentation

We define a context-sensitive segmentation at the peaks of the HCDF (see Section 3.2). This strategy considers prominent harmonic changes as segment boundaries, therefore producing segments of varying duration according to the specific harmonic changes in the audio content. The use of context-sensitive segmentation in the feature extraction process of musical analysis systems has been shown to improve their accuracy compared to fixed segmentation approaches, which are less aware of musical structure [33, 34].

4. EXPERIMENTS AND RESULTS

To assess the degree to which the harmonic information conveyed by TIV harmonic audio features in Section 3 discriminate musical style, we evaluate the proposed features in two classical music style classification tasks from musical audio: historical periods (e.g., Baroque or Romantic) and composers. Furthermore, we compare the accuracy of the above features to the state-of-the-art template-based and complexity features described in Sections 2.1 and 2.2. To study the accuracy of different groups of features, we consider the two following sets: (template-based $\mathbf{F}$ and tonal complexity $\mathbf{G}$) and (TIV basic $\mathbf{B}$, TIV complexity $\mathbf{Q}$, harmonic rhythm $\mathbf{R}$). Finally, we inspect the impact of different context-sensitive vs. fixed-window segmentation strategies.

4.1 Experimental Procedure

For our experiments, we consider the *Cross-Era* [1] and *Cross-Composer* [2] datasets, which include 1600 and 1100 pieces, respectively. In detail, the *Cross-Era* dataset has 400 pieces per classical style period and features the following four periods: Baroque, Classical, Romantic, and Modern. The *Cross-Composer* dataset includes 100 pieces for each of the 11 featured classical music composers across all style periods. These datasets are further divided into the subsets presented in Table 3. The datasets provide pre-extracted NNLS chroma features at a resolution of 100ms (10Hz) for each piece.

Dataset	No. Classes (Z)	Items per Class
Cross-Era-Full	4	400
Cross-Era-Piano	4	200
Cross-Era-Orchestra	4	200
Cross-Comp-11	11	100
Cross-Comp-5	5	100

Table 3. Balanced subsets obtained from the *Cross-Era* and *Cross-Composer* datasets [12].

Based on [12], we employ the following classification procedure. Using the subsets listed in Table 3, we compute the features and calculate their piece-wise mean (μ) and standard deviation (σ). Then, we perform a stratified split into three cross-validation (CV) folds, one for testing and two others for training the model. Next, we use the two training folds to compute a Linear Discriminant Analysis (LDA) matrix to reduce the dimensionality of all three folds to $L = Z - 1$ with Z being the number of classes per task. We then perform a five-fold grid search on the two training folds to train an SVM classifier while optimizing its hyperparameters. We conduct this procedure three times, with each fold serving for testing once. To evaluate the robustness of the model concerning the random distribution into folds, we repeat the procedure ten times with re-initialized folds to calculate the accuracy deviation between the different classes (i.e., inter-class deviation).

To counteract problems stemming from adopting tracks from the same CD recording on the training and test folds (known as the album effect [35]), we take additional measures to prevent the model from adapting to the acoustic conditions of specific recordings. To this end, inspired by [11], we apply a composer filter (for period classification) or a performer filter (for composer classification) during the CV procedure that forces pieces from the same composer/performer to be placed within the same fold, thus avoiding overfitting while making the task more challenging and closer to real-world application scenarios.

4.2 Influence of Different Types of Segmentation

We analyze the impact of different audio segmentation strategies on the classification of classical music periods. Table 4 displays the classification accuracy for the TIV Basic ($\mathbf{B}$), TIV Complexity ($\mathbf{Q}$), and Harmonic Rhythm ($\mathbf{R}$) feature groups, as well as the combination of all the above features (through concatenation), on the *Cross-Era* dataset. As segmentation strategies, we consider fixed-size segmentation with a single resolution of 100ms (FS), fixed-size segmentation with multiple resolutions (MR)—100ms, 500ms, 10s, and global—and harmonic structural

Table 4. Classification accuracy for different types of segmentation: fixed-size (FS), fixed-window with multiple temporal resolutions (MR), harmonic structural segmentation (HS), and a combination of the last two approaches.

segmentation (HS). Additionally, we consider combining the two approaches presented in Section 3.3 (MR + HS).

For the *Cross-Era-Piano* and *Cross-Era-Full* datasets, the MR strategy shows slightly higher accuracy than other segmentation strategies. For other scenarios such as the *Cross-Era-Orchestra* dataset, combining the MR and HS approaches leads to similar or slightly better results. Overall, the MR strategy obtains the highest accuracy values in most cases and is less computationally expensive than the HS approach. Therefore, we opt for the MR strategy in all subsequent experiments, using the HS strategy only for the harmonic rhythm feature group $\mathbf{R}$.

4.3 Style Period and Composer Classification

Using the MR strategy, we perform style period and composer classification experiments on a larger set of feature combinations and show the results in Table 5. We first compare the template-based ($\mathbf{F}$) and TIV basic ($\mathbf{B}$) feature groups, which capture similar harmonic aspects. Indeed, we observe that these groups perform similarly on most datasets, with accuracy differences of 2.98% and 4.74% on the *Cross-Era-Piano* and *Cross-Comp-5* datasets, respectively. The tonal complexity ($\mathbf{G}$) and TIV complexity ($\mathbf{Q}$) groups show a greater performance accuracy difference in the *Cross-Era-Piano* dataset (7.85%) and a smaller difference in the *Cross-Era-Full* dataset (3.33%). Concerning the two largest datasets (*Cross-Era-Full* and *Cross-Comp-11*), the best feature groups result from combining TIV features with those proposed in [10, 11], achieving 74.04% and 38.25% accuracy, which correspond to an improvement of 2.88% and 4.74%, respectively, compared to using only the features proposed in previous work.

From these findings, we draw two main conclusions. First, conceptually similar feature groups lead to quite similar classification accuracies—an encouraging finding, which proves that our approach is valid (a kind of "sanity check" against [10, 11]) and indicates that the features exhibit the intended mid-level semantic properties (feature groups describing related harmonic properties behave similarly for classification). Second, the novel features at least partially capture complementary information such that their combination improves upon individual groups. Overall, we do not reach the state-of-the-art results on the *Cross-Era-Orchestra* and *Cross-Era-Full* subsets, which were obtained in [13] using chord transition features in combination with template-based and complexity features, surpassing our results by 6.01% and 4.16%. However, since TIV-based features improve upon the ones of [10,11], we hypothesize that, in combination with the chord transition features of [13], they might be able to reach even better classification accuracies.

4.4 Harmonic Features Correlation

We adopt hierarchical clustering to assess the degree of information (and redundancy) of harmonic audio features. Figure 1 shows the hierarchical clustering of all harmonic features detailed in Sections 2.2, 2.1, and 3, which we adopt in our experiments. Features are computed at a fixed-size 100ms resolution with average and standard deviation statistics.

Template-based ($\mathbf{F}$) and TIV basic ($\mathbf{B}$) features appear strongly correlated, often ending up in the same cluster. This suggests they may be capturing similar musical properties. For example, the two top-most features $F_{\mathrm{IC5},\sigma}$ and $B_{\mathrm{Diatonicity},\sigma}$ are direct neighbours and are both based on perfect-fifth relationships. Tonal Complexity ($\mathbf{G}$) and TIV Complexity ($\mathbf{Q}$) features also appear correlated, albeit to a slightly lower degree. For example, the green cluster is mainly composed of features from these groups. On the other hand, the red cluster contains several TIV Complexity features and none from the Tonal Complexity group, suggesting that those, in particular, describe different harmonic characteristics. The adopted global statistics, mean and standard deviation, tend to be grouped under the same cluster, suggesting to capture complementary information.

5. CONCLUSIONS AND FUTURE WORK

In this paper, we proposed a novel set of mid-level and perceptually-inspired harmonic audio features based on TIVs, which provide indicators for musical dissonance, chromaticity, dyadicity, triadicity, diminished quality, diatonicity, and whole-toneness, as well as quantify perceptual relations of short- and long-term harmonic structures, tonal dispersion, harmonic changes, and complexity. Features are computed using context-sensitive harmonic structure segmentation and a fixed-size segmentation with multiple temporal resolutions.

Proposed TIV harmonic features were assessed in two classical music style period and composer classification tasks using five different datasets. The novel TIV harmonic features have been compared to state-of-the-art harmonic features proposed in [10–12] and showed similar results, slightly outperforming in four out of the five datasets, with an improvement of up to 4.74%. A high degree of re-

dundancy with existing state-of-the-art features has been found. However, the results suggest that new information is captured in the proposed TIV harmonic features, namely in what concerns the horizontal or long-term harmonic structure, e.g., tonal dispersion and distance between audio segments, and harmonic rhythm. While the context-sensitive segmentation strategy introduced slight improvements to classification accuracy, these do not seem to outweigh its higher computational cost.

Finally, for research reproducibility, we made the implementation of the proposed system publicly available online at `github.com/fcfalmeida/style-ident`. In future work, we may consider optimizing the segmentation strategy, expanding it to account for multiple time scales, conducting classification experiments on other musical genres, and experimenting with different machine learning approaches such as deep learning.

ABSTRACT

Given the recent advances in music source separation and automatic mixing, removing audio effects in music tracks is a meaningful step toward developing an automated remixing system. This paper focuses on removing distortion audio effects applied to guitar tracks in music production. We explore whether effect removal can be solved by neural networks designed for source separation and audio effect modeling.

Our approach proves particularly effective for effects that mix the processed and clean signals. The models achieve better quality and significantly faster inference compared to state-of-the-art solutions based on sparse optimization. We demonstrate that the models are suitable not only for declipping but also for other types of distortion effects. By discussing the results, we stress the usefulness of multiple evaluation metrics to assess different aspects of reconstruction in distortion effect removal.

1. INTRODUCTION

With the emergence of musical recordings, audio effects have become indispensable in the music production process. They are used by musicians as a creative tool to alter the sound of their instruments, and by sound engineers to craft a balanced mix from multiple recording tracks [1].

For the task of mixing and automatic remixing [2], the *dry* (i.e., unprocessed) source tracks are required. Given the recent advances in automatic mixing [3, 4] and music source separation (MSS) [5], a system could facilitate the adjustment of a stereo mixture to the taste and preferences of the user similar to [6]. However, when separating sources with a system trained on music stems (e.g., `MUSDB18` [7]) the mixing process is not considered, and, hence, the output of such a system contains the *wet* (i.e., processed) signal. As nonlinear distortion is one of the most commonly used effects for electric instruments, this work focuses on musical distortion effects that are used for aesthetic means (e.g., guitar overdrive/distortion pedals) and applied in the process of mixing (e.g., tape saturation). These distortion effects result in added harmonics, intermodulation distortion, and a compressed sound [8].

This paper investigates different deep neural network (DNN) approaches regarding their applicability to the audio effect removal problem. Our contributions can be summarized as follows:

- We show that recovering the clean signal from clipped or overdriven guitar signals can be efficiently solved with neural networks designed for source separation. The models achieve high quality and fast inference in contrast to solutions based on sparse optimization.
- We found that the superior performance of the models evaluated on the de-overdrive task can be traced back to superimposing the overdriven signal with the clean signal. We show that the architectures are suitable not only for declipping but also for other types of distortion effects.
- By discussing the results, we highlight that the metrics under evaluation prove beneficial in measuring different aspects of the reconstruction and can be advised for further investigations.

This work is organized as follows: Sec. 2 gives a formal introduction to audio effect removal and introduces the types of distortions that were used throughout this study. Sec. 3 briefly discusses previous work on iterative and DNN-based declipping approaches. The methods under evaluation are outlined in Sec. 4. Sec. 5 describes the data that were used for training, reports details about the experimental setup, and presents the chosen objective evaluation metrics. In Sec. 6, we evaluate the results of the comparative study of four different neural network architectures on the task of distortion removal in guitar signals for the SoX overdrive implementation. Then, we compare the same architectures on the declipping task to one state-of-the-art declipping algorithm using guitar signals as well as generic music signals. Lastly, Sec. 7 gives a conclusion and presents an outlook for future work. Audio examples are available online at *joimort.github.io/distortionremoval/*.

Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

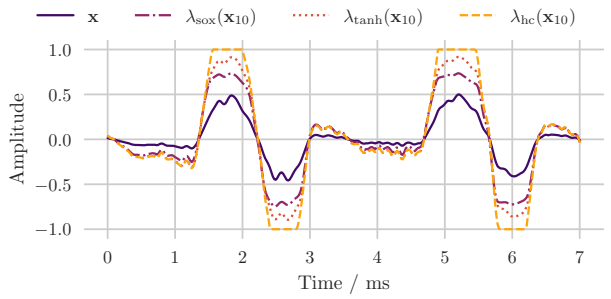

Figure 1. Example of different distortion types applied to a guitar signal. The input signal $x(k)$ is amplified before being modified by a wave-shaper function.

2. PROBLEM FORMULATION

We introduce audio effect removal as the task of recovering the original discrete audio signal $\mathbf{x} \in \mathbb{R}^n$ from the processed discrete signal $\mathbf{y} \in \mathbb{R}^n$, which is obtained by applying the possibly nonlinear and time-varying function f to the signal $\mathbf{x}$:

$$\mathbf{y} = g(\mathbf{x}) = \alpha f(\mathbf{x}) + (1-\alpha)\mathbf{x}, \tag{1}$$

with $\alpha \in [0, 1]$ denoting the weight of the wet signal, and g the summation function of the dry and wet signal. The goal is to find an estimation of the original signal $\hat{\mathbf{x}}$ by estimating the inverse function $\hat{\mathbf{x}} = \hat{g}^{-1}(\mathbf{y})$.

Generally, distortion effects clip the input signal and can be divided into systems that apply hard-clipping or soft-clipping. As this work focuses on both types of distortion, we introduce the following generic formulation of a wave-shaper that maps the amplified signal $\mathbf{x}_\gamma = 10^{\frac{\gamma}{20}}\mathbf{x}$ to a fixed range:

$$f(\mathbf{x}) = \lambda(\mathbf{x}_\gamma) \quad \text{with} \quad \lambda : \mathbb{R} \to [-\theta_\text{c}, \theta_\text{c}]. \tag{2}$$

Here, γ denotes the gain in decibels, λ the arbitrary wave-shaper function, and θ_c the fixed clipping threshold. For the case of hard-clipping, λ is defined as:

$$\lambda_{\text{hc}}(x_{\gamma,k}) = \begin{cases} x_{\gamma,k}, & \text{if } |x_{\gamma,k}| \leq \theta_\text{c} \\ \theta_\text{c}\text{sgn}(x_{\gamma,k}) & \text{otherwise,} \end{cases} \tag{3}$$

with sgn denoting the sign function, and $x_{\gamma,k}$ the k-th time sample of the amplified signal. Fig. 1 highlights the difference between different distortion types. Hard-clipping cuts off the amplitude when it exceeds a defined threshold (as typical for saturation in digital signal processing). Soft-clipping (e.g., $\lambda_{\tanh}(x_{\gamma,k}) = \tanh(x_{\gamma,k})$) gradually applies a smooth transition before reaching a fully saturated state (as typical for saturation in analog amplifiers).

Modeling the characteristics of distortion pedals in reality is more complex: [9] provides an overview on different methods and discusses DNN-based approaches. In order to simplify the problem for our investigation, we focus on wave-shaping. The overdrive algorithm of the audio editing software SoX [10] serves as an example of soft-clipping (λ_{sox}) but, in contrast to (2), it is dependent on previous samples. Furthermore, it blends the wet signal with the dry one ($\alpha < 1$).

3. RELATED WORK

To the best of our knowledge, there has been no previous research on distortion audio effect removal. Therefore, this section outlines the most relevant iterative and DNN-based declipping approaches since declipping is a special case of distortion audio effect removal.

3.1 Iterative Declipping Methods

Previous research on approaches to declipping has focused mainly on unsupervised algorithms that recover the signal under the assumption of a generic regularization such as signal sparsity [11]. Usually, these approaches target the hard-clipping case only (see (3)). While early approaches were based on auto-regressive models, (e.g., [12]) recent state-of-the-art methods evolved by combining ideas from inverse problems and sparse regularization [13].

Recently, [11] and [13] discussed popular declipping algorithms. One of the current state-of-the-art methods is A-SPADE, which will serve as a baseline for this study. The algorithm is briefly introduced in Sec. 4.

3.2 DNN-Based Declipping

In contrast to iterative algorithms, to date, there are only few contributions comprising supervised DNNs.

Kashani *et al.* [14] introduced a declipping method based on the U-Net architecture [15]. It operates on magnitude spectrograms while the waveform of the output is obtained by reusing the phase information from the distorted input signal. The system is trained and evaluated on pairs of hard-clipped and clean speech samples.

Mack and Habets [16] proposed an architecture comprising a BLSTM-based deep filtering method that works on complex spectrograms and hence also considers phase information. Similar to [14], they train the system on speech data only. Unlike any other approach, they not only investigate the system on the hard-clipping case but also on the soft-clipping case.

Tanaka *et al.* recently proposed APPLADE [17], a declipping method that takes advantage of the sparse optimization techniques described above together with deep learning. Accordingly, they embed a DNN in the iterative algorithm to enhance the thresholding operation. They report a slightly higher performance than previous algorithms, better robustness to mismatches between training and test data, and faster inference.

4. METHODS

This section describes four neural network architectures that we selected from the literature and evaluated on the distortion removal task. We approach the distortion effect removal problem from the perspective of filtering the added harmonics and intermodulation distortion, similar to [16]. Therefore, we include one model from the domain

of audio effect modeling and three architectures originally proposed for music source separation. [1] For the latter models, instead of multiple output channels for different sources, we use only one output channel and consider them as general audio-to-audio transformation architectures.

CRAFx was proposed as a system for modeling time-varying audio effects with a neural network [9, 18]. The end-to-end model operates on the signal in the time domain and is divided into an adaptive front-end (encoder), a bi-directional long-short-term-memory (BLSTM)-based structure that applies the modeled effect in the latent space, and a synthesis back-end (decoder). In contrast to the other DNN-based models presented in this section, this architecture employs architectural priors (e.g., learnable nonlinear activations) in the context of audio effects.

Open-Unmix (UMX) was introduced as a reference implementation for music source separation [19]. The architecture is based on the BLSTM model from [20] and uses magnitude spectrograms as input features. The essential element of Open-Unmix is its three-layer BLSTM network that enables to learn both long- and short-time dependencies [21].

An element-wise multiplication of the input spectrograms with the estimated masks yields the final output. Commonly, spectrogram-based source separation models are compared with the oracle performance of an ideal ratio mask (IRM) that is defined as the ratio between the reference and the test spectrogram [22] in decibels. For reconstruction, the phase of the input signal is used. The model was adapted for a sampling rate of $f_s = 16\,\mathrm{kHz}$. We include this model in our evaluation as a standard frequency domain MSS model that relates to the BLSTM-based declipping model from [16] (cf. Sec. 3.2).

Wave-U-Net was proposed as one of the first end-to-end approaches for music source separation based on time domain signals [23]. Hence, it incorporates not only the magnitude but also the phase of music signals. It adapts the U-Net architecture [15] to one-dimensional audio signals. We decreased the models' number of learnable parameters from 17M to approximately 1M by reducing the number of layers from 12 to 8 resulting in a reduced receptive field, as we experienced overfitting for our datasets. Since the model was successfully employed not only for source separation but automatic mixing as well [3], we assume a general suitability for audio-to-audio transformation tasks. Moreover, the model is highly related to the U-Net-based declipping model from [14] (cf. Sec. 3.2).

Demucs was initially designed to be an end-to-end model for music source separation in the time domain [24]. While it builds on the Wave-U-Net model, it introduces several improvements to the architecture. The model comprises a convolutional encoder, a BLSTM structure, and a convolutional decoder. As for Wave-U-Net, we decreased the number of trainable parameters from 66M to 1M by reducing the number of blocks from 12 to 6 resulting in a reduced receptive field.

A-SPADE was introduced as a sparsity-based declipping algorithm that outperforms previous similar approaches [25]. For each time frame of the clipped signal $\mathbf{y}$, it approximates a solution of the following problem:

$$\min_{\mathbf{x},\mathbf{z}} ||\mathbf{z}||_0 \text{ s.t. } \mathbf{x} \in \Gamma(\mathbf{y}) \text{ and } ||\mathcal{F}(\mathbf{x}) - \mathbf{z}||_2 \leq \epsilon, \quad (4)$$

where $\mathbf{z}$ denotes the unknown discrete Fourier coefficients of each time frame and $\mathcal{F}$ the Fourier transform operator. Γ is defined as the feasible space of solutions (i.e., clipping consistency constraint). We included the algorithm in the evaluation of the declipping task as a baseline that delivers state-of-the-art performance [11, 13].

5. EXPERIMENTS

Our experiments focus on the following three scenarios: **a)** We conducted experiments on guitar recordings that were processed using the overdrive algorithm of the audio editing software SoX [10] (CEG-OD). **b)** We performed the same experiments as in the previous scenario while processing the same clean guitar recordings with hard-clipping (CEG-HC). **c)** We tested the systems on an extensive dataset comprising various hard-clipped sounds (SignalTrain-HC) to evaluate their performance against a popular declipping algorithm when the models are trained given an increase in the amount and variety of data.

5.1 Data

The models were trained on two different datasets to assess the distortion audio effect removal capabilities. The audio signals from a dataset that contains a single instrument class (e.g., electric guitar) exhibit consistent signal statistics. In order to restrict the statistics that need to be modeled in a first step, we chose to concentrate on dry guitar samples as target data.

Since a large-scale, polyphonic dataset from clean electric guitar sounds is, to the best of our knowledge, not available [2], we used an internal dataset, which we refer to as CEG (Clean Electric Guitar) dataset. The monaural data were gathered from various sources, mainly commercial audio loop packages and recordings of solo guitar, and has a duration of $1.68\,\mathrm{h}$. All signals were re-sampled to a common sampling rate of $16\,\mathrm{kHz}$ in order to speed up convergence during training. To create the input dataset CEG-OD, the overdrive algorithm of SoX was applied to the data using five uniformly sampled gain levels in the range of $\gamma \in [20, 50]\mathrm{dB}$. Likewise, the input dataset for the hard-clipping task, CEG-HC, was created using hard-clipping (see (3)) with gain levels from the same distribution. Both datasets have a total length of $8.4\,\mathrm{h}$.

Although CEG represents a good source of data for our experiments due to its specificity of timbre, it remains a

[1] Two of the methods under evaluation, Demucs and Wave-U-Net, do not explicitly filter the signals in the audio domain, rather they perform a nonlinear mapping. Nevertheless, they were both successfully employed for MSS, which is a filtering problem.

[2] A publicly available guitar dataset for the recognition of audio effects exists (IDMT-SMT-Audio-Effects [26]). However, the dataset contains primarily homogeneous monophonic sounds and therefore, we choose to use the CEG dataset instead.

limited resource in terms of size and variety. Before attempting to train a system to handle recordings in real environments (e.g., a commercial song), we need to investigate how the current models at our disposal handle the availability of more and diverse training data. For this purpose, we also performed experiments on the SignalTrain dataset, which consists of more than 24 h of music and randomly-generated test signals [27]. By applying hard-clipping to these clean data using a uniformly-sampled input SDR value in the range $\mathrm{SDR}_{\mathrm{inp}} \in [1, 20]\mathrm{dB}$, we created SignalTrain-HC. During evaluation, we applied each input SDR in the set $\mathrm{SDR}_{\mathrm{inp}} \in \{1, 3, 5, 7, 10, 15, 20\}\mathrm{dB}$ to each sample in the test set.

Each dataset was split into non-overlapping subsets for training (80%), validation (10%) and testing (10%). We evaluated the models on the test split.

5.2 Experimental Setup

During the supervised training procedure, Adam [28] was used as optimizer with initial learning rates according to the model's original implementations. The learning rate was reduced by a factor of 10 after 150 epochs of no decrease in the validation loss. All models were optimized using the source-to-distortion ratio (SDR) between their full output sequences $\hat{\mathbf{x}}$ and the respective target sequences $\mathbf{x}$ in each batch $\mathcal{B}$ of N elements (not to be confused with the definition in the `BSS_eval` toolkit [29]):

$$\mathcal{L}_{\mathcal{B}}(\mathbf{x}, \hat{\mathbf{x}}) = \frac{1}{N} \sum_{i \in \mathcal{B}} 10 \log_{10} \left(||\mathbf{x}_i||^2 / ||\mathbf{x}_i - \hat{\mathbf{x}}_i||^2 \right). \quad (5)$$

We stopped all trainings after 1000 epochs. All models processed audio sequences that are randomly extracted from each clip in the dataset; the length of the extracted sequences is equal to 2 s (2.3 s for CRAFx due to its architecture). We used a batch size of 16 for all experiments.

5.3 Objective Metrics

In speech enhancement and source separation, the ubiquitous measure to estimate the quality of a system is the SDR. However, applying (2) to a signal does not retain its energy. Therefore, we follow the approach of [30]: the **scale-invariant SDR (SI-SDR)** is obtained by rescaling the target signal s such that the residual $s - \hat{s}$ is orthogonal to s by using the optimal scaling factor $\hat{s}^T s / ||s||^2$.

An evaluation exclusively based on the objective similarity of the signals does not necessarily imply a correlation with human perception [31, 32]. Accordingly, we observed that the SI-SDR scores occasionally disagreed with our qualitative evaluation. Therefore, we also considered three metrics based on human perception.

The **perceptual evaluation of audio quality (PEAQ)** [33] is a widely used perceptual metric [11, 13, 34, 35] that measures the amount of degradation between two audio signals. The output of PEAQ is an Overall Difference Grade (ODG), which can reach values between 0 (*imperceptible impairment*) and -4 (*very annoying impairment*). Even though PEAQ is used in declipping and audio restoration studies [11, 13, 34], it was developed for audio codecs.

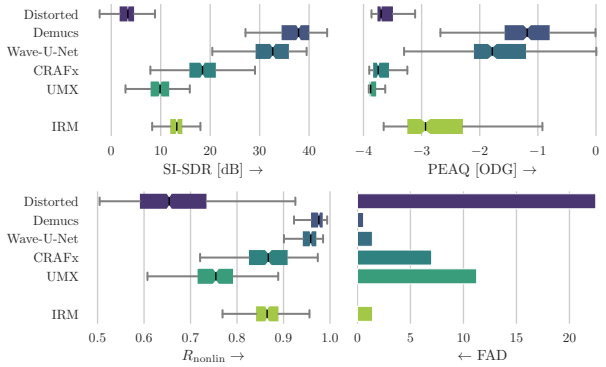

Figure 2. Box plot of scores for the CEG-OD dataset. The boxes show the first and third quartile of the data while the median is indicated with a line in the box. Higher scores indicate superior performance except for FAD. The results suggest that U-Net-based models performing convolutions in the time domain are the most promising approach to solving the task of overdrive removal.

The **R-nonlin metric** [36], in contrast, was developed specifically for detecting nonlinear distortions and, like PEAQ, considers the human auditory system. R_{nonlin} is defined between 0 (*high distortion*) and 1 (*no distortion*).

The **Fréchet audio distance (FAD)** was recently proposed as a reference-free evaluation metric for music enhancement algorithms. It has shown to correlate more with human perception than the SDR [37]. In order to obtain the FAD, the embedding statistics of both the whole clean and distorted test set are generated using a VGGish model [38]. The FAD is calculated based on the Fréchet distance between two multivariate Gaussians computed from both the test and the reference embeddings. [39].

6. RESULTS

In this section, we provide the results of the experiments introduced in the previous section.

6.1 De-Overdrive (CEG-OD)

Fig. 2 shows the results of the models that remove overdrive from guitar tracks.

Firstly, in SI-SDR, both Demucs and Wave-U-Net perform exceptionally well and even outperform the ideal-ratio-mask by more than 24 dB. While CRAFx yields considerably worse performance, it also surpasses the IRM oracle. UMX is the least performing of all the models in our comparison. It should be noted that for UMX, a model that operates on magnitude spectrograms, the IRM represents its upper limit in performance.

Similar results are obtained with PEAQ, R_{nonlin} and FAD: while Demucs and Wave-U-Net yield the best scores and surpass the IRM, the ones for CRAFx and UMX are considerably worse. It seems that directly processing the signals in the time domain using a U-Net-based architecture represents the most promising approach for the removal of the overdrive effect.

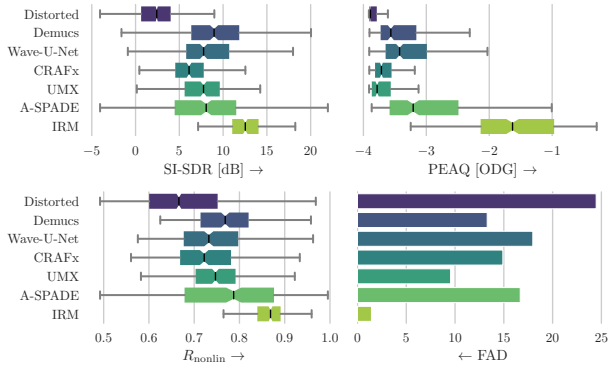

Figure 3. Box plot of scores for the CEG-HC dataset. It is difficult to clearly determine the best model, although Demucs represents a good compromise for all the metrics.

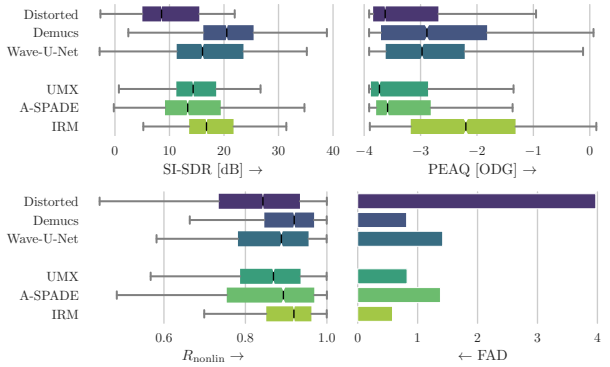

Figure 4. Box plot of scores for the SignalTrain-HC dataset. Demucs can be regarded as the best model regarding the median score across all metrics.

6.2 Declipping (CEG-HC)

Fig. 3 shows the results on the task of declipping on guitar recordings. Generally, we experienced a drop in the scores: now the models have been trained on declipping, which is an ill-posed problem, as missing parts of the signal need to be reconstructed. Additionally, we report scores for our declipping baseline, A-SPADE.

Despite the general performance drop, Demucs surpasses the results of A-SPADE in terms of SI-SDR by almost $1\,\mathrm{dB}$. While UMX and Wave-U-Net yield similar performances, CRAFx is the method with lowest scores.

Regarding PEAQ, no method surpasses the IRM and the A-SPADE algorithm. As before, Demucs and Wave-U-Net have similar performance: while PEAQ slightly favors the latter, SI-SDR favors the former. In contrast to the previous results, CRAFx has no significant advantage over UMX.

While Demucs achieves the best score for R_{nonlin} among the neural models, it does not surpass A-SPADE since the difference in their score is marginal. Interestingly, UMX achieves better results than CRAFx and Wave-U-Net. As the R_{nonlin} metric was explicitly designed to detect nonlinear distortions, we conclude that UMX' outputs contain fewer nonlinear distortions than the outputs of CRAFx and Wave-U-Net.

Surprisingly, when computing the FAD, UMX outperforms all other methods, including A-SPADE. This might be accounted to the fact that the FAD is based on the mel spectrum, whereas UMX optimizes the magnitude spectrogram. While Demucs and CRAFx outperform A-SPADE in FAD as well, the score for Wave-U-Net is slightly worse. The FAD for the IRM is relatively small because the difference between the reference and test embeddings from the VGGish model can be traced back to the masking operation and quantization. Demucs seems to constitute a good compromise regarding performance since it yields first- or second-best results for all metrics.

6.3 Declipping (SignalTrain-HC)

Fig. 4 shows the results for declipping SignalTrain-HC. Due to the lower gains that are used to prepare the data (see Sec. 5.1), the overall performance seems to be superior but cannot be directly compared to the previous results. Because of its considerably worse performance in the previous task, CRAFx was left out of the evaluation.

Demucs surpasses all other models in SI-SDR, including IRM and A-SPADE. Moreover, Wave-U-Net and UMX both surpass A-SPADE but not the IRM. PEAQ gives a similar ranking of the methods: only UMX cannot reach the A-SPADE baseline. None of the neural methods surpasses the IRM. In terms of R_{nonlin}, the same ranking is obtained, with Demucs surpassing, Wave-U-Net reaching, and UMX just missing A-SPADE. The FAD highlights that UMX and Demucs deliver comparable performance, outperforming the baseline, but not surpassing the IRM.

When only looking at SI-SDR or PEAQ, we notice the superiority of the time domain models. Future research should investigate whether the waveform in the time domain is the best input representation for the task, compared to, e.g., the real and imaginary part of a spectrogram [40] or both the waveform and the spectrogram [41]. Ultimately, Demucs can be considered the best model in our experiments for the task of declipping on SignalTrain.

6.4 Discussion

Qualitative Evaluation Although the abundance of evaluation metrics in the literature has the potential to analyze the results in very detailed ways, it does not always aid the judgement of which method is best given the individual context. Often, different applications have different requirements concerning the sound quality and can afford some types of distortions or artifacts to be left in the signal. Therefore, we report some qualitative considerations that need to be taken into account concerning our results, with the aim of finding some descriptive patterns among them. Fig. 5 shows spectrograms of a hard-clipped guitar signal and the outputs of all models under evaluation.

We found that the characteristics of the artifacts that each model produces are consistent, independent from the task it is applied to. Nevertheless, for the time domain-based models, the artifacts are less prominent in the de-overdrive task. Here, Demucs often produces outputs that

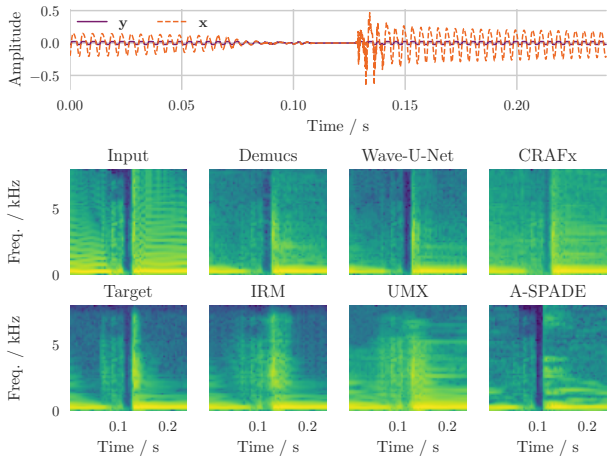

Figure 5. Spectrograms of a clipped guitar signal ($\gamma = 45\,\mathrm{dB}$), its target signal, and the output of each method. The respective time domain input and target signal are shown at the top. While all methods significantly reduce the harmonics, it can be observed that IRM and UMX smear the transients. A-SPADE relies on the strongest bins in the clipped spectrum, which leads to tonal artifacts.

are virtually indistinguishable from the original signal.

Generally, Demucs is the model that most often produces high quality results. Especially for inputs with a low amount of distortion, it can reconstruct the original sound without any perceptual artifact. Wave-U-Net behaves similarly, although it often cannot reach the same quality.

UMX generally removes the distortion characteristics very well at the cost of strong phasing artifacts: Despite the absence of input distortions, the spectral features of the output are not necessarily consistent with the ones of the target. This is most likely due to UMX re-using the phase of the distorted input to reconstruct the signal in the time domain and the frame-wise processing. Moreover, Fig. 5 highlights that the transients are smeared by re-using the phase of the degraded signal.

CRAFx does not suffer from phasing artifacts, but occasionally leaves part of the distortion features in the output. In some cases, the model fails to reconstruct the onset of some notes, penalizing the listening experience.

Finally, A-SPADE is the model that exhibits the strongest and most frequent artifacts, especially for strongly clipped signals. Although it considers phase information by working in the complex frequency domain, it leads to non-optimal solutions. Nevertheless, distortion features (like those left by Demucs) or transient smearing (left by UMX) do not occur.

Influence of the Dry Signal We have observed a substantial difference in performance between models that need to remove overdrive (CEG-OD dataset) and models that need to remove hard-clipping (CEG-HC dataset). The superior performance of the models trained and tested on CEG-OD can be mainly traced back to the presence of the non-distorted signal in the overdrive output and not to the soft-clipping character of the specific overdrive implementation. We verified this hypothesis by training Wave-U-Net on hard-clipped data superimposed with the clean signal (even when the amplitude of the clean signal is considerably low). We obtained results similar to those in the de-overdrive task (median results without superposition: SI-SDR $= 7.2\,\mathrm{dB}$, with superposition: SI-SDR $= 34.4\,\mathrm{dB}$). While the performance drop is present for all metrics, it is less pronounced for UMX which seems not to utilize the additional information in the signal.

Inference Speed The benefits of Demucs in the context of declipping go beyond the quality of its outputs: using a neural approach also has advantages regarding inference speed. Inference with A-SPADE is comparably slow (real-time factor on CPU $\times\mathrm{RT} \in [4.2, 27.3]$ depending on $\mathrm{SDR}_{\mathrm{inp}}$ [13]), being an iterative approach that requires a computation of the Fourier transform and its inverse at each iteration. Demucs ($\times\mathrm{RT} = 0.072$), Wave-U-Net ($\times\mathrm{RT} = 0.113$) and UMX ($\times\mathrm{RT} = 0.026$) instead, allow for fast inference on the CPU and even surpass real-time constraints independently on $\mathrm{SDR}_{\mathrm{inp}}$ without sacrificing the quality of the results.

Evaluation Metrics The results highlight how our evaluation metrics focus on different aspects of the reconstructions: While SI-SDR measures differences between two audio signals in the time domain, PEAQ focuses on the perceptual quality without differentiating between degradation related to nonlinear distortions and artifacts/quality. In contrast, R_{nonlin} specifically highlights nonlinear distortions that have not been removed. Finally, FAD focuses primarily on the degradation that is observable in the mel spectrum. Hence, each metric proves beneficial in measuring specific aspects in the analysis of audio effect removal systems and can be advised for further investigations.

7. CONCLUSION

We showed that recovering the clean signal from clipped or overdriven audio signals can efficiently solved with neural networks designed for source separation. We found that Demucs achieves high quality according to the chosen evaluation metrics, especially when the distortion algorithm to be removed blends the distorted sound with the original one. This outcome highlights the potential of the proposed approach for other audio effects that mix dry and wet signals (e.g., parallel compression, reverberation, delay, modulation effects).

Moreover, we showed that Demucs, Wave-U-Net, and UMX outperform one state-of-the-art declipping method on our test data. This outcome is promising, considering that the dataset to train such a system is potentially much larger than the size of the dataset we used. By discussing the results, we stressed the usefulness of multiple evaluation metrics suitable to assess distortion removal systems.

Future work should include gathering more clean electric guitar data and generating a dataset using high-quality distortion emulations, which is required to improve generalization on real-world data. Furthermore, the knowledge from sparsity-based declipping algorithms could yield a valuable prior for declipping through DNNs.

ABSTRACT

Optical Music Recognition (OMR) systems typically consider workflows that include several steps, such as staff detection, symbol recognition, and semantic reconstruction. However, fine-tuning these systems is costly due to the specific data labeling process that has to be performed to train models for each of these steps. In this paper, we present the first segmentation-free full-page OMR system that receives a page image and directly outputs the transcription in a single step. This model requires only the annotations of full score pages, which greatly alleviates the task of manual labeling. The model has been tested with early music written in mensural notation, for which the presented approach is especially beneficial. Results show that this methodology provides a solution with promising results and establishes a new line of research for holistic transcription of music score pages.

1. INTRODUCTION

The majority of music creations, both historical and modern, are only available through music scores. Unfortunately, most of them have never been stored in a structured digital format, such as MEI [1] or Humdrum **kern [2], that allows their indexing, retrieval, and digital processing. The high cost of performing a manual transcription of these documents demands processes that solve this task automatically.

Optical Music Recognition (OMR) is the research field that studies how to computationally read music scores [3]. Most OMR literature is framed within a multi-stage workflow, where several steps, such as image binarization [4], staff-line removal [5], symbol classification [6, 7], and notation assembly [8], are considered. These pipelines, although effective to some extent, are hard to manage in a production environment, as they imply the development of several models to obtain a complete OMR system.

With the advent of machine learning technologies, namely those related to deep neural networks, OMR systems have evolved towards alternatives that simplify these complex workflows. Specifically, two trends emerged from this advance. On the one hand, complex multi-stage pipelines for symbol isolation and retrieval have been replaced by object detection algorithms [9], where symbols are directly located in the image. On the other hand, holistic strategies—commonly referred to as end-to-end approaches [10, 11]—are also used to transcribe music scores. In this case, the system directly outputs the transcription of a single-staff image.

Although the advances brought about by these new technologies have simplified these pipelines, these systems still rely on other models to complete the transcription of scores. In the case of the object detection approach, models for notation reconstruction and sequence encoding need to be implemented to obtain a readable representation of the music score. End-to-end approaches, in turn, are only able to transcribe single music staves, so staff detection algorithms have to be implemented to retrieve all the information from the page and be recognized individually [12, 13]. The latter pipeline is represented in the upper workflow of Fig. 1.

Following the path of end-to-end approaches, in this paper we present the first segmentation-free strategy for full-page music transcription that unifies the two required steps—see the lower workflow in Fig. 1—based on evolving the current state of the art. For this model to be trained, only page-level annotations—which could be available in any music encoding—are required. This greatly alleviates the labeling of music scores, as additional OMR-specific data preprocessing steps are avoided.

The motivation for implementing this idea is to solve some issues of pipeline-based end-to-end approaches. The main inconvenience is that they are composed of two models that are trained specifically on independent tasks—that is, each document has to be manually labeled twice. First, bounding boxes and region classes have to be inserted to train the staff detection model. Once this information has been retrieved, the corresponding symbolic music representation must be written for each staff present in the dataset to train the staff-level recognition system. Therefore, labeling a corpus to train a production-ready OMR system for full-page transcription is costly—due to the need for manual segmentation and transcription of individual music staves—and time-consuming [14]. Another issue is that there has to be assumed an accumulated er-

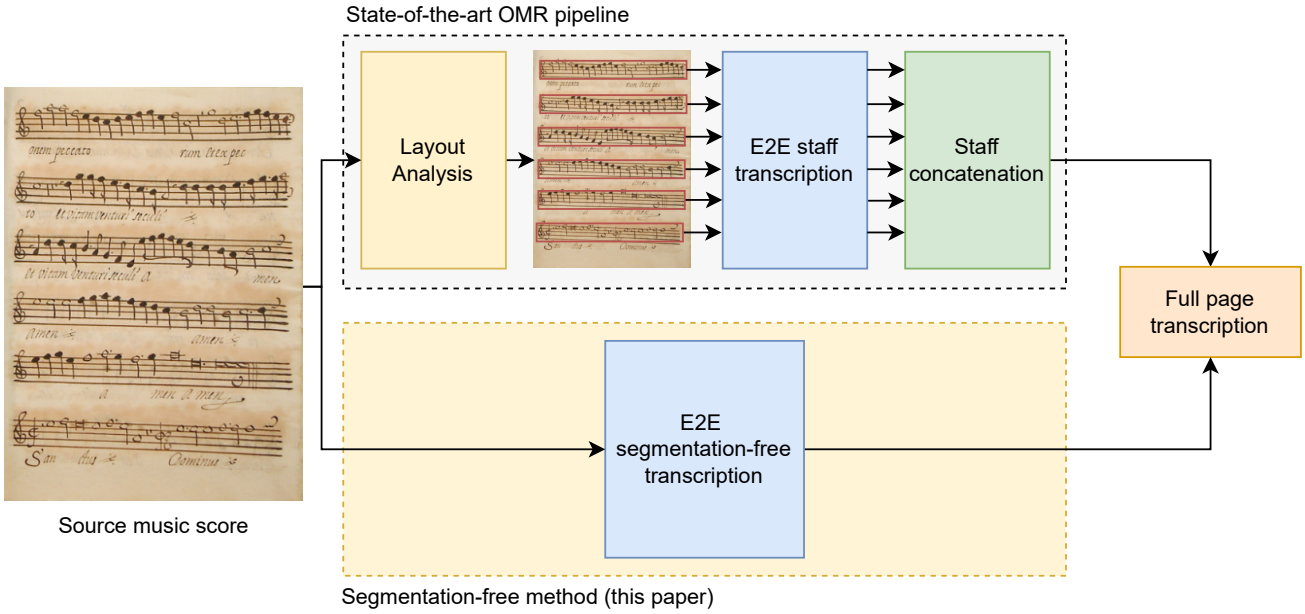

Figure 1: General overview of the current full page OMR pipeline (top) in contrast to this paper proposal (bottom), where a previous layout analysis is not needed to transcribe the music symbols in the score.

ror that is carried over from one step to the next, as some works have studied [12, 15]. That is, the performance of a specific step is highly related to the effectiveness of the previous one, which is also dependent on their predecessors, thus creating a snowball effect.

2. EXTENDING OMR TRANSCRIPTION SYSTEMS

In this section, we explain how state-of-the-art end-to-end OMR models work, what issues they present when transcribing a complete music document, and how they can be adapted to a full-page scenario.

2.1 End-to-end staff transcription systems

The state-of-the-art end-to-end music staff transcription systems are neural models that directly output the music notation sequence of a given single-staff image. These networks are based on two main blocks: first, there is an encoder block, which filters an input image to learn and establish its relevant features. Commonly, this part is approached with Convolutional Neural Networks (CNN). Then, the output of this module is processed by the decoder block, which models temporal dependencies in the obtained features—which are represented as a vector sequence—to enhance results. This second module is commonly implemented with Recurrent Neural Networks (RNN). The whole model, referred to in the literature as a Convolutional Recurrent Neural Network (CRNN), is trained using the Connectionist Temporal Classification (CTC) [16] loss strategy, which maximizes through expectation-maximization the probability of obtaining a music sequence in a given notation alphabet. That is, the CTC method forces the network to align the output sequence to the available information extracted from the image, retrieving the full transcription in a single step. One important step to understand the model is how the output of the encoder is adapted to be processed as a sequence in the decoder. State-of-the-art implementations [10] reshape this obtained feature map—which is a 3D structure of size (h, w, c), where h is the height of the feature map, w is its width, and c is the number of filters (*channels*) obtained from the last convolutional layer—, by concatenating all the consecutive frames on the height axis of the image. That is, we obtain a sequence-like 2D structure that now has a shape of $(w, c \times h)$. This methodology has proven to be effective to transcribe both printed music staves [17] and handwritten ones [10, 11].

2.2 The issues with full-page images

The methodology described in the previous section is ideal for single-staff images, as it solves the transcription problem by reading the obtained feature map from left to right. However, in the case of page images, this formulation cannot be applied. The main issue with this formulation is that a single frame—which is an image column—contains more than one symbol. This is troublesome in two ways. First, transcription and retrieval of the score would result in a costly task, as ground-truth should be written and read from top to bottom and then from left to right, introducing undesirable post-processing methods to obtain a readable score. The second problem is related to the training of the system, as the CTC method should maximize the probability of non-consecutive temporal symbols in a few time steps. That is, the network has to classify symbols from different staves in the same image columns. This implicit interpretation is wrong, as these symbols are located in farther positions of the sequence, as they belong to different staves.

2.3 From one staff to full page

To transcribe full-page music scores, a new interpretation of the obtained features map is considered. It is required to use an alternative reshape method from the output of the encoder block. In this paper, we apply a score unfolding reshape method. Instead of concatenating frame-wise elements along the height axis, as it is done for staff transcription, we reshape the image in the concatenation of all of its rows, obtaining then a $(h \times w, c)$ sequence. From a high-level perspective, this method can be understood as a staff concatenation process, as it is depicted in Fig. 2. This operation has to be done from top to bottom of the page, as it is crucial to correctly transcribe the music score.

Processing the feature maps this way prevents the aforementioned issues, as the score can be labeled as it is naturally read—from top to bottom and left to right—and the CTC method will not face the problem of collision of non-consecutive times, as now the used sequence does not have merged features from different staves.

This methodology, although theoretically a valid solution, presents some points that should be noted. The adaptation of the current music transcription models only needs the transcription of the full page for training, as the model directly outputs the music sequence from the input image. By avoiding the previously required object detection algorithm from the pipeline, now the system has to face two main challenges: (i) identifying all the staves in the score and (ii) transcribing them into an ordered sequence. The second challenge is solved by the reshape method, as we force the model to align and read all the staves in a specific order. In this case, the CTC *blank* token—which is an additional element introduced in the notation vocabulary to indicate time step separations—denotes both music element separations and staff breaks, since the single-staff-like produced sequence identifies the first symbol of the next staff as a consecutive timestep to the last symbol of the previous one. Challenge (i), however, is somewhat relegated to the network learning. The hypothesis is that, by not modifying the sequence structure in the decoder block, this alignment can be learned and mapped by the encoder. This hypothesis needs to be validated by the performance of the proposed models during experimentation.

2.4 Further considerations

This paper evolves the already established OMR staff recognition models by implementing a learned music score unfolding. Theoretically, this method is still a single-staff transcription system. All the staves of the pages can be understood as a single long staff that, due to physical constraints of paper, had to be divided into several staves. This methodology implicitly learns to reconstruct this original interpretation and transcribe the resulting long single-staff image in one step. The alignment process between the different staves is learned by the network during training.

It is important to note that, at this point, the proposed method is suitable only for monophonic staves, as polyphony requires additional information and processing to be transcribed holistically. Vocal music scores—such as those written in mensural notation—can benefit from this approach because polyphony is usually written through a series of independent monophonic voices. For this reason, the experiments will be carried out with early music scores written in mensural notation, as detailed in Section 3.2.

3. EXPERIMENTAL SETUP

In this section, we describe the proposed models to address full-page OMR, present the used corpora during experimentation, and define the metrics used to evaluate the performance of our proposals [1] .

3.1 Models

As mentioned throughout this paper, we are adapting state-of-the-art OMR models to full-page transcription. However, two additional variations have been included in the proposed model to extend the study on this topic. All the presented models have a fully convolutional block, which acts as an encoder of the input image features. This network is composed of stacked convolutional layers, which end up producing a feature map of size $(h/32, w/8, c, b)$, h and w being the height and the width of the input image, c the filters in the last convolutional layer, and b the batch size. The downscale of the original image size is produced by pooling operators. Then, the decoding architectures proposed for processing the sequence obtained after the reshaping procedure are described below.

3.1.1 Recurrent Neural Network

We follow the implementation of the original CRNN-CTC staff transcription model from [10], where the reshaped feature map is fed into a Bidirectional LSTM (BLSTM) and linearly projected onto the music notation dictionary. Specifically, we implemented a BLSTM with 256 units, whose output matches the output space of the fully convolutional network.

3.1.2 The Transformer

The base model of this work uses RNNs to process the reshaped feature map as a sequence. However, a recent recurrent-free model has gained popularity in the Natural Language Processing (NLP) field: the Transformer [18]. This model replaces the RNN architecture by implementing sequence modeling through attention mechanisms and position learning. This model solves some common issues that RNNs have—such as processing long sequences, training time effort, and contextual information retrieval—at the cost of needing more data to converge. As we have observed in the reshape step, the model would have to process significantly long sequences in one step, something that can have a negative impact on the performance of RNNs. For this reason, the first alternative model implemented in this paper replaces the recurrent layer of the CRNN model with a Transformer encoder (referred to as

[1] Source code for the implementation of the presented models can be found in `https://github.com/antoniorv6/e2e_poliphony`

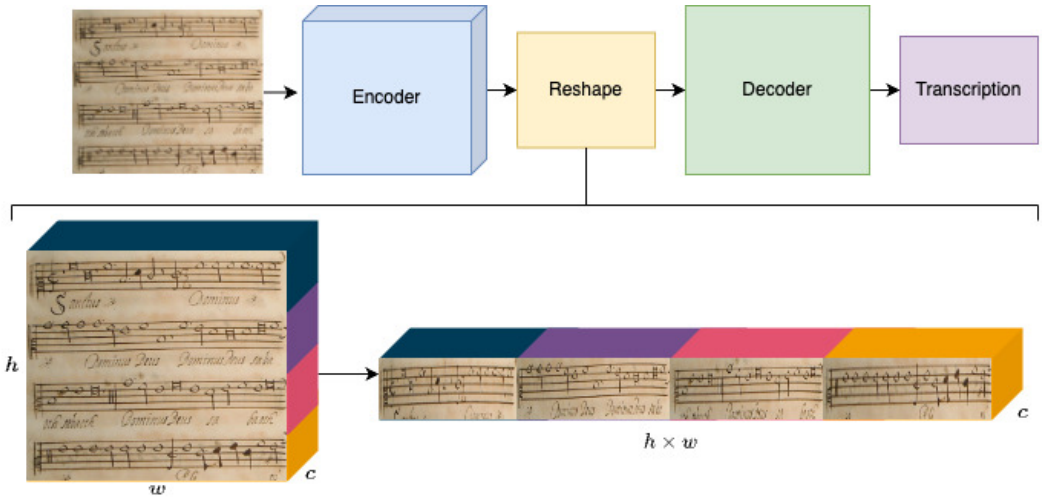

Figure 2: Graphic visualization of the reshape method to adapt current systems to full-page transcription. The reshape module learns how to separate and concatenate the staves on a page in a single line. Note that the original image has been used in the reshape for clarity of explanation, but the alignment is done in the *feature space* extracted by the encoder.

.

CNNT hereafter). In particular, we implemented one encoder layer with an embedding size of 512, a feed-forward dimension of 1024, and 8 attention heads.

3.1.3 Sequence-processing-free module

One of the challenges the model has to face during the score recognition is the alignment of the staves extracted from a 2D image to build a 1D sequence. This leads to the question of how a sequence processing module could impact learning this specific task while performing backpropagation. In analogous text recognition models, like [19], the solution lies in preserving the prediction space in 2 dimensions, applying backpropagation directly to the retrieved feature map before being reshaped. We have implemented this model to analyze the impact of the sequence processing module on the score page transcription. It is also based on fully convolutional layers, so it will be referred to as FCN in the results section.

3.2 Corpora

Two mensural-notation music datasets with different characteristics in engraving style were used, in order to represent the different challenges that the model can face in these real-case scenarios.

The first corpus is "Il Lauro Secco" [20] (denoted as SEILS), which corresponds to an anthology of 150 typeset printed images of the 16th-century Italian madrigals.

The second corpus is the CAPITAN dataset [10], which contains a complete ninety-six pages manuscript from the 17th-century containing a handwritten *missa*.

Specific details about the used corpora can be found in Table 1, and Fig. 3 depicts examples of these documents.

3.3 Data augmentation

One constraint that our proposed model can find observing Table 1 is the scarcity of data, as these kind of early music documents usually have few pages completely labeled. To address this potential issue, we applied a data augmentation process to increase the number of samples per corpus. This procedure is composed of several image distortion operations, such as reduction, erosion, dilation, or perspective modifications. These distortions are randomly applied for each batch sample, allowing us to obtain massively extended corpora that also have an added variability for the samples. The SEILS corpus is increased up to 29000 pages and the CAPITAN dataset to 24000.

	SEILS	**CAPITAN**
Num pages	150	123
Max page size	1200 × 813	1593 × 2126
Min page size	1200 × 813	1100 × 780
Avg staves per page	4	10
Max staves per page	9	12
Min staves per page	1	2
Avg symbols per page	222	136
Max symbols per page	331	220
Min symbols per page	110	23
Unique symbols	183	321

Table 1: Details of the corpora regarding the pages' features, such as sizes in pixels, number of samples and staves per page, number of symbols present and unique symbols per dataset (*vocabulary*).

3.4 Metrics

Currently, there are no OMR-specific metrics to evaluate the performance of the transcription systems. In this paper, we resort to the Symbol Error Rate (SER), which is the most commonly used metric in the OMR literature for end-

(a) SEILS (b) CAPITAN

Figure 3: Music page examples from the used corpora.

Model	Augmentation	SEILS	CAPITAN
CRNN	-	6.3	26.6
	✓	**4.3**	**15.5**
CNNT	-	12.9	28.4
	✓	7.2	18.2
FCN	-	23.3	89.5
	✓	13.3	22.5
Staff-based [12]	-	3.6	10.8

Table 2: Test SER (%) obtained for the studied models. Castellanos et al.'s work is included in the last row as a reference value to observe how current OMR pipelines work to transcribe the used corpora in this paper.

to-end approaches. This metric is computed as

$$\text{SER}\,(\%) = 100\,\frac{\text{ED}(\hat{S}, S)}{|S|}\,,$$

where ED is the edit distance between the transcription hypothesis $\hat{S}$ and its corresponding ground truth, S. $|S|$ is the length (in tokens) of S. We chose this metric because it represents accurately the recognition performance of the model and correlates with the effort that a user would have to invest to manually correct the output sequence.

The datasets have been split into fixed partitions, where 60% of the samples have been used for training, 20% have been used for validation, and 20% for testing.

4. RESULTS

Table 2 shows the results obtained by the studied methodology on the test set for each corpus. Results reported by Castellanos et al. [12] are included to establish a reference value from a state-of-the-art algorithm based on a standard OMR pipeline (the one depicted in Fig. 1-top). Note that this reference model is trained under more favorable conditions, as it addresses the full-page transcription in two separate tasks, which have specific data for training each. However, it requires much more labeling work to build the training sets than our segmentation-free implementation. Therefore, it should be understood only as a reference and not as a competing approach.

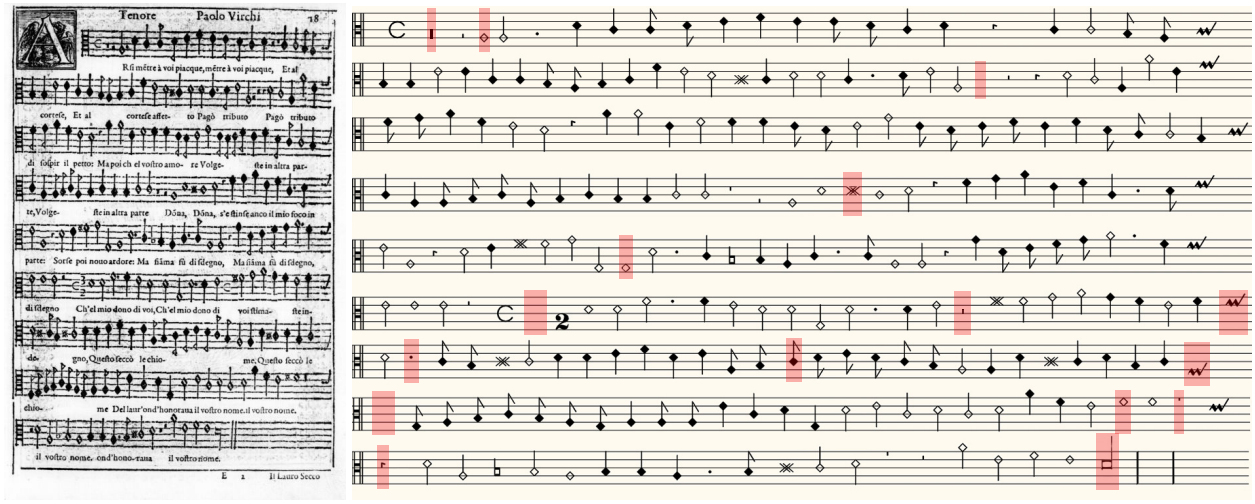
The results obtained show that the extended models were able to transcribe full-page scores with fair SER values, below 30% except for the FCN without data augmentation in the CAPITAN dataset. These error values also scale depending on the engraving complexity of each corpus, being the printed documents (SEILS) easier to transcribe than the handwritten ones (CAPITAN). The model that reported the best results was the combination of the convolutional network with the RNN decoder (CRNN), which obtained an error rate of 4.3% in the SEILS corpus and 15.5% in CAPITAN.

The models that use sequence processing decoders (CRNN and CNNT) performed better than the single FCN network. This was expected to some extent, as these architectures exploit and optimize sequential information to improve their performance, which is a considerable advantage over the FCN approach. In fact, they also seem to bring some robustness to the model against the scarcity of training data, if we compare their results with the high error rate of the FCN when no data augmentation was applied to the CAPITAN corpus.

Continuing the data dependency analysis, it can be observed that applying data augmentation, significantly improved the overall performance of all models. The most notable case of this dependency was found in the FCN network on the CAPITAN corpus, where overfitting issues seemed to be solved with the augmented database. For the other models, improvements were reported as well, reducing the SER by approximately 30%–40%. In other words, the models are able to work with few samples, but they require a considerable amount of data to obtain their best results.

Comparing the two sequence processing decoders, we observe that RNNs performed better than CNN Transformers in all cases. The reason for this is aligned with the results obtained in works that explore the use of these models on document transcription [22]. Looking at the Table 1, we observe that both models contain, on average, short sequences. Transformers, by replacing recurrence with self-attention and position encoding, improved computation time and accuracy at the cost of more data needed to converge. However, the Transformers literature has reported relevant improvements with long sequences, containing approximately 512 tokens, with which the RNNs have convergence problems. In this case, the Transformer model is in a disadvantageous scenario, where few data samples are available to train and the output sequences are relatively short, which is a much better scenario for RNN-based decoders.

For the sake of visualization, Fig. 4 presents the results obtained in a test set page from the SEILS dataset by the best model (CRNN). As can be seen, the system produces a good transcription, in which most of the symbols are correctly labeled and aligned within their corresponding



(a) Original page.

Figure 4: Visualization of the transcription produced by the CRNN model in a music page from the SEILS dataset. Errors are highlighted. Note that the output is actually produced on a single line, but a multi-line representation of the score has been reconstructed to facilitate comparison with the original document. In this particular case, the obtained SER is 6.1% (higher than the average on this corpus).

staves. If we analyze the produced errors, most of them are subtle—such as vertical position misplacement— and can be easily corrected with score editing software. This happens often with narrow symbols—such as rests—whose manual annotation would also have been difficult to perform.

5. CONCLUSION

In this paper, we present a first segmentation-free end-to-end approach for full-page OMR. This method is trained with weakly-annotated data: it only requires a set of page images with their corresponding transcription, in contrast to current state-of-the-art full-page OMR pipelines that require spatial information—such as bounding boxes or pixel-wise regions. Our methodology extends the current staff-level end-to-end systems to full-page transcription by applying a concatenation step that learns how to process the two-dimensional sequence document.

We evaluated three variants of this model with two early music collections written in mensural notation, which have been used in many other works as a benchmark for OMR. The reported results showed that the proposed system produces competitive results for full-page transcriptions. Although precision is slightly lower than a multi-stage OMR pipeline, the proposed segmentation-free approach stands as an interesting alternative for those models. The model provides a favorable trade-off between the cost of labeling and the system's accuracy.

Several avenues for future research arise from this work. First, it only covers the extent of historic vocal music in mensural notation, where only monophonic staves are found. In fact, the method can handle any page representing monophonic staves but, in modern music, the coverage is more restricted, since polyphony is much more common. This scenario could be an interesting case to analyze alternative architectures for OMR, such as attention-based systems [23] or non-CTC-based image-to-sequence architectures [24], which do not have to be constrained by the specific layout.

Another aspect to consider in the future is the need for data. Although one of the goals of this work is to reduce the labeling effort, the models still require a large number of fully annotated pages. We believe that further research needs to be done to study both transfer learning and self-supervised learning approaches to address this issue.

ABSTRACT

Vocoders are models capable of transforming a low-dimensional spectral representation of an audio signal, typically the mel spectrogram, to a waveform. Modern speech generation pipelines use a vocoder as their final component. Recent vocoder models developed for speech achieve a high degree of realism, such that it is natural to wonder how they would perform on music signals. Compared to speech, the heterogeneity and structure of the musical sound texture offers new challenges. In this work we focus on one specific artifact that some vocoder models designed for speech tend to exhibit when applied to music: the perceived instability of pitch when synthesizing sustained notes. We argue that the characteristic sound of this artifact is due to the lack of horizontal phase coherence, which is often the result of using a time-domain target space with a model that is invariant to time-shifts, such as a convolutional neural network.

We propose a new vocoder model that is specifically designed for music. Key to improving the pitch stability is the choice of a shift-invariant target space that consists of the magnitude spectrum and the phase gradient. We discuss the reasons that inspired us to re-formulate the vocoder task, outline a working example, and evaluate it on musical signals[1]. Our method results in 60% and 10% improved reconstruction of sustained notes and chords with respect to existing models, using a novel harmonic error metric.

1. INTRODUCTION

In modern speech synthesis pipelines a first model generates a low-dimensional audio representation, usually the mel spectrogram, from text; and a second model, named Vocoder, transforms the mel spectrogram to an audio waveform. Theoretically, vocoders designed for speech could be directly applied to musical signals; however closer inspection reveals features and constraints that are exclusive to the music domain. For example, unlike speech, music signals can be polyphonic and contain longer sustained notes whose pitch precision and stability is essential.

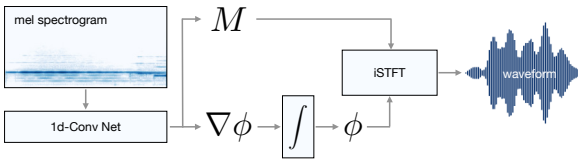

Figure 1: Our proposed model for mel spectrogram inversion. A one dimensional CNN estimates the magnitude and the phase gradient from the mel spectrogram. The phase gradient is then integrated to estimate the phase spectrum and finally audio is obtained via the inverse STFT.

The stability of a sustained pitched note manifests in the time-domain audio signal as the steady repetition of a periodic waveform. Periodic patterns are by definition not shift-invariant, except for shifts of an integer number of periods, therefore they require some form of auto-regression in order to be reproduced accurately. As expected, time-domain vocoders using shift invariant architectures [1, 2], despite other advantages such as generation efficiency, produce jitters that are perceived as pitch and timbre instability. For this reason, other time-domain generative models for audio include an autoregressive mechanism in the neural architecture [3–5]. In practice, time-domain models are required to learn all possible shifts of periodic patterns, a space that increases exponentially for polyphonic music, and how to create smooth sequences of these patterns.

Inspired by a recent generative model for single notes [6], we propose a new vocoder model for music (Fig. 1), where the target of the neural network is an intermediate frequency-domain audio representation that is shift-invariant for sustained notes. This representation is composed of the magnitude spectrum and the phase gradient, and can be later turned to audio via: 1. a phase integration algorithm and 2. the inverse STFT. The proposed design can be used with an efficient shift-invariant neural architecture and still yield stable reconstruction of sustained notes. Specifically, our contributions include:

- a formulation of the mel spectrogram inversion task, matching shift-invariant network and target, in order to improve the perceived stability of sustained notes
- a phase integration algorithm
- an evaluation metric measuring pitch stability for multiple notes

2. BACKGROUND

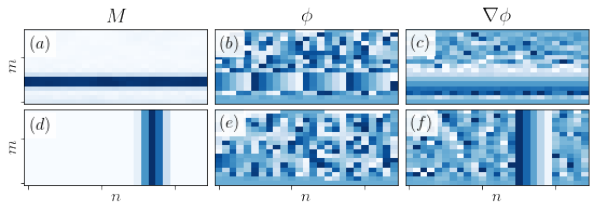

Figure 2: Magnitude M, phase ϕ and phase gradient $\nabla\phi$ patterns for a sinusoidal (top row) and an impulse (bottom row) signal. While the magnitude spectrum is easy to interpret visually, patterns in the phase spectrum are harder to decipher, but become evident in the phase gradient.

A discrete audio signal x can be analyzed in the time-frequency space using the STFT:

$$X[m,n] = \sum_i x[i+nR]w[i]e^{-j\omega_m i}, \tag{1}$$

where m and n are the integer frequency bin and time frame indices, R is the hop size between successive frames, w is a window function defined in the $[-N/2, N/2)$ interval, with N being the frame size and $\omega_m = 2\pi m/N$ the angular frequency. The STFT is a complex-valued matrix, as such it can be represented in the polar form:

$$X[m,n] = M[m,n]e^{-j\phi[m,n]}. \tag{2}$$

The magnitude component M highlights the energy of the signal at various locations in the time-frequency grid: it is easier to interpret and more widely used than the phase component ϕ. However, the phase spectrum is of primary perceptual importance to reconstruct the audio signal precisely, and while harder to interpret at first sight, it does contain patterns that can guide model design choices (Fig. 2).

In Sect. 2.1 we describe two patterns that form in the magnitude and phase spectrum corresponding to the occurrence of ideal sinusoidal and impulsive signal components.

2.1 Sinusoidal and impulsive components

2.1.1 Sinusoidal components

In the magnitude spectrum, sinusoidal components such as any single harmonic of a pitched instrument's sustained note, show up as horizontal lines (Fig. 2(a)). While the magnitude spectrum does not depend on the frame index n, and is therefore shift-invariant, the phase spectrum depends linearly on n (Fig. 2(b)), and the rate of change is given by the frequency of the sinusoidal component. Failing to reconstruct this linear relation between phase and time results in loss of horizontal phase coherence, perceived as unstable pitch, because errors are attributed to sudden changes of the frequency of the sinusoidal component.

2.1.2 Impulsive components

Impulsive components such as the attack of a percussion instrument show up as vertical lines in the magnitude spectrum (Fig. 2(d)). While the magnitude spectrum does not depend on the frequency index m, the phase spectrum depends linearly on m (Fig. 2(e)), and the rate of change depends on the offset between the location of the impulse and the frame center. Failing to reconstruct this linear relation between phase and frequency results in loss of vertical phase coherence, which is perceived as smeared transients, because the errors are attributed to the location of the impulse.

2.2 Phase gradient

The linear patterns that emerge in the phase for sinusoidal and impulsive components are better highlighted in the two components of the phase gradient $\nabla\phi = (\phi'_i, \phi'_m)$.

The partial derivative of phase along the time dimension ϕ'_i is called *instantaneous frequency*. For the bins that belong to sinusoidal components, ϕ'_i is constant and the phase can be propagated horizontally:

$$\phi[m, n+1] = \phi[m,n] + R\phi'_i[m,n]. \tag{3}$$

The partial derivative along the frequency dimension ϕ'_m is called *local group delay*. For the bins that belong to impulsive components, ϕ'_m is constant and the phase can be propagated vertically:

$$\phi[m+1, n] = \phi[m,n] + \phi'_m[m,n]. \tag{4}$$

In the time-frequency reassignment literature (see e.g. [7]), the phase gradient components are used to assign the energy of a spectral bin (m,n) to a nearby point of maximum contribution $(\dot{m}, \dot{n})$:

$$\begin{aligned} \dot{m}[m,n] &= m + \Delta m[m,n] \\ \dot{n}[m,n] &= n + \Delta n[m,n], \end{aligned} \tag{5}$$

where $\Delta n[m,n]$ (Fig. 2(f)) and $\Delta m[m,n]$ (Fig. 2(c)) represent time and frequency bin offsets and are derived from the phase gradient

$$\begin{aligned} \Delta m[m,n] &= \phi'_i[m,n]\tfrac{N}{2\pi} - m \\ \Delta n[m,n] &= -\phi'_m[m,n]\tfrac{N}{2\pi R}. \end{aligned} \tag{6}$$

In the following sections, we discuss how the phase gradient can be used for mel spectrogram inversion.

2.3 Mel spectrogram inversion

The log-amplitude mel spectrogram (simply mel spectrogram from now on) is a low-resolution time-frequency representation that is derived from the power spectrogram M^2, by first warping the frequency axis using the mel scale, then scaling the values to log-amplitude. Estimating the original audio signal x from the mel spectrogram requires recovering the information that has been lost in the direct computation, i.e. the phase information and

the linearly-spaced and higher frequency resolution of the magnitude spectrum.

While the majority of the recent approaches try to learn this inverse transformation end-to-end, this is especially hard for a polyphonic music signal. To precisely reproduce a sustained note, an end-to-end model needs to learn: 1. different patterns for every combination of phase shift and period of a periodic waveform, and 2. how to activate them in the right sequence [6]. Accomplishing both tasks is challenging for speech and arguably even more so for music, which contains generally longer pitched sounds with wider pitch range, possibly multiple concurrent fundamental frequencies (polyphony), and whose absolute precision is essential.

Instead of reconstructing the signal in the time domain, we propose to use as output space an intermediate time-frequency representation consisting of three channels: the magnitude spectrum and the two components of the phase gradient: (M, ϕ'_i, ϕ'_m). The phase gradient is later integrated to estimate the phase spectrum ϕ, and finally audio is computed via the inverse STFT.

A model trained on our proposed output representation does *not* need to learn: 1. the shift variations of periodic waveforms as those are explicitly modeled by the inverse STFT, and 2. how to sequence phase, which is handled via the phase integration algorithm. Differently from the phase spectrum, the phase derivative along time is shift-invariant, thus it is a more suitable target for a shift-invariant architecture, such as the convolutional neural network.

The approaches that have been suggested in the recent years for neural audio synthesis in the time-domain have to use auto-regression to achieve horizontal phase coherence. For example, autoregression is at the core of models like WaveNet [3] and WaveRNN [4], however the fact that it is applied at the rate of audio samples make these model prohibitively expensive for the generation of high-resolution audio signals.

Audio domain shift-invariant convolutional neural vocoders can generate audio samples with much higher efficiency, but are not suited to reconstruct long pitched components precisely. This holds regardless of the training strategy, and includes for example generative adversarial networks (GAN) based models [1, 2] and diffusion based models [8, 9]. A recent neural vocoder for speech mel spectrogram inversion [5] adds an autoregressive loop that works on chunks of audio. The autoregressive nature of this architecture allows performing temporal integration, the operation needed to reconstruct stable sinusoidal components, while advancing by audio chunks rather than samples improves efficiency. However, the poor reconstruction quality observed when applying this model to music signals suggests that it is difficult to learn signal properties such as the rotation of phase from data with sufficient generalization.

In the neural audio synthesis literature, using instantaneous frequency has been considered explicitly in [6], where it is generated alongside the magnitude spectrum in order to reconstruct the audio of single notes, conditioned on the pitch contour and a timbre embedding.

2.4 Phase integration

Recovering the phase spectrum from the phase gradients requires an integration step. Theoretically, perfect integration should be possible under specific constraints, such as continuous phase gradient spectrum and window functions with infinite support. In practice, however there is no closed-form solution for integrating typical discrete phase gradient spectra [10].

Well-known phase gradient integration algorithms have been developed in the Time-Scale Modification (TSM) literature. The standard Phase-Vocoder (PV) algorithm propagates the phase derivative along the time dimension to modify the duration of sinusoidal components [11]. The PV is able to preserve horizontal phase coherence, but struggles with vertical phase coherence, leading to smeared transients. Improvements to the standard phase-vocoder algorithm [12–14] use the magnitude spectrum to identify sinusoidal and/or impulsive components, and can propagate phase in either direction (time or frequency) depending on the local properties of the signal.

The phase gradient integration algorithm that we develop (Sect. 3.2) is inspired by these recent variations, and leads to subjectively improved reconstruction quality, alongside increased computational efficiency. A formal evaluation of the integration algorithm is out of the scope of this manuscript and left as future work.

3. MODEL

In this section we describe our proposed model for mel spectrogram inversion. The model is composed of a time-wise convolutional neural network (Sect. 3.1) that estimates magnitude and phase gradient from the mel spectrogram, and a phase integration algorithm (Sect. 3.2) that estimates the phase spectrum given the phase gradient. The time-domain reconstructed audio is finally obtained via inverse STFT from the magnitude and phase spectra.

3.1 Network architecture

The neural network is a stack of 8 1-d (time) convolutional layers with 1536 hidden channels, a kernel size of 3 frames and ReLU activations (Fig. 3). The input and output have the same number of time frames, but different numbers of frequency bins, and their center frequencies are different, i.e. log-spaced for the mel spectrogram input and linearly spaced for the magnitude and phase gradient outputs. The frequency bins of the input and the magnitude channel of the output are independently standardized using the mean and standard deviation values computed from the training set. We found that a direct path from the input to the magnitude channel of the output leads to significant improvements in the reconstruction of magnitude and the training speed. This direct path consists only of a frequency warping operation from mel- to linear-scale.

The phase gradients (ϕ'_i, ϕ'_m) are computed using the Auger-Flandrin technique [15]. Although we have not ex-

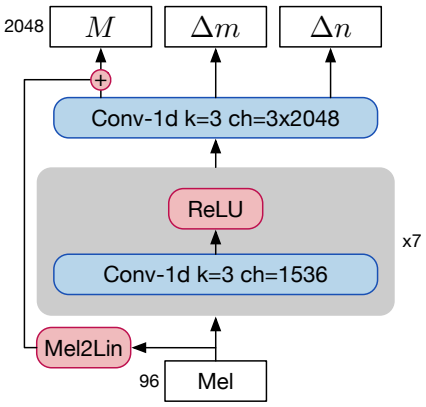

Figure 3: Convolutional network architecture

perimented with other ways to compute the phase gradient, it was argued [16] that using a less precise method, such as finite differences might perform just as well. Instead of using the phase gradients directly, we use the vertical and horizontal bin offsets (Eq. (6)), which are derived from the two components of the phase gradient. In order to remove outliers, the absolute bin offsets are clipped to 4.0 on the frequency dimension and to $N/2R$ on the time dimension.

The model uses linear output activation on all output channels except for the magnitude channel, where we apply a scaled $\tanh$ activation $f_\beta(x) = \beta \tanh(x/\beta)$ with $\beta = 5$ to use mostly the linear regime while also preventing overflow [6]. The three channels are then scaled and offset appropriately to match the statistics of the targets.

3.1.1 Losses

The magnitude channel is trained with a Mean Square Error (MSE) loss term, and a further MSE loss term computed on the first 20 linear-frequency cepstral coefficients (LFCC).

$$\mathcal{L}_1 = (\hat{M} - M)^2 \tag{7}$$

$$\mathcal{L}_2 = (\text{DCT}_{:20}(\hat{M}) - \text{DCT}_{:20}(M))^2, \tag{8}$$

where $\hat{M}$ indicates the estimated magnitude spectrum, M the target magnitude spectrum, and DCT the normalized Discrete Cosine Transform; in these and the following loss formulas the $[m, n]$ indices and the global average operation have been omitted for simplicity. While $\mathcal{L}_1$ acts on point estimates, $\mathcal{L}_2$ pushes the spectral envelope towards its true value, leading to faster convergence and better reconstruction quality.

The phase gradient channels are trained with another MSE loss, weighted by the power spectrum of the target signal M^2. A matrix $\lambda \in [0, 1]$, computed from the phase gradient (Sect. 3.2), is used to distinguish sinusoidal and impulsive components. The idea is that the phase derivative along the time/frequency dimension contributes to the loss only for sinusoidal/impulsive components:

$$\mathcal{L}_3 = \begin{cases} M^2(\hat{\Delta m} - \Delta m)^2 & \lambda > 0.5 \\ M^2(\hat{\Delta n} - \Delta n)^2 & \lambda \leq 0.5, \end{cases} \tag{9}$$

where $(\hat{\Delta m}, \hat{\Delta n})$ are the estimated bin offsets.

Finally, because λ is a function of $\nabla\phi$ and is used for integration, we add a loss term:

$$\mathcal{L}_4 = M^2(\hat{\lambda} - \lambda)^2, \tag{10}$$

where $\hat{\lambda}$ is computed using the phase gradient estimates and λ using the target values. The final loss is a weighted sum of all the loss terms:

$$\mathcal{L} = \sum_l \alpha_l \mathcal{L}_l, \tag{11}$$

where all weights are set to 1 except $\alpha_2 = 0.1$ to balance the contribution of all terms during training.

Differently from time-domain methods for mel spectrogram inversion, we found reconstruction losses to yield satisfying results and did not add any adversarial loss. Evaluating the advantages of including adversarial losses is left for future research.

3.2 Phase integration

The algorithm we use for integrating phase from phase gradients relies on the classification of spectral bins into either sinusoidal, transient or noise components.

The classification uses the phase gradient and relies on the following rationale [7]: around sinusoidal/impulsive components the reassigned frequency/time is approximately constant along frequency/time

$$\lambda[m, n] = e^{-(\frac{d}{dm}\dot{m}[m,n]/\frac{d}{dn}\dot{n}[m,n])^2}, \tag{12}$$

where the derivatives d/dm and d/dn are computed with centered finite differences.

After computing λ, the phase gradients are propagated horizontally (Eq. (3)) if $\lambda > \lambda^{\text{S}}$, vertically (Eq. (4)) if $\lambda < \lambda^{\text{I}}$, and set to a random value otherwise. λ^{I} and λ^{S} are threshold values for impulsive and sinusoidal components, and are used to identify the spectral bins over which respectively vertical or horizontal phase coherence should be enforced. We empirically set $\lambda^{\text{I}} = 0.4$ and $\lambda^{\text{S}} = 0.5$, as these values performed well on early trials.

4. EXPERIMENTS

In this section we discuss how we evaluate the pitch stability of the proposed model, comparing to strong baseline vocoder models from the speech synthesis literature.

4.1 Experimental Setup

We compare the reconstruction of the proposed `phase-gradient` model against state-of-the-art approaches: `melgan` [1][2], `hifigan` [2][3], `cargan` [5][4], and `diffwave` [8][5]. All models have been trained on the same data, containing 13 hours of ambient music loops

[2] https://github.com/descriptinc/melgan-neurips
[3] https://github.com/kan-bayashi/ParallelWaveGAN.git
[4] https://github.com/descriptinc/cargan
[5] https://github.com/lmnt-com/diffwave

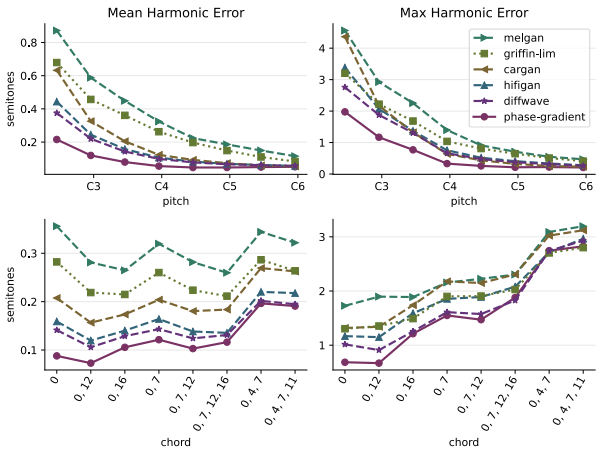

Figure 4: Harmonic error of different mel spectrogram inversion models for synthesized notes in the (C2, C7) range (top row). `phase-gradient` model achieves lower error than the baseline models on the entire range. The values have been smoothed with a moving average with size/stride equal to 12/6 semitones to filter out noise. The bottom row shows the error when adding more notes in different combinations, where the error is averaged over the entire pitch range, and the numbers on the x axis indicate the intervals in semitones that are played simultaneously, e.g. "0, 4, 7" is the major triad.

from commercial libraries[6], split into training, validation and test in the ratio of 80/10/10, which we refer to as the Ambient dataset. The audio from these loop libraries is converted to mono at 44.1kHz, 16-bit, the spectrograms are computed with a frame size of 2048 samples and hop size of 256 samples, and finally 96 bands are used for the mel spectrogram.

All neural networks were trained from scratch. The `phase-gradient` network was trained using 2 Volta GPUs in parallel and batches of 32 examples, with the Adam optimizer and learning rate set to $3e{-}5$. The training was stopped after 1024 epochs, when the validation loss converged, which took approximately 2 days.

As a further non machine-learned baseline, we consider a reconstruction algorithm `griffin-lim`, which generates audio from the mel spectrogram by first warping the frequency axis and the values to obtain a magnitude spectrogram, then applying the Griffin-Lim algorithm [17] for 500 iterations.

4.2 Pitch stability

To evaluate the pitch stability of our model, we used FluidSynth[7] to synthesize a dataset of one second long notes and chords in the (C2, C7) range, using a set of four different sounds: a rhodes piano, a church organ, a string ensemble and a nylon guitar.

[6] we used the following loop packs licensed from Big Fish Audio Ltd.: Ambient Piano, Ambient Skyline 3, Ambient Waves, Eclipse: Ambient Guitars, Ethereal Harp, Zen Ambient Vol. 2

[7] http://www.fluidsynth.org

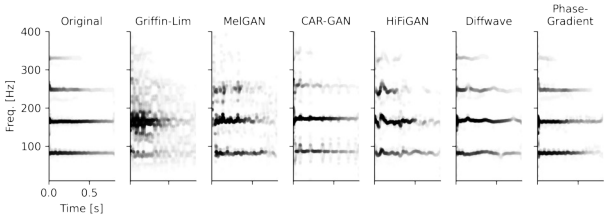

Figure 5: Reconstructions of an E2 nylon guitar note using different mel spectrogram inversion models. The figure shows the reassigned spectrograms [7] which highlight the instability on the fundamental and the harmonics caused by the lack of temporal phase coherence.

Measuring stability with a pitch tracker is only feasible for single notes, and we found that errors computed with a pitch tracker even for monophonic signals did not reflect our perception of reconstruction quality. A possible explanation is that pitch-trackers average out errors in the harmonic frequencies, which is inconvenient in this context because the precise location of the overtones is important for timbre perception [18].

For this reason, we define a harmonic error metric H_{err} as the sum of the frequency errors of the fundamental and the first 4 harmonic frequencies, expressed in the pitch scale:

$$H_{\text{err}}[p,h,n] = 12|\log_2(\frac{\hat{f}_{p,h}[n]}{f_{p,h}[n]})|, \tag{13}$$

where $f_{p,h}[n]$ and $\hat{f}_{p,h}[n]$ are the frequencies of the h-th harmonic of the p-th note, at frame n, for the original and the reconstructed audio respectively; the frequencies are estimated as the closest peaks to the nominal frequency of the partial, using quadratic interpolation, on a magnitude spectrum computed using frame/hop size equal to 4096/256 samples. We look at the mean and maximum values of the harmonic error, as a way to summarize the expected and worst case reconstruction errors.

Results show that our `phase-gradient` model was able to reconstruct the single notes with lower mean and maximum harmonic error over the entire range of notes, especially in the lower pitch range (Fig. 4(a)). A possible explanation for the larger improvement on the low register is that the long waveform period of lower-pitched notes makes them challenging to learn in the time-domain, given the high number of phase variations. A visualization of the different models' reconstruction of the same E2 guitar note is provided in Fig. 5.

We also synthesized different combinations of notes, to test the reconstruction quality on more challenging signals. The combinations include octaves, major 12ths, perfect fifths, an open- and a close-position voicing of the major triad, and a close-position voicing of the major seventh chord. As expected, the harmonic error increases when adding more notes (Fig. 4(b)), as they are harder to recognize in the input mel spectrogram. The `phase-gradient` model is able to yield lower mean and maximum harmonic error on all the considered combi-

	FAD (↓)			H_{err} (↓)		MOS (↑)	RTF (↑)	#Params
	Ambient	NSynth	N+C	Notes	Chords	NSynth		
`griffin-lim` [17]	10.59	6.16	6.79	0.28	0.24	1.42 ± 0.11	7.14	0
`melgan` [1]	2.07	2.80	2.84	0.36	0.30	1.58 ± 0.15	179.90	4M

`oracle`	0.51	0.33	0.00	0.00	0.00	4.34 ± 0.15	—	—

Table 1: Reconstruction results

nations of notes. However, the decrease in the reconstruction quality, particularly on close-position chord voicings, suggests possible connections with the target's frequency resolution.

4.3 Reconstruction quality

To evaluate the overall reconstruction quality of the proposed model, we compute the Frechét Audio Distance (FAD) [19] on the Ambient dataset, the dataset of 1920 one second long notes and chords ("N+C") used in Sect. 4.2, and the NSynth dataset [20]. The results are shown in Table 1 alongside aggregated mean harmonic error results from the experiment discussed in Sect. 4.2.

The FAD metric compares embedding statistics generated on two potentially different sets of audio signals, i.e. evaluation and reference set. On the Ambient and NSynth datasets we compute the FAD between the reconstructed test split (evaluation) and the original training split (reference). On N+C, the reconstructed and original signals from the *entire* dataset are used as evaluation and reference sets. An ideal model (`oracle`) is added to provide reference values, useful when the evaluation and reference sets are different.

The aggregated mean harmonic error results are computed over two meaningful subsets of the N+C dataset: a "Notes" dataset, representing all single notes, and a "Chords" dataset, containing all note combinations with more than one pitch class (see Fig. 4 bottom row).

We conducted a small listening test to evaluate a set of notes reconstructed with different models. The set includes G2 and G3 notes randomly selected from NSynth, for each instrument family. The 5-scale Mean Opinion Score (MOS) values and the 95% confidence intervals are shown in Table 1.

The results show that the `phase-gradient` model is competitive with other state-of-the-art models, despite having simpler neural network and training procedure. The fact that `hifigan` model is able to score lower FAD than the proposed model on the Ambient and N+C datasets suggests it has higher reconstruction accuracy on different sonic characteristics.

Specifically, we noticed that `hifigan` was able to reconstruct impulsive components such as transients and percussive onsets with higher energy and often more accurately than the `phase-gradient` model, while struggling with the stability of pitched notes and chords. The `diffwave` model exhibited high frequency "hissing" noise, but was otherwise surprisingly stable on harmonic components. This quality likely stems from the wide ~7s receptive field, obtained using the entire reverse process at generation time instead of a fast sampling schedule [8]. As reported by its authors in [5], we confirm that the reconstructions made by the `cargan` model contained "boundary artifacts that appear as repeated clicks", compromising their usability. Finally, the reconstructions obtained with the `melgan` model were characterized by heavy phase artifacts such as metallic sounds, and very unstable pitch.

Generation time is also shown in Table 1 in terms of real-time factor (RTF), defined as the number of seconds of audio that can be generated per second, evaluated on a single NVidia Volta GPU. `phase-gradient`'s generation is faster than real time, and close to `cargan`. While `phase-gradient`'s neural network is as fast as `hifigan` and `melgan`, 99% of the generation time is spent during the auto-regressive phase integration stage, suggesting a clear direction for optimization.

5. CONCLUSIONS

In this work we have proposed a new mel spectrogram inversion model designed for music that achieves improved reconstruction of sustained notes and chords, compared to state-of-the-art models from the speech synthesis literature. This improvement is obtained using a frequency-domain target representation that is time shift invariant for harmonic signal components. The proposed model is able to reconstruct single notes and chords respectively 60% and 10% more precisely than existing models, when evaluated with a novel harmonic error metric, while still being competitive on generic loop reconstruction. Potential directions for improvement include using pitch-shift augmentation, investigating log-frequency target representations, and training a separate time-domain model to supply the percussive components.

ABSTRACT

In this paper, we introduce LA-Chorus, a chorus detection model based on **L**atent feature **A**ugmentation and ResNet-FPN architecture. We make three contributions. Firstly, we propose a method for implicitly augmenting chorus data in the latent space during the training stage. Compared to augmentations on audio surfaces such as time stretching and pitch shifting, latent augmentations indicate changes at a higher level in original audio, thereby increasing the diversity and sufficiency in training. Second, we apply Feature Pyramid Network (FPN) to generate additional embeddings from low dimension to high dimension, consequently achieving a multi-scale training paradigm. Lastly, we release Di-Chorus, a new diversified dataset of 13 genres and 14 languages for the community of music structure analysis. In conjunction with other public datasets, we conduct comprehensive experiments to evaluate the performance of our proposed method compared to other state-of-the-art models, where LA-Chorus outperforms other SOTAs by a considerable margin, meanwhile the proposed latent audio augmentation shows dominant advantages over traditional augmentation methods.

1. INTRODUCTION

Chorus detection, aiming for identifying the most "catchy" or "memorable" part of a song, is one of the fundamental tasks in music structure analysis (MSA) [1]. Chorus detection essentially helps better understand music compositions with computational modelling methods and has various applications, such as automatic chorus preview functions in music software that allow users to efficiently select songs from a large library according to their preference [2].

Currently, chorus detection models are based on deep neural network (DNN) architectures with a supervised MSA method, where annotations of different segments are used as target variables during the training stage [3–5]. The common approach is to regard chorus detection as a binary classification task, where each frame (or several frames) is assigned with a class label according to the corresponding segment annotation, and the model is trained to classify these labels [6].

To better perform this classification task, we identify two critical questions: (1) how to locate chorus with high precision as the resolution of feature maps decreases when model goes deeper, and (2) how to learn sufficient variations of chorus characteristics. The first issue requires incorporating chorus positional information into the latent representations learned by models, resembling the task of object detection in computer vision that aims to find the boundaries of target objects [7]. Nevertheless, as the network goes deeper, latent representations begin to lose positional meanings because of the reduced-sized feature maps (i.e. the resolution decreases) [8]. To address the problem of shrinking resolution in feature maps, previous chorus detection methods first used neural network architectures as backbones to generate audio embeddings, and then applied positional modifications on the networks. For example, [3] introduced a multi-task model that jointly detects chorus segments and their boundaries using convolutional neural network (CNN) to increase positioning precision, and [5] proposed a multi-scale CNN model that up-samples/down-samples the original audio features to better capture both global and local information. In this paper, we incorporate Feature Pyramid Networks (FPN) [8], a popular framework for object detection from computer vision, into a standard ResNet [9] as our model's backbone. It is designed specifically to tackle the problem of feature maps' decreasing resolutions by appending a network of reversed size order for each feature map with lateral connection, which will be discussed in Section 3.

The second issue, as learning sufficient chorus characteristics, can be addressed by using a diversified training dataset to feed the model such that it will generalize well at testing time. Nevertheless, despite the promising progress of emerging music annotations such as Isophonics [10], SALAMI [11], and Harmonics [12], the scarcity of labeled data (as they are costly to retrieve) and the deficiency of data diversity have always been challenging for music information retrieval (MIR) and other machine learning fields. To combat this problem, some traditional augmentation techniques have been proposed on the original inputs, such as rotating or flipping the images in computer vision [13], or time stretching [14] and pitch shifting [15] in audio signal processing. Recently, implicit augmentation methods, which focus on the augmentation in latent space, have shown remarkable performance over the pre-

Chen, B. Zhu, Z. Ma, "Latent Feature Augmentation for Chorus Detection", in *Proc. of the 23rd Int. Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

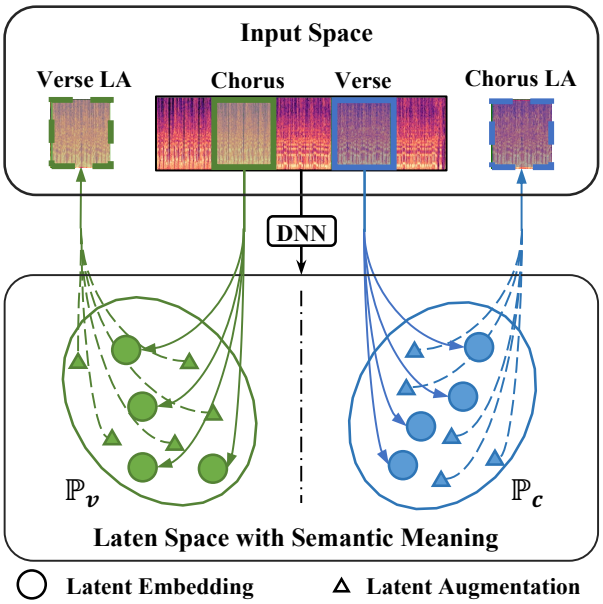

Figure 1. Illustration for implicit audio augmentation in MSA with two annotation types (verse and chorus) from a constant Q transformation (CQT) spectrogram excerpt of "Smooth Criminal" in *Isophonics* [10]. The spectrogram is first encoded into latent embeddings by frame, where chorus embedding and verse embedding follow latent distributions $\mathbb{P}_c$ and $\mathbb{P}_v$ respectively. Then latent augmentations are sampled around embeddings of verse/chorus segments, which correspond to augmented verse/chorus segments in the input space (represented by dashed lines, meaning they are NOT shown explicitly in the input space).

vious "shallow" methods in computer vision [16, 17]. The motivation is that latent representations may carry semantic meanings of original images (e.g. human age, gender, facial expressions) [18]. Such discoveries are also consistent with some works in audio signal processing, where latent audio representations have been found to capture distinctive audio features [19]. For example, [20] investigated the latent spaces of timbre and pitch of various instrument sounds encoded by a GM-VAE model; [21] introduced a Cycle-GAN based model for musical timbre transfer; and [22] disentangled pitch and rhythm representations to produce music analogies. According to these previous works, the latent features of audio correspond to semantic meaning of music and acoustic, such as timbre, rhythm pattern, etc. Therefore, augmentations in the latent space would correspond to changes of semantic features in the input audio segments, which leads to more variations than that of the augmentations in the shallow space. To our best knowledge, there is currently no application of latent augmentations in audio signal processing. In this paper, we illustrate this intuition by an MSA example in Figure 1.

Thus, we propose LA-Chorus, a supervised chorus detection model based on ResNet-FPN architecture that leverages implicit audio augmentations on latent features, which can better locate chorus positions and meanwhile enrich variations in training samples with semantic meanings. Moreover, since songs for most of the public datasets are not easy to retrieve, we further release a diversified collection of songs on YouTube for our MSA community, namely Di-Chorus, which contains 237 songs from 13 genres in 14 languages with annotations by experts. The rest of the paper is structured as follows: the next section introduces related works in chorus detection and latent augmentations, after which we discuss model structure and inference method. The experiment section presents LA-Chorus's performance on public datasets as well as Di-Chorus compared against other state-of-the-art models, followed by an ablation study showing the effectiveness of latent augmentations. Finally, the last section concludes our findings and contributions.

2. RELATED WORK

2.1 Chorus Detection

The origin of chorus detection tightly relates to thumbnailing, which aims to find a short preview (thumbnail) as a meaningful representation of a song [23]. Common approaches for thumbnailing includes evaluating the repeated sections of the audio waveform based on chroma transformation [24], selecting segments with the most repetition [25], and detecting significant change points with self-similarity matrix [26]. On the other hand, MSA assumes that songs contain different types of segments (e.g. chorus, verse, bridge, etc.) with certain structures [27]. Based on the assumption, many chorus detection algorithms in MSA took an unsupervised fashion in the early stage: [28] used heuristics to predict segment labels based on a restricted template for song structures; [29, 30] both applied Hidden Markov Model to derive different song sections; and [31] performed spectral clustering on the co-occurrence matrix generated from k-nearest neighbors.

With the advancement of deep learning in computer vision and natural language processing, DNN gradually makes its presence in MIR, among which ResNet [9], a CNN-based model with residual connections, becomes one of the most popular DNN architectures in recent MIR literature [4, 32]. At the same time, the emergence of labeled databases such as SALAMI [11] and Harmonix [12] make supervised learning gradually attractive for chorus detection, leading to the current paradigm of supervised chorus detection based on deep learning: [33] introduced a hybrid generative model with LSTM to directly predict segment labels; [3] proposed a multi-task method that jointly detects chorus segments and their boundaries; and [5] further proposed a multi-scale network with self-attention convolution to extract latent features of song segments, generating the current state-of-the-art results for chorus detection. In LA-Chorus, we will incorporate Feature Pyramid Network (FPN) [8], a top-down network that dedicates to the object positioning task, into ResNet as our model's backbone. The proposed framework is able to generate latent features with rich positional information and semantic meanings for later augmentation process, which will be discussed in detail in Section 3.

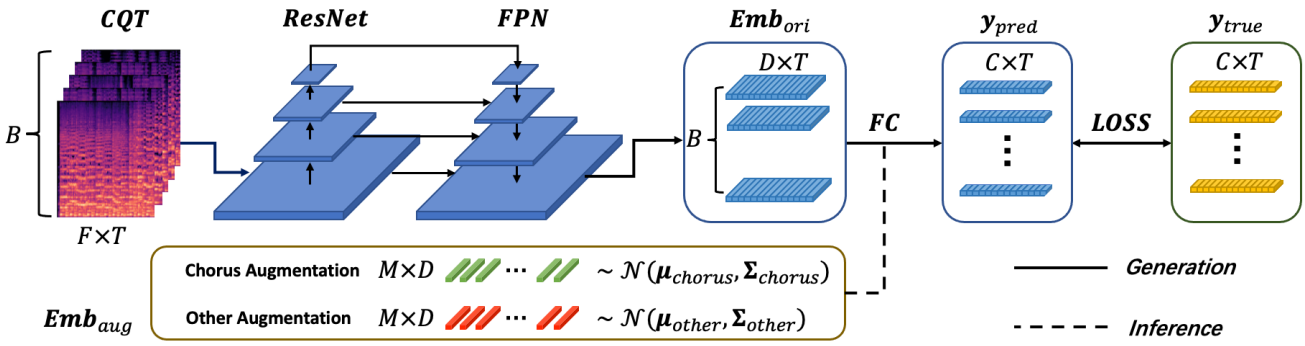

Figure 2. Model structure for LA-Chorus. The solid line represents the model generation processes in the forward pass, while the dashed line represents the inference (i.e. not explicitly generated in the forward pass).

2.2 Audio Data Augmentation

To enhance the diversity and variation in original audio features, traditional audio augmentation techniques such as time stretching, pitch shifting, noise perturbing and SpecAugment [34] are often implemented when transforming audio signals into spectrograms [14, 15]. In this paper, we take a different perspective: augmenting latent representations instead of original audio signals, motivated by the recent advancement of implicit augmentation methods in computer vision, represented by implicit semantic data augmentation (ISDA) and its variants [16, 17]. The ISDA model first used a backbone network to encode input images into latent space with semantic meaning, and then formulated a multi-variate Gaussian distribution for latent features in each class, which was estimated by their mean and covariance within the class via direct calculation. Then augmentations were sampled from the estimated distribution, and the model was later optimized by a novel cross-entropy loss tailored for latent augmentations. In this paper, we will demonstrate how this implicit augmentation method is utilized in audio to improve chorus detection.

3. PROPOSED METHOD

The structure of our proposed model is illustrated in Figure 2. We first use ResNet architecture to encode audio spectrograms into latent embeddings, Then, we apply the latent augmentation by sampling from estimated latent distributions for frames in the "chorus" class and the "non-chorus" (other) class respectively. Finally, the augmented representations are sent to a fully-connected layer to generate probability predictions. At learning and inference stages, we adopt a special cross-entropy loss that handles infinite number of latent augmentations via an upper bound, which saves the cost of sampling procedure.

3.1 ResNet-FPN

We first obtain the constant Q transform (CQT) spectrograms with F frequency bins and T frames in time domain after padding. Then a *ResNet-50* architecture is implemented as the embedding extractor $\mathcal{G}_\theta$ to extract latent embedding. Specifically, the ResNet consists of four stages that contains 3, 4, 6 and 3 residual CNN blocks respectively, where 64 convolution filters of 7×7 kernel size and a max-pooling layer of 3×3 kernel size are designed prior to these residual blocks to process the inputs.

With the size of each feature map reducing as CNN goes deeper, semantic information in deep audio features increases [8]. However, at the same time, the resolution of the feature map decreases and undermines the precision of chorus positioning. To solve this problem, we modify the backbone $\mathcal{G}_\theta$ by incorporating a Feature Pyramid Network (FPN) [8] into our ResNet architecture to construct latent features of high resolution from latent features with semantic information but of low resolution,as shown in Figure 2. The FPN design, different from the bottom-up ResNet part, takes a top-down approach that comprises four 1×1 convolutional layers that corresponds to four residual blocks of ResNet, which maps the low-dimensional outputs of ResNet to high-dimensional latent features with lateral connections.

As a result, the final latent representation $\mathbf{A}$ is of shape $T \times D$, where T is the number of frames and D is the number of latent dimensions. Because of the CNN and FPN designs in our backbone, latent embeddings not only contain both temporal and frequent information of the input audio, but also integrate feature maps of multiple resolutions to better locate chorus segments, further benefiting the latent augmentations later.

3.2 Latent Augmentations on Audio Features

To enrich variations, we apply latent augmentations on each representation $\mathbf{a}_i \in \mathbb{R}^D$ in the song, where $\mathbf{a}_i$ denotes the i_{th} row in $\mathbf{A}$. Similar to other latent variable models such as VAE variants [35] and flow-based models [36], we make a fundamental assumption that latent features within the same class follow the same latent distribution. Specifically, a latent augmentation $\tilde{\mathbf{a}}_i \in \mathbb{R}^D$ for latent feature $\mathbf{a}_i$ follows a multi-variate Gaussian distribution $\mathcal{N}(\mathbf{a}_i, \mathbf{\Sigma}_{y_i})$, where y_i indicates the label class ("chorus" or "other") for frame i, and $\mathbf{\Sigma}_{y_i} \in \mathbb{R}_+^{D \times D}$ represents the covariance matrix for class y_i. Then, we can sample from the distribution regarding to each $\mathbf{a}_i$ to get latent augmentations. In practice, a hyperparameter $\lambda > 0$ is imposed on the covariance matrix $\mathbf{\Sigma}_{y_i}$ to control the deviation of augmentations,

which leads to the final distribution of augmented latent representation $\tilde{\mathbf{a}}_i$:

$$\tilde{\mathbf{a}}_i \sim \mathcal{N}(\mathbf{a}_i\,, \lambda\boldsymbol{\Sigma}_{y_i}). \tag{1}$$

To estimate the covariance matrix $\boldsymbol{\Sigma}$ for different classes, we mathematically calculate the covariance matrix estimate $\hat{\boldsymbol{\Sigma}}_c$ for class c (c is either "chorus" or "other") within the dataset:

$$\hat{\boldsymbol{\Sigma}}_c = \frac{1}{N_c}\sum_{i=1}^{N_c}(\mathbf{a}_i - \bar{\mathbf{a}})(\mathbf{a}_i - \bar{\mathbf{a}})^T, \tag{2}$$

where $\bar{\mathbf{a}} = 1/N_c \sum_{i=1}^{N_c} \mathbf{a}_i$ is the mean of latent features in class c, and N_c is the number of frames belong to class c. This covariance estimate is updated at each iteration after the generation of new latent features during training stage.

Finally, the augmented latent features $\tilde{\mathbf{A}}$ are sent to a fully connected layer with weight $\mathbf{W} \in \mathbb{R}^{D\times C}$ and bias $\mathbf{b} \in \mathbb{R}^C$ to generate the probability predictions, with $\tilde{\mathbf{a}}$ being row-vectors in $\tilde{\mathbf{A}}$:

$$\hat{\mathbf{y}} = \mathcal{F}_\phi(\tilde{\mathbf{A}}) = \tilde{\mathbf{A}}\mathbf{W} + \mathbf{b}. \tag{3}$$

In the next section, we will show an computationally efficient method for learning, which considers infinite augmentations but requires no explicit calculation of the augmented features $\tilde{\mathbf{A}}$.

3.3 Inference and Learning

Given a dataset of size N, a basic approach to formulate a loss function that treats each augmented latent features as a new sample point, and sample M augmentations for each latent feature, which results in an augmented dataset of $N \times (M+1)$ samples. Then we use cross-entropy loss function to train the model. This method is effective when M is relatively large, however, it is computationally expensive as we need to compute extra loss values for $N \times M$ augmentations.

Instead of computing the loss function with discrete augmentations, we adopt the loss function from [16] that incorporates latent augmentations from the continuous domain. For the final fully-connected layer, we denote $\mathbf{w}_c$ as the column vector in $\mathbf{W}$ and b_c as the bias element in b for class c, then the limit of the cross-entropy loss for M augmentations when M approaches to infinity equals:

$$\lim_{M\to\infty} -\frac{1}{N}\sum_{i=1}^{N}\frac{1}{M}\sum_{j=1}^{M}\log\Big(\frac{\exp(\mathbf{w}_{y_i}^T\mathbf{a}_i^{(j)} + b_{y_i})}{\sum_{c=1}^{C}\exp(\mathbf{w}_c^T\mathbf{a}_i^{(j)} + b_c)}\Big) \tag{4}$$

which is equivalent to calculating the expectation w.r.t. $\tilde{\mathbf{a}}_i$:

$$\mathcal{L} = -\frac{1}{N}\sum_{i=1}^{N}\mathbb{E}_{\tilde{\mathbf{a}}_i}\Big[\log\Big(\frac{\exp(\mathbf{w}_{y_i}^T\tilde{\mathbf{a}}_i + b_{y_i})}{\sum_{c=1}^{C}\exp(\mathbf{w}_c^T\tilde{\mathbf{a}}_i + b_c)}\Big)\Big] \tag{5}$$

$$= \frac{1}{N}\sum_{i=1}^{N}\mathbb{E}_{\tilde{\mathbf{a}}_i}\Big[\log\Big(\sum_{c=1}^{C}\exp(\tilde{\boldsymbol{\xi}})\Big)\Big] \tag{6}$$

where $\tilde{\boldsymbol{\xi}} = (\mathbf{w}_c - \mathbf{w}_{y_i})^T\tilde{\mathbf{a}}_i + (b_c - b_{y_i})$.

Since $\log()$ is a concave function, from Jensen's inequality, we can show:

$$\mathcal{L}_{upper} = \frac{1}{N}\sum_{i=1}^{N}\log\Big(\mathbb{E}_{\tilde{\mathbf{a}}_i}\big[\sum_{c=1}^{C}\exp(\tilde{\boldsymbol{\xi}})\big]\Big) \tag{7}$$

$$\geq \mathcal{L}. \tag{8}$$

As $\tilde{\mathbf{a}}_i$ follows $\mathcal{N}(\mathbf{a}_i\,, \lambda\boldsymbol{\Sigma}_{y_i})$ in Eqn. (1), and $\tilde{\boldsymbol{\xi}}$ is a linear transformation of $\tilde{\mathbf{a}}_i$, then $\tilde{\boldsymbol{\xi}}$ will also follow a Gaussian distribution:

$$\tilde{\boldsymbol{\xi}} \sim \mathcal{N}\big(\boldsymbol{\xi}\,, \Delta\big), \tag{9}$$

where $\boldsymbol{\xi} = (\mathbf{w}_c - \mathbf{w}_{y_i})^T\mathbf{a}_i + (b_c - b_{y_i})$ and $\Delta = \lambda(\mathbf{w}_c - \mathbf{w}_{y_i})^T\boldsymbol{\Sigma}_{y_i}(\mathbf{w}_c - \mathbf{w}_{y_i})$.

Given the moment generating equation $\mathbb{E}[\exp(tx)] = \exp(t\mu + \frac{1}{2}\sigma^2t^2)$ for $x \sim \mathcal{N}(\mu, \sigma^2)$, we can express Eqn. (7) as follows:

$$\mathcal{L}_{upper} = \frac{1}{N}\sum_{i=1}^{N}\log\Big(\sum_{c=1}^{C}\exp(\boldsymbol{\xi} + \frac{1}{2}\Delta)\Big) \tag{10}$$

$$= -\frac{1}{N}\sum_{i=1}^{N}\log\Big(\frac{\exp(\mathbf{w}_{y_i}^T\mathbf{a}_i + b_{y_i})}{\sum_{c=1}^{C}\exp(\mathbf{w}_c^T\mathbf{a}_i + b_c + \frac{1}{2}\Delta)}\Big), \tag{11}$$

which gives us a tractable upper-bound of Eqn. (6)

Therefore, we do not need to explicitly sample augmentations from its distribution in Eqn (1). Instead, only the covariance matrix $\boldsymbol{\Sigma}_c$ of latent features for each class requires update at each iteration, which speeds up the convergence compared to discrete estimation.

The algorithm for learning the embedding extractor $\mathcal{G}_\theta$ and the fully-connected layer $\mathcal{F}_\phi$ is demonstrated in Algorithm 1 below. Because the model is underfitted at beginning epochs, the hyperparameter λ for controlling augmentation deviation is set to be $\lambda_0 \times \frac{\text{epoch}}{\text{total epoch}}$ to alleviate the impact of augmentation at the starting stage of training.

Algorithm 1 Algorithm for training LA-Chorus

Require: Padded CQTs batches; ResNet extractor $\mathcal{G}_\theta$; A fully connected layer $\mathcal{F}_\phi$; Initial covariance matrix $\boldsymbol{\Sigma}_c$ for each class; Initial λ_0 for scaling augmentation

```
for epoch = 1, 2, ..., I do
    for batch = 1, 2, ..., K do
        Encode the CQT batch into latent features
        {a_i}_{i=1}^T via ResNet-FPN extractor G_θ
        Update G_θ and F_φ by computing:
        ∇_{θ,φ} L_upper from Eqn (11)
    end for
    Update Σ_c across all batches with Eqn. (2)
    λ ← λ_0 × epoch/I
end for
return G_θ and F_φ
```

4. EXPERIMENTS

In this section, we conduct comprehensive experiments to evaluate LA-Chorus's performance against other state-of-

Dataset	#Songs	#Genres	#Lang.	#Quality
Di-Chorus	237	13	14	3

Table 1. Key statistics of Di-Chorus.

the-art (SOTA) methods in chorus detection. We first introduce the experimental setups, where details of our newly released dataset Di-Chorus and hyperparameter settings in LA-Chorus are discussed. Then we present the results of chorus detection by LA-Chorus and other methods on popular public datasets, followed by an ablation study that demonstrates the effectiveness of different modules in our proposed method.

4.1 Experimental Setup

For a fair comparison purpose, we conduct our experiment under the same settings in [5] with a cross-dataset paradigm (i.e. testing on different datasets that are not used in training). Specifically, we use 890 songs that contain chorus segments in *Harmonix* [12], along with 38 songs of Michael Jackson and 83 songs of The Beatles in *Isophonics* set [10] for training and validation. At testing time, we use three public datasets and our released dataset Di-Chorus to evaluate our model and other methods. The public datasets used for testing are: 100 "Popular" songs from *RWC* [37, 38], 210 "Popular" songs (denoted as *SP*) and 198 "Live" songs (denoted as *SL*) from *SALAMI* [11], which are chosen in consistence with the testing sets in [5].

Our newly released dataset, Di-Chorus [1] (denoted as DC), contains 237 music annotations of songs on YouTube labeled by experts. Compared to previous datasets mentioned above, songs in Di-Chorus are more easy-to-access from the appended YouTube URLs, and are more diversified since it consists of musics tracks in 14 languages as opposed to other existing datasets that are mostly in English (e.g., Harmonics) or just two or three languages (e.g., RWC and SALAMI). In addition, we also include three different recording qualities to improve the variation within dataset: Studio, Live and Original Sound Track (OST) which contains non-music segments. The key statistics are summarized in Table 1 below.

To demonstrate the performance of our proposed model on the above datasets, we compare LA-Chorus against the following methods:

- **CNMF** [39]: an unsupervised matrix factorization method from *MSAF* [40].
- **SCluster** [31]: a spectral clustering method based on frame co-occurrence matrix from *MSAF* [40].
- **Highlighter** [41]: an CNN model that takes an unsupervised approach to detect emotional highlights as chorus segments.

[1] We provide some demos of Di-Chorus in the supplementary material. Di-Chorus will be made publicly available upon acceptance for retrieval.

Models	AUC on Different Datasets			
	RWC	SP	SL	DC
CNMF	.526	.543	.478	.488
SCluster	.533	.545	.551	.568
Highlighter	.804	.703	.671	.553
Multi2021	.819	.675	.633	-
DeepChorus	.842	.780	.765	.811
LA-Chorus	**.906**	**.887**	**.831**	**.872**

Table 2. AUC results for chorus detection in various models.

Models	F1-score on Different Datasets			
	RWC	SP	SL	DC
CNMF	.403	.422	.340	.332
SCluster	.427	.448	.392	.603
Highlighter	.407	.303	.251	.283
Multi2021	.643	.473	.380	-
DeepChorus	.675	.611	.501	.662
LA-Chorus	**.728**	**.619**	**.526**	**.707**

Table 3. F1-score results for chorus detection in various models.

- **Multi2021** [3]: a CNN model based on a multi-task learning objective that jointly predicts chorus segments and their boundaries.
- **DeepChorus** [5]: a CNN model based on multi-scale networks and self-attention, which is the current state-of-the-art method for chorus detection.

Then, we validate the prediction results by AUC score (Area Under Curve) and F1 score. To evaluate these two metrics, we first create a sequence of the song length from the original annotation, with each element indicating the class of the corresponding segment. Then we can calculate AUC and F1 score for each song independently and take the average over them as the final result.

For the training details, we resample the audio at 22050 Hz and use CQT as our input feature with 12 bins per octave, where Han windowing function is applied with a hop size of 512 for extraction. The model is trained for 100 epochs with a batch size of 32 and a learning rate of 10^{-4} with a cosine decay scheduler. The code is implemented in PyTorch and run at a Tesla-V100-SXM2-32GB GPU.

4.2 Chorus Detection

We retain the experiment results for the chosen SOTAs on RWC, SP and SL from [5], and test them on Di-Chorus with the default settings in their papers, as shown in Table 2 and Table 3 by AUC score and F1-score respectively. Note we do not test Multi2021 [3] on Di-Chorus, since their code is not open-sourced.

For AUC metric, LA-Chorus outperforms other SOTAs

on all datasets by a big margin. Compared to *DeepChorus* [5], which is considered as the current best method for chorus detection, our method improves the performance by over 0.06 across all datasets. The performances on F1-score also exhibit a similar pattern, where LA-Chorus generates better predictions over other models with a considerable improvement on each dataset. In particular, our model performs exceptionally well on the widely used *RWC* dataset that reaches to an AUC score of 0.906 and an F1-score 0.728. We give most of the credits to the implicit augmentation design in our model, and we illustrate this perspective in the ablation study section.

4.3 Ablation Study

To analyze the effectiveness of FPN and latent augmentation, we test our LA-Chorus by separate modules: 1) ResNet backbone only, 2) ResNet with FPN, and 3) ResNet with latent augmentation (denoted as + *LA*). To demonstrate the efficacy of applying latent augmentations over traditional audio augmentation techniques in the input space, we further show the results of applying 4) time stretching (denoted as + *TS*) and 5) pitch shifting (denoted as + *PS*) to the ResNet backbone, with the results summarized in Table 4 for AUC and Table 5 for F1-score below (Note we do not apply TS or PS in our proposed method).

From the results, we can observe that by incorporating FPN, we improve the vanilla ResNet backbone by a remarkable increase of over 0.05 on most of the datasets under both AUC and F1-score metrics, expect for *SALAMI-Live* where the result remains the same. Such findings indicate that FPN is an effective method to locate music segments by increasing the resolution of feature maps, which, without any augmentation, can already generate predictions that are comparative to *DeepChorus*.

On the other hand, when we apply implicit augmentations to latent features generated by ResNet (without FPN), significant improvements of over 0.10 are witnessed for both AUC and F1 scores on most datasets. The results are even notably better than that of the *ResNet+FPN* combination who contains important positional information, implying the dominant role of latent augmentation in the strong performance of LA-Chorus. The results from *ResNet+TS* and *ResNet+PS* further corroborate the benefit of leveraging latent augmentations for chorus detection. Although there are some effects after adopting these two traditional augmentation methods, their improvements on the original model seem incremental compared to that of *ResNet+LA*. Instead, the implicit augmentation method outperforms traditional augmentation methods by a significant margin for both metrics on each dataset, which implies a clear advantage for adopting latent augmentations.

4.4 Discussion of Limitation

Despite of the prominent performance of LA-Chorus, we believe there are still some potential limitations for future explorations. First, further investigation is needed to verify that the latent augmentations are realistic to human when transforming them back to input domain. One possible way is to train a reversed model (such as a decoder or flow-based model) that reconstructs latent features to the original inputs. Second, the AUC and F1 metrics might not measure whether the output is overfragmented or underfragmented. It's needed to design metrics that are more perceptually relevant for chorus detection task. Finally, we only focus on detecting chorus segments in this paper, whereas in MSA, there are other annotation types (e.g. verse, bridge, etc.) to be modeled [4, 33]. We believe LA-Chorus only requires minor modifications in the class dimension of latent augmentations (i.e. augmenting chorus, verse, bridge, etc.) before being applied to predict other label types in music structure analysis.

Ablations	AUC on Different Datasets			
	RWC	SP	SL	DC
ResNet	.801	.773	.767	.751
ResNet + FPN	.865	.830	.767	.807
ResNet + LA	.882	.854	.824	.847
ResNet + TS	.818	.787	.765	.762
ResNet + PS	.822	.777	.789	.766
LA-Chorus	.906	.887	.831	.872

5. CONCLUSION

In this paper, we introduced a novel chorus detection model based on ResNet-FPN architecture with latent augmentations on audio features. The proposed method, different from traditional augmentation algorithms focusing on the input space, augments audio features in the latent space to explore semantic changes in audio data. Besides, we released a new diversified dataset, Di-Chorus, with expert annotations, which contains songs with 13 genres in 14 languages and 3 qualities. Comprehensive experiments have been conducted on public datasets and Di-Chorus, where LA-Chorus shows superior performance against other methods. Lastly, the effectiveness of different modules in LA-Chorus are validated by an ablation study. In the future, we plan to investigate more details on the semantic changes of audio data via latent augmentations and the extensibility of LA-Chorus to other MIR tasks.

ABSTRACT

We propose AccoMontage2, a system capable of doing full-length song harmonization and accompaniment arrangement based on a lead melody. [1] Following AccoMontage, this study focuses on generating piano arrangements for popular/folk songs and it carries on the generalized template-based retrieval method. The novelties of this study are twofold. First, we invent a harmonization module (which AccoMontage does not have). This module generates structured and coherent full-length chord progression by optimizing and balancing three loss terms: a micro-level loss for note-wise dissonance, a meso-level loss for phrase-template matching, and a macro-level loss for full piece coherency. Second, we develop a graphical user interface which allows users to select different styles of chord progression and piano texture. Currently, chord progression styles include Pop, R&B, and Dark, while piano texture styles include several levels of voicing density and rhythmic complexity. Experimental results show that both our harmonization and arrangement results significantly outperform the baselines. Lastly, we release AccoMontage2 as an online application as well as the organized chord progression templates as a public dataset.

1. INTRODUCTION

Accompaniment arrangement is a difficult music generation task involving structured constraints of melody, harmony, and accompaniment texture. A high-quality arrangement could help with various downstream tasks and applications, such as compositional style transfer [1], automatic accompaniment [2], and score-informed source separation and music synthesis [3].

As one of the most promising arrangement systems, AccoMontage [4] uses a generalized template-based approach to first search for roughly-matched accompaniment phrases as the reference and then re-harmonize the selected reference via style transfer. It generates much more coherent results than purely learning-based algorithms, especially for full-length song arrangements.

However, AccoMontage is not yet a "complete" accompaniment generation system in the strict sense, as it still calls for chord input from users and cannot harmonize a melody. To this end, we develop AccoMontage2, a system capable of full-length song harmonization and accompaniment arrangement based on a lead melody by equipping AccoMontage with two extra components: 1) a novel harmonization module, and 2) a graphical user interface.

The main novelty of our system lies in the harmonization module. We first collect a high-quality chord progression dataset and re-organize the phrases with respect to different styles to serve as reference templates. Then, we use dynamic programming (DP) to generate structured and coherent chord progressions given a query lead melody with phrase annotation. Specifically, the DP algorithm optimizes a multi-level loss function consisting of three terms: 1) a micro-level loss for note-wise melody-chord matching, 2) a meso-level loss for phrase-template matching, and 3) a macro-level loss for the whole-piece coherency. The first term evaluates the dissonance between the melody and the candidate chords. The second term prefers chord progressions with the same length as the target melody phrases. The third term computes how well the candidate phrases connect with each other to form an organic whole. Experimental results show that both our harmonization and arrangement results significantly outperform the baselines.

In addition, we develop a graphical user interface which allows the user to select different styles of chord progression and piano texture. Currently, chord progression styles include R&B, Dark, Pop-standard, and Pop-complex. Piano texture styles include several levels of voicing density and rhythmic complexity.

We release the AccoMontage2 as an online application [2] as well as the organized chord progression templates as an open-source dataset.

In brief, the contributions of our paper are as follows:

- A complete system for full-length song harmonization and accompaniment arrangement;
- An effective harmonization algorithm with state-of-the-art performance;

- A graphical user interface for controllable piano accompaniment generation.

2. RELATED WORKS

2.1 Melody Harmonization

Melody harmonization refers to the task of generating a harmonic chordal accompaniment for a given melody [5, 6]. It has been typically formulated as a prediction task, *i.e.*, to predict a sequence of chord labels conditioned on the lead melody. Recent mainstream methods range from hidden Markov models [7, 8] to deep neural networks [9–11]. Such models are typically trained to fit a groundtruth melody-chord mapping, but do not account for the fact that one melody can be harmonized with various styles in terms of genre, chord complexity, *etc*. In fact, the current state-of-the-art models [10, 11] only support simple triads and up to a few common seventh chords. Also, predictions are made locally, where neither phrase-level progression nor inter-phrase structures are explicitly considered.

In this paper, we re-formulate melody harmonization with a novel template matching approach. The usage of existing templates for music generation has been a popular idea. Existing template-based methodologies include learning based unit selection [2,12], rule-based score matching [13,14], and genetic algorithms [15]. In our case, we match the lead melody with chord templates from a library based on rule-based criterion and subject to user control. Such an idea is inspired by the fact that music producers tend to pick up off-the-shelf chord templates instead of harmonizing from scratch. In addition, they also have control on what style of the chords to use.

Existing template-matching attempts for harmonization typically focus on half-bar level [16]. In contrast, our model deals with phrase-level matching. We design three loss terms that measure melody-chord fitness at note-wise, intra-phrase, and inter-phrase levels, respectively. Our chord library is finely organized, supporting up to ninth chords with voice leading and various genres. Our model can therefore generate structured and coherent full-length chord progressions with different styles.

2.2 Accompaniment Arrangement

The task of accompaniment arrangement aims to generate an accompaniment conditioned on a given lead sheet (*i.e.*, a lead melody with chord progression). The quality of arrangement is related to chordal harmony, texture richness, and long-term structure. For this task, existing learning-based models often do well in harmony and texture, but are less capable of long-term generation [1, 17–21]. Previous template-matching models can easily maintain long-term structures, but suffer from fixed elementary textures and often fail to generalize [13–15].

To break such a dilemma, the AccoMontage system [4] introduces a generalized template-matching methodology, where phrase-level accompaniment templates are first searched by rule-based criterion, and then re-harmonized via deep learning-based style transfer. The search stage and the style transfer stage each optimize high-level structure and local coherency, thus guaranteeing the arrangement of high-quality accompaniment.

In this paper, we integrate our harmonization module with AccoMontage and upgrade it to a complete accompaniment generation model. An input melody is first harmonized with stylistic chord progression and then arranged with piano textures. With an additional GUI design, our model offers a flexible degree of control, including harmony styles and texture complexity.

3. METHODOLOGY

The system diagram of our AccoMontage2 system is shown in Figure 1. It can achieve full-length song harmonization and accompaniment arrangement. The input of the system is a query lead melody with phrase annotation. The harmonization module will first harmonize the melody. The generated chord progression will be sent into AccoMontage together with the original melody to arrange accompaniment. Lastly, a GUI is provided for users to adjust chord and accompaniment styles.

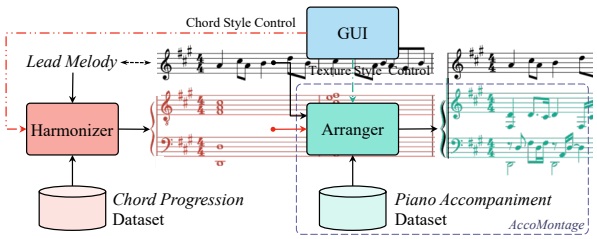

Figure 1: Diagram of AccoMontage2 system.

For the rest of this section, we first introduce the structure of the dataset and how we re-organize it in Section 3.1. Then we describe the harmonization module in Section 3.2. After that, we provide an overview of the AccoMontage system in Section 3.3. Finally, we show how the GUI is constructed to enable style controllability in Section 3.4.

3.1 Dataset Curation

A self-collected chord progression dataset is used as the reference templates for our harmonization algorithm. We create the dataset based on an existing chord progression collection [22] that contains 64,524 MIDI files, most of which are chord progression tracks with different style labels. The original dataset [22] cannot be adapted to our model directly for several reasons. First, some tracks are not pure chord progression, containing mixed melody segments. Second, many style labels are unnecessary. For example, two different styles may have similar musical elements that are hard to differentiate. Third, there are redundant progressions only different in their keys.

To solve the problems above, we process and reorganize the dataset as follows. First, we remove the MIDI files that contain melody segments and complex rhythmic textures. Second, based on our subjective assessment, we

manually define a style mapping function to map the original style labels to newly defined ones. [3] The newly defined styles are: "Pop-standard", "Pop-complex", "Dark", and "R&B". While Pop-standard contains only triad chords, Pop-complex contains seventh, ninth, and sometimes even more chromatic ones. Note that some templates do not have an original style label and are thus labeled as "Unknown". Third, we remove all the redundant progressions.

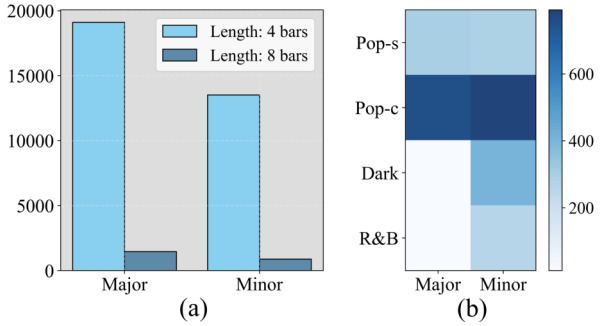

Figure 2: Statistics of the curated dataset.

The final curated dataset contains 5762 pieces of chord progression templates. Each template has 3 additional labels: 1) The length label. Templates are either of 4 bars or 8 bars in length in our dataset. Figure 2 (a) shows a distribution of the length of the templates. 2) The mode label. We currently only label the mode of the templates as either major or minor. 3) The style label. As mentioned above, four styles in total are acquired. The distribution of different styles among modes are shown in Figure 2 (b).

Finally, we represent the reference template space as a collection of tuples:

$$r = \{(r_m^{\text{chord}}, r_m^{\text{label}})\}_{m=1}^{N}, \tag{1}$$

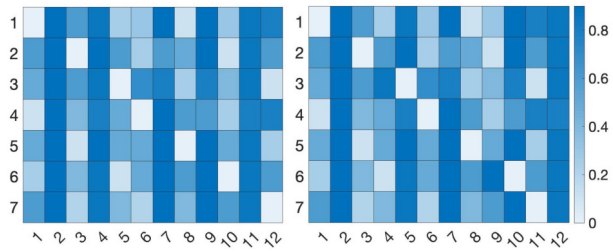
where r_m^{chord} and r_m^{label} are the chord progression and the labels of the i^{th} reference template; N is the volume of the reference space. r_m^{chord} can be seen as a sequence of chords. We quantize and sample the chords at 8th notes from the original chord progression track. Each chord is represented as its root note and a label to indicate whether the corresponding triad is a major triad or a minor triad.

3.2 Harmonization Module

We design a harmonization model that generates structured and coherent full-length chord progression for a given lead melody with phrase annotation. The model takes a multi-phrase melody as input and outputs a list of optimal chord progression identities. Each identity contains a group of progressions that have the same Roman numeral sequence (*e.g.*, I-vi-ii-V) but different styles (*e.g.*, Pop-standard or R&B) and are up for the user to choose. The model considers three levels of losses that involve melody-chord correspondence and is optimized by a dynamic programming (DP) algorithm. Specifically, the DP algorithm optimizes a multi-level loss function consisting of three terms: 1) a micro-level loss for note-wise melody-chord matching, 2) a meso-level loss for phrase-template matching, and 3) a macro-level loss for the full piece coherency.

3.2.1 *Micro-level loss*

The micro-level loss L_{mic} computes the level of dissonance between a melody phrase and candidate progressions note by note. We mainly consider the interval between a melody note and the root of the chord in the corresponding position. The more dissonant the interval is (tritone, minor seconds, etc.), the higher the loss. On the other hand, the more harmonious the interval is (unison, perfect fourth, perfect fifth, etc.), the lower the loss. In addition, the mode of the piece and the harmonic function of the chords will also affect the dissonance level. We refer to the "rank order of consonances and their degree of recurrence" [23] and design the micro-level loss shown in Figure 3, where matrix (a) is for major mode and matrix (b) is for minor. For both matrices, each row represents the degree of the chord (we only consider diatonic chords, *e.g.*, 1 for tonic and 5 for dominant) and each column represents the interval between the melody note and the key center. In Figure 3, the darker the shade, the more dissonant we consider the pair of the melody note and chord is, in which case we set a higher micro-level loss.



(a) Major (b) Minor

Figure 3: Micro-level loss indicating note-wise melody-chord dissonance.

For the i^{th} phrase, L_{mic} is computed by summing up the micro-level loss note by note and then dividing it by the length of the phrase. We further normalize L_{mic} to the range of $[0, 1]$.

3.2.2 *Meso-level loss*

The meso-level loss L_{mes} considers the integrity of a candidate. It encourages chord progressions with the same length as the target melody phrases and penalizes the rest. For a given phrase of melody, we consider chord progressions of the same length and we also concatenate shorter chord progressions to make them candidates. Here, we introduce a transition score to penalize the concatenated candidates. We concatenate two progressions r_m^{chord} and r_n^{chord} from the reference template space, and the transition score considers the very two bars connecting them (*i.e.*, the last bar of r_m^{chord} and the first bar of r_n^{chord}). In specific, we count the occurrence of this two-bar chord progression in the dataset and then normalize it by applying a logarithmic function with N, the size of the reference template space

[3] A detailed description of style mapping is provided in our dataset.

as the base. Suppose the occurrence is $c \in \mathbb{N}$, the transition loss of this $m \to n$ concatenated candidate is defined as:

$$T_{m\to n} := 1 + \log_N \frac{1}{c} \tag{2}$$

Moreover, as we do not wish to penalize the non-concatenated candidates, we introduce δ_1 such that $\delta_1 = 1$ if the candidate is concatenated and $\delta_1 = 0$ otherwise. On the other hand, we do not wish to consider candidates with length not equal to the length of the phrase. Hence we introduce δ_2 such that $\delta_2 = 1$ if the candidate has equal length as the melody phrase, and $\delta_2 = e^{-10}$ otherwise. The meso-level loss of the i^{th} phrase is explicitly:

$$L^i_{\text{mes}} := \delta_1 T_{m\to n} + (\frac{1}{\delta_2} - 1) \tag{3}$$

3.2.3 Macro-level loss

The macro-level loss L_{mac} computes how well the candidate phrases connect with each other. We consider how smooth the transition is from the previous progression to the current progression using the same transition loss as in Section 3.2.2. For the i^{th} phrase and its corresponding progression candidate, L^i_{mac} denotes the macro-level loss of the i^{th} phrase

$$L^i_{\text{mac}} := \begin{cases} 0 & i = 1 \\ T_{m'\to n'} & i = 2, \cdots, p \end{cases} \tag{4}$$

Here, $T_{m'\to n'}$ is the transition loss defined the same way as in Section 3.2.2. m' and n' index progression candidates to be connected. p is the total number of phrases.

Finally, we define the total loss of the s^{th} candidate of the i^{th} phrase by a weighted sum

$$\begin{aligned} L^{i,s}_{\text{total}} = (\beta(1 - L^{i,s}_{\text{mic}}) + (1-\beta)(1 - L^{i,s}_{\text{mes}})) \\ + \max_t \{L^{i-1,t}_{\text{total}} + \alpha(1 - L^{i,s}_{\text{mac}})\}, \end{aligned} \tag{5}$$

where α, β are parameters that we can tune between 0 and 1. Then we use DP to integrate the three levels of losses and search for the optimal chord progressions which minimize the total loss L^i_{total} at $i = p$.

3.3 An Overview of AccoMontage

Based on the harmonization results from the last section, we apply AccoMontage [4] to generate complete piano accompaniments in full length. The AccoMontage system offers a hybrid search-style transfer methodology for accompaniment arrangement: given a lead melody together with a chord progression inferred from Section 3.2, it first searches for reference pieces of accompaniments by dynamic programming. It then re-harmonizes the reference accompaniment to the given chord progression by deep learning-based style transfer. Such a pipeline is inspired by common practice that delicate music textures can often be applied in bulk, instead of composing from scratch.

Specifically, reference accompaniment pieces are searched phrase by phrase based on: 1) phrase-level fitness to the melody, and 2) transition smoothness between consecutive phrases. The overall searching process is optimized by the Viterbi algorithm [24]. The re-harmonization is implemented with a VAE framework which is capable of chord-texture disentanglement [1]. By varying the chord representation, we can re-harmonize the accompaniment while keeping its texture. The whole pipeline of AccoMontage secures a delicate accompaniment arrangement with coherent and structured texture. We refer readers to the original work [4] for more technical details.

3.4 Graphical User Interface for Controllability

AccoMontage2 provides a GUI for users to select styles of harmonized chords and accompaniment textures. The process begins with uploading a MIDI file with a melody track and setting the original chord progression styles and piano texture styles. Three labels have to be assigned manually, including phrase boundaries, key, and mode (major or minor in the current version of the system).

The system will then proceed to generation. When the generation is finished, users are able to: 1) listen to and download the generated audio; 2) select a new harmonization style for each individual phrase or the whole; 3) reset the texture style and re-generate the accompaniment. Figure 4 shows the GUI interface of AccoMontage2.

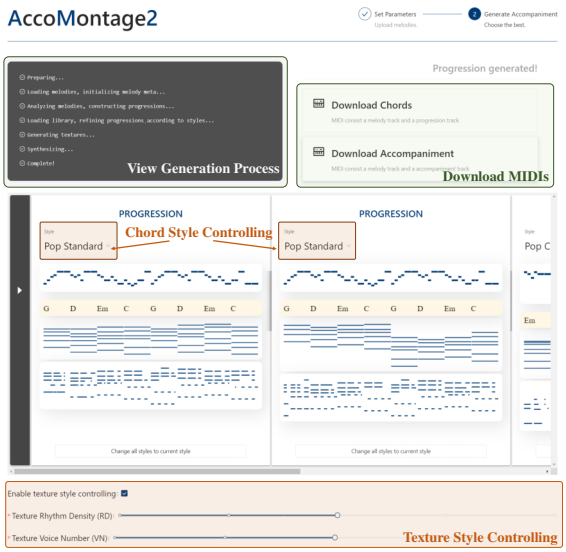


Figure 4: A screenshot of the Graphical User Interface.

4. GENERATION RESULTS

In this section, we showcase one long-term generation result of the AccoMontage2 system. We set $\alpha = 0.1$ and $\beta = 0.5$ in the harmonization algorithm and test our model on a 24-bar melody piece with phrase label `A8A8B8`. The first track in Figure 5 shows the original melody piece and the other two tracks are two different versions of accompaniment generation.

The result shows that AccoMontage2 is able to achieve high controllability in chord style and texture style. On the top of track two (I) and track three (II) in Figure 5, we present using chord notations the harmonization results

Figure 5: Harmonization and accompaniment arrangement results for *Dinners 1* from the Nottingham Dataset. The 24-bar melody has an `A8A8B8` phrase structure, and the AccoMontage2 system achieves a high degree of style controllability.

of chord style "Pop-standard" and "Pop-complex" respectively. Track two and track three are the whole accompaniment results. While track two (I) is based on "Pop-standard" and a sparse texture style, track three (II) is based on "Pop-complex" and a dense texture style. We see that both results match with the melody in harmonicity and are able to provide chord and texture variations.

5. EVALUATION

We conduct two comparative experiments to validate our AccoMontage2 system, one for harmonization and the other for accompaniment arrangement. We first show the dataset and the baseline model in Section 5.1 and 5.2. Then we present the experimental results in Section 5.3 and 5.4. Audio examples of our proposed system and ablation studies are available via our GUI link.

5.1 Dataset

For the harmonization experiment, we use Nottingham Dataset [25], which provides around 1000 pairs of the query lead melody and the ground-truth chords. For arrangement generation experiments, we use the POP909 Dataset [26], in which each piece contains a lead melody, annotated chords, and a piano accompaniment. For both data sources, we first select the pieces of meter $\frac{2}{4}$ and $\frac{4}{4}$ and then randomly sample 6 pieces for our experiment. We manually annotate their phrase segmentation and only allow the phrase length of 4 bars and 8 bars.

5.2 Baseline Method

We apply the chord generation model [9] based on bidirectional long short-term memory networks (BLSTM) [27] as our baseline model. This model takes a symbolic melody

with the information of time signature, measure, and key as input, and outputs a harmonization result of a sequence of major and minor triads. The BLSTM model considers temporal dependencies by storing both past and future information, reflecting musical context in both forward and backward directions, It is trained on a lead sheet database provided by Wikifonia.org and has achieved reasonable results quantitatively and qualitatively.

5.3 Harmonization Results

We conduct a survey to evaluate the harmonization performance of our model. Our survey has 6 groups of harmonization results and each subject is required to listen to 3 (chosen randomly). Within each group, the subject first listens to a single melody. Each melody is a full-length song randomly selected from the Nottingham Dataset, with an average length of 32 bars (64 seconds). We harmonize the melody using our model and the BLSTM baseline, and additionally acquire an original harmonization using the ground truth chord labels. The subjects are then required to evaluate all three versions of harmonization. The rating is based on a five-point scale from 1 (very poor) to 5 (very high) according to three criteria:

1. **Harmonicity**: How well do the melody and chords stay in harmony with each other;
2. **Creativity**: How creative the harmonization is;
3. **Musicality**: The overall musicality.

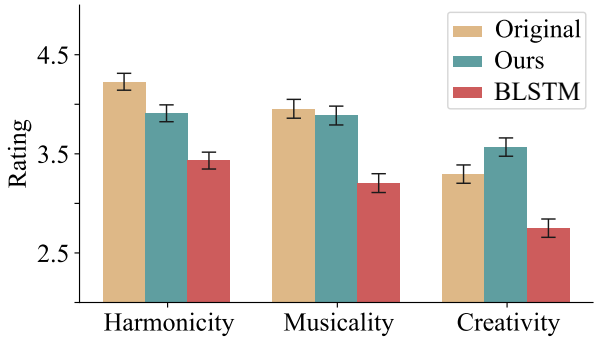

Figure 6: Subjective evaluation for melody harmonization.

A total of 15 subjects with diverse musical backgrounds participated in our survey and we obtain 44 effective ratings for each criterion. As shown in Figure 6, the height of the bars denotes the mean values of the ratings. The error bars stand for the mean square errors (MSEs) computed via within-subject ANOVA [28]. For harmonicity, the original receives the best rating, while our model performs significantly better than the BLSTM baseline. As for the overall musicality, our model is comparable with the original harmonization. For creativity, our model reaches the best. Note that our model supports complex harmonization with voice leading and ninth chords, while the original and the baseline support up to seventh chords in plain root position. Such evaluation results demonstrate that our model introduces *tension* to "flavor" the music while the overall musicality is not affected. For all three criteria, the rating results are statistically significant (p-value $p < 0.05$).

5.4 Accompaniment Generation Results

We conduct another survey to evaluate our model in terms of overall accompaniment generation. In our survey, each subject still listens to 3 groups of generation results (randomly chosen from 6 groups). Within each group, the subjects first listen to a 32-bar melody randomly selected from the POP909 Dataset. Our model generates piano accompaniment through the complete AccoMontage2 pipeline. For the BLSTM baseline, we feed its harmonization results to AccoMontage and obtain the baseline accompaniment. As POP909 contains piano arrangements created by professional musicians for each song, we also have the original accompaniment. The subjects are then required to evaluate all three versions of accompaniment based on the same scale and criteria as in Section 5.3.

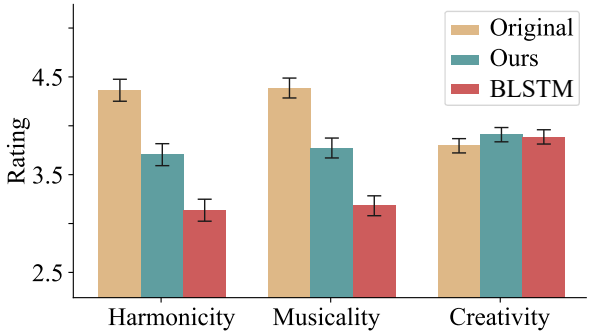

Figure 7: Subjective evaluation for accompaniment arrangement.

We collect a total of 44 effective ratings for each criterion. Figure 7 shows the evaluation results in the same format as in Section 5.3. We report a significantly better performance of our model compared with the BLSTM baseline in harmonicity and musicality ($p < 0.05$), and a marginally better performance than both the baseline and the original in creativity.

6. CONCLUSION AND FUTURE WORK

In conclusion, we contribute a pipeline of algorithms to automatically harmonize and arrange piano accompaniments for melodies of whole-piece popular and folk songs. The system is named after AccoMontage2, built upon its original version which uses a hybrid approach to select accompaniment candidates, edit the candidates using style transfer, and then concatenate them into an organic whole. AccoMontage2 contains two novel modules: a state-of-the-art harmonizer and a GUI for controllable arrangement via interfering in the harmonization and arrangement styles.

In the future, we plan to further optimize the arrangement pipeline by: 1) automatically labeling the melody phrase, 2) extending the model capability to deal with triple meters, and 3) exploring full-band arrangement.

ABSTRACT

In this work, we provide a broad comparative analysis of strategies for pre-training audio understanding models for several tasks in the music domain, including labelling of genre, era, origin, mood, instrumentation, key, pitch, vocal characteristics, tempo and sonority. Specifically, we explore how the domain of pre-training datasets (music or generic audio) and the pre-training methodology (supervised or unsupervised) affects the adequacy of the resulting audio embeddings for downstream tasks.

We show that models trained via supervised learning on large-scale expert-annotated music datasets achieve state-of-the-art performance in a wide range of music labelling tasks, each with novel content and vocabularies. This can be done in an efficient manner with models containing less than 100 million parameters that require no fine-tuning or reparameterization for downstream tasks, making this approach practical for industry-scale audio catalogs.

Within the class of unsupervised learning strategies, we show that the domain of the training dataset can significantly impact the performance of representations learned by the model. We find that restricting the domain of the pre-training dataset to music allows for training with smaller batch sizes while achieving state-of-the-art in unsupervised learning—and in some cases, supervised learning—for music understanding.

We also corroborate that, while achieving state-of-the-art performance on many tasks, supervised learning can cause models to specialize to the supervised information provided, somewhat compromising a model's generality.

1. INTRODUCTION

In this work, we consider a broad array of classification and labelling tasks under the umbrella of music understanding. Such tasks include the labelling of genre, origin, mood, musical key, instruments, era, emotion and pitch present in music. These tasks have many applications in industry, particularly in music streaming and recommendation services where automated understanding of audio can assist in a range of tasks such as organizing, filtering and personalizing content to a listener's taste and context.

Recent research in automated audio understanding has focused on training convolutional [1–12] and / or attention based [13–21] networks on moderately large collections of frequency-domain audio [2,5–8,12–14,18,20,21], time-domain audio [3, 10, 11, 19] or multi-format / multi-modal [4, 9, 21, 22] data. Such models are often trained on tags encompassing some of the musical labels listed above, achieving promising results [1,3,6,11,13–15,22]. More recent works propose unsupervised strategies for music understanding such as contrastive learning [2, 4, 5, 8–10, 21] or predictive / generative approaches [7, 20, 21, 23]. Unsupervised strategies are appealing because they require no annotated data and generalize well to new tasks [2, 21], but lag the performance of supervised learning at a similar scale [2, 10]. Generative learning strategies [7, 23] have been shown to achieve competitive, and sometimes state-of-the-art (SOTA), performance in several music understanding tasks [24], although, currently there is no evaluation demonstrating the effectiveness of this approach to any of the aforementioned approaches, at comparable scale.

Modern music streaming services have very large music catalogs that amount to many petabytes of audio data if uncompressed. Due to the scale of this data it is desirable to build models that are efficiently scalable, and understand audio in a general enough way that, as needs or requirements change, they may be used to solve novel problems without reprocessing such data. Models in the order of 10M or 100M parameters are currently relatively cost-effective to both train and apply inference to industry-scale catalogs, whilst models consisting of billions of parameters, e.g. that evaluated in [24], are typically impractical, or very expensive, for both training and inference.

More recently, research has adopted approaches producing generalized audio embeddings [2, 4–10, 12, 18, 19, 25] in a supervised or unsupervised way, by training models on large amounts of labelled or unlabelled audio. When such models are applied to novel audio, the internal state of the models has been found to contain much of the information necessary for previously unseen tasks. This is demonstrated by training shallow classifiers (probes) on embeddings consisting of the activations of a given model layer, that map these values to a downstream task. Such an approach achieves competitive results using either unsuper-

Ehmann, "Supervised and Unsupervised Learning of Audio Representations for Music Understanding", in *Proc. of the 23rd Int. Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

vised [25] or supervised [6] learning. Most importantly, the embeddings on which the probes are trained are many orders of magnitude smaller than the audio itself and only need to be computed once per audio file. Such embeddings can be stored efficiently, and downstream classifiers can be trained with significantly less resources. The excellent performance, generality, and scalability of this approach are crucial factors for its utility in industry.

This approach to audio understanding has been highlighted in recent benchmarks such as HARES [2] and HEAR [26], where embeddings are evaluated across a number of audio understanding tasks pertaining to a range of content types. Any score aggregation across these benchmarks to determine a "best" embedding is difficult due to the disparate range of metrics employed and furthermore, may obfuscate the strengths and weakness of any given approach. However, evaluating across a common range of tasks can be useful in comparing such strengths and weaknesses. We find that the current tasks evaluated in the HEAR and HARES benchmarks are lacking in evaluation on music content. Wrt. polyphonic music, the HARES benchmark includes only the Magnatagatune dataset, and the HEAR benchmark includes only GTZAN genre and music / speech datasets. While other public music datasets exist, such benchmarks are somewhat limited by the requirement to provide access to the audio of all datasets.

Here, we do not intend to establish a new open benchmark, but investigate the effectiveness of supervised and unsupervised learning for audio embeddings employed specifically for music understanding, across as broad an array of tasks as is available within time and resource constraints. For supervised learning we train models on large scale datasets of annotated magnitude log-mel spectrograms both in the music domain and in the general audio domain. For unsupervised learning we train contrastive models using SimCLR loss [27, 28] on the same sets of magnitude log-mel spectrograms, excluding annotations.

The contributions of this work are as follows: we provide a broad analysis of supervised and unsupervised learning strategies for pre-training audio models for music understanding; we show that for multilabel / multiclass classification of music, large-scale supervised learning on music data achieves SOTA performance, in many cases outperforming both prior SOTA and unsupervised learning by significant margins; we show that supervised learning on labelled music data does not generalize as well as unsupervised learning to novel tasks not covered in those labels; finally, we show that the domain of pre-training audio datasets has a significant impact on the performance of embeddings, particularly for unsupervised learning.

2. PRE-TRAINING METHODOLOGY

To achieve the objectives outlined in Section 1, we follow a familiar transfer learning paradigm (Figure 1) where models are pre-trained using supervised or unsupervised learning. Thereafter, the frozen activations from a layer of that model, forming embeddings, $\mathbf{z}$, are mapped to a downstream task using a simple network $p(\mathbf{z})$.

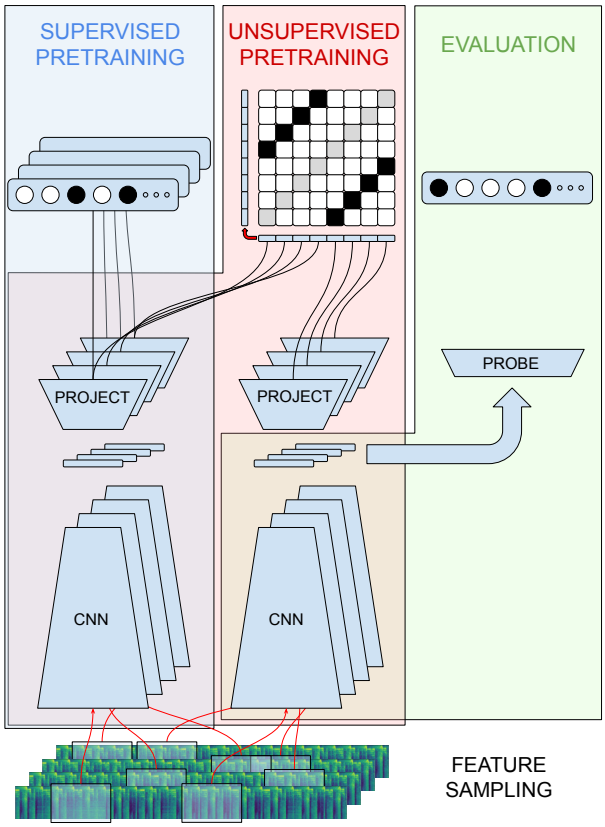

Figure 1. System diagram of both pre-training approaches employed in this paper, and evaluation.

2.1 Supervised and Unsupervised Training

In the supervised setting we learn a function $f(\mathbf{X}) \Rightarrow \hat{\mathbf{y}}$ mapping features $\mathbf{X}$ (log-mel spectrograms) to binary labels, $\mathbf{y}$, by applying Adam optimization [29] to the binary cross-entropy loss function,

$$L_s(\mathbf{y}, \hat{\mathbf{y}}) = \frac{-1}{NK} \sum_{i=0}^{N-1} \mathbf{y}_i \log(\hat{\mathbf{y}}_i) + (1 - \mathbf{y}_i) \log(1 - \hat{\mathbf{y}}_i),$$

where batch size $N = 512$, and K is the number of labels.

In the unsupervised setting, we employ the SimCLR objective [27, 28], which has been shown to provide promising results for both music and audio understanding [2, 10]. The SimCLR objective employs correlated (positive) pairs of samples by mapping each feature to an embedding space, $f(\mathbf{X}) \Rightarrow \mathbf{z} \in \mathbb{R}^m$, with embedding dimensionality $m = 1728$. A projector, then maps the embedding space to a loss space $h(\mathbf{z}) \Rightarrow \mathbf{v} \in \mathbb{R}^n$, with dimensionality $n = 1024$. Here, each element is then compared to all other elements in a batch via distance function, $d(\mathbf{v}_i, \mathbf{v}_j) = \mathbf{v}_i \cdot \mathbf{v}_j / \|\mathbf{v}_i\| \|\mathbf{v}_j\|$. The loss is then computed as the normalized temperature-scaled cross entropy,

$$L_u(\mathbf{v}_i, \mathbf{v}_j) = -\log \frac{\exp\left(d(\mathbf{v}_i, \mathbf{v}_j)/\tau\right)}{\sum_{k=0}^{2N-1} \mathbb{1}_{[k \neq i]} \exp\left(d(\mathbf{v}_i, \mathbf{v}_k)/\tau\right)},$$

which is summed across $2N$ examples in $N = 1920$ positive pairs, where $i = j$, for all values of both $i \in [0, N-1]$

and $j \in [0, N-1]$. Here, $\mathbb{1}_{[k \neq i]}$ is an indicator function evaluating to 1 for $k = i$, otherwise evaluating to 0. $\tau = 0.1$ denotes a temperature hyper-parameter.

SimCLR loss can be interpreted as a one hot classification problem—for each example, identifying its positive pair amongst all other (negative) examples in the batch. Because the batch-size determines the number of negative examples in the batch, and hence, the likelihood of non-trivial negatives, a large batch size of N pairs is crucial to this learning strategy, with larger batch sizes resulting in notable performance improvements [9]. However, batch sizes are limited to the memory of the available compute resources (e.g., of GPUs / TPUs). Hence, when considering compute costs, it is desirable to reduce batch size.

The primary objective of this work is to provide a comparative analysis of the utility of supervised and unsupervised learning strategies for a range of music understanding tasks under different data sources. As such we do not propose to investigate or innovate on the model architecture defining $f(\mathbf{X})$ itself, and employ the Short-Fast Normalizer-Free Net F0 (SF-NFNet-F0) of [2]. This architecture was chosen due to its demonstrated excellent performance in audio understanding, its design intent specifically for audio, and its use of efficient operations such as grouped convolutions. Furthermore, this architecture does not employ batch-normalization, improving training time and resource requirements, particularly when using SimCLR loss, by removing the need to globally synchronize data between GPU devices at each batch-normalization layer. Our intent was to reproduce this model as accurately as possible. However, due to the information available to us at the time of publication, there may be some discrepancies between our implementation and that in [2]. To ensure reproducibility, we release a Tensorflow implementation of the model used in this paper with SCOOCH configurations [1] for each of the models trained [2]. Our SF-NFNet-F0 implementation contains 62.4M parameters.

In both supervised and unsupervised settings we employ mixup [30] directly on the sampled log-mel spectrograms in real-time during training for data augmentation. We acknowledge that additively combined audio sources do not result in additively combined magnitude spectrograms due to both constructive and destructive interference. However, such an augmentation is an efficient operation to perform in real-time data sampling pipelines, mitigating data bandwidth bottlenecks that may be caused by more complex operations. We employ mixup by shuffling features within each batch and additively combining the shuffled features (and labels for supervised learning) to the original batch. Mixup gains are sampled from a beta distribution with parameters $\alpha = 5.0$ and $\beta = 2.0$, for each feature in a batch.

In all pre-training contexts, we use an Adam optimizer with a learning rate following a warm-up cosine decay schedule, first increasing to 0.0002 over 5k steps, then decreasing to 0.0 over 195k steps. While dense projectors, $h(\mathbf{z})$ are an inherent part of the unsupervised SimCLR learning approach, we find projectors to also be useful in the supervised setting, adding a non-linear transformation between the learned embeddings, $\mathbf{z}$, and the supervised labels, $\hat{\mathbf{y}} = h(f(\mathbf{X}))$. We notice such an approach has also been useful in computer vision [31]. Hence, in all contexts we employ a projector consisting of 3×4096 node hidden layers with ReLU activation. Supervised models were trained on 8 v100 GPUs taking approximately 30 hours, while unsupervised models were trained on 16 A100 GPUs taking approximately 80 hours.

2.2 Datasets

Pre-training datasets can have a significant impact on supervised and unsupervised model performance. In the supervised context, there has been evidence that models are less generalizable to unseen tasks [2], perhaps due to the information present in the supervised labels. In the unsupervised context, less investigation has been conducted into the effect of the content of pre-training datasets. In this context, the problem of sampling positive and non-trivial negative examples within a dataset is closely tied to the diversity of content in that dataset. Furthermore, when employing mixup as a data augmentation strategy, the content of the pre-training dataset also defines the additive noise that is applied to features during training.

We compare pre-training on two large datasets, namely **Musicset** and a version of **Audioset** [32]. The Audioset training set contains $\approx$ 1.7M distinct labelled content pieces, and Musicset $\approx$ 1.8M. Audioset consists of 10 second snippets of various audio sources: music, speech and environmental audio (4,791 hours, $\approx$ 602 GB of audio feature data). Musicset, in contrast, focuses solely on music; it consists only of labelled complete songs, each up to several minutes in length (117,497 hours, $\approx$ 14.7 TB of audio feature data). Musicset is, to our knowledge, the largest dataset of expert-annotated audio ever trained on. While it is not publicly available, we believe it valuable to report the results of models trained on this dataset to communicate the effectiveness of supervised learning at this scale.

For supervised learning, in addition to the features themselves, the labels differ. Each dataset's vocabulary is distinct but similar in size (527 labels for Audioset and 500 labels for Musicset), however, Figure 2 shows the label density and distribution of both datasets differs.

2.3 Feature Sampling

The features, $\mathbf{X}$, are log-magnitude log-mel spectrograms produced from waveforms sampled at 16 kHz. We use 96 HTK-log-mel spaced, power normalized, frequency bins with center frequences from 0 Hz to 8 kHz, analyzed with a window size of 25 ms, a Fourier transform size of 2048 bins and a hop size of 10 ms. We sample 3 s snippets of each content piece in real-time (during training) across the pre-training dataset, forming features, $\mathbf{X} \in \mathbb{R}^{96 \times 300}$. Sampling features in real-time from full-length tracks has the benefit of a high ratio of distinct features per static dataset size by reducing redundant (overlapping) data storage. For

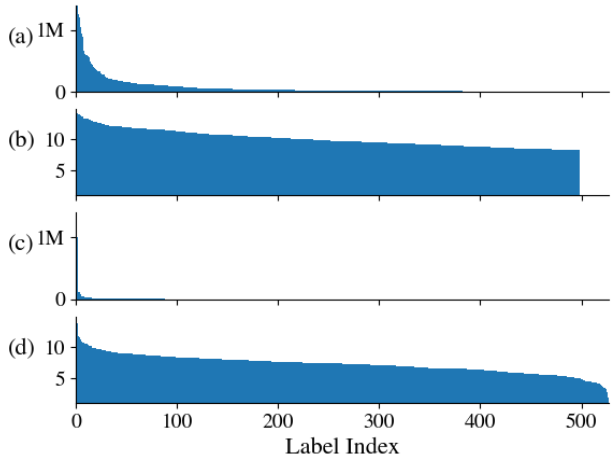

Figure 2. Label density distributions for Musicset and Audioset. (a), (b) plots the sorted Musicset label counts on a linear (in millions) and logarithmic scale, respectively. (c), (d) plots the same data for Audioset, respectively.

example, a 183 second song (6.8MB) results in 18k distinct features (each 112kB) with the above parameters.

To build a batch from a dataset, we first select a uniform random sample of tracks (with replacement); then, from each selected track, we choose a random 3-second spectrogram snippet, without padding. In the unsupervised context, we need to select positive and negative pairs for each selected snippet. Positive pairs are sampled from the same 10 second "track" for Audioset; for Musicset, positive examples are also sampled from the same track, although we require positive pairs to be centered on frames less than 5 seconds apart in the track's timeline. As negative examples, the SimCLR objective implicitly uses all other samples in a batch. We also tried forcing examples from the same track, but further away from the anchor than the positive, into every batch as hard negatives. Such an approach has shown promising results in music segmentation [33], however, we found that for music labelling at the averaged track-level this did not change our results significantly. As such, we omit this approach from our evaluation.

3. EVALUATION

To evaluate embedding performance, we take the global average pooled activations of the final convolutional layer in the SF-NFNet-F0 architecture for 3 second feature snippets sampled along the length of each audio timeline at a frequency of 0.5 Hz, then average these sampled embeddings along the length of the timeline (with the exception of NSynth datasets as described later in this section). We found similar results training probes on both the timeline-averaged embeddings, and individual embeddings sampled directly from track timelines, with slight improvements when using timeline-averaged embeddings in some cases.

Each of the embeddings derived from pre-trained models have different levels of predictive power and will underfit / overfit with different parameters for each downstream-dataset / pre-trained model combination. To demonstrate the potential of embeddings, and to investigate whether a given embedding can achieve SOTA performance on a given dataset, it is important to optimize the probe parameters for each dataset. However, in cases where such a transfer learning methodology is SOTA, it is important to constrain the probe to the limitations imposed in previous works so that it is the quality of embeddings that are evaluated, and not that of the probes. With these considerations, we adopt a hybrid strategy based on the prior SOTA for each dataset. We optimize the parameters of probes in all cases except where the prior SOTA adopts a similar transfer learning methodology, in which case, we constrain the probes to the parameter ranges investigated in those prior works. Regardless of prior works, we restrict all probes to simple multi-layer perceptron (MLP) classifiers which can be trained on a single 32 core CPU in less than 1 hour to maintain the aforementioned benefits of efficiency and scalability that such a transfer learning approach provides.

In all cases, we train probes using Adam optimization with a cosine learning rate schedule with 1,000 steps of warmup followed by a decay to zero over the remainder of the steps. We optimize the learning rate, number of training steps, and l2-regularization of each probe to achieve best performance / prevent overfitting.

In total we evaluate the performance over annotations of 7 distinct collections of audio, comprising 15 distinct datasets in total. An overview of datasets is shown in Table 1, and probe configurations in Table 2. We also publish more detailed SCOOCH configurations for probes, tag-level results, and model weights for the Musicset-ULarge model as a baseline for future research. [3] The remainder of this section covers specific notes on each dataset.

Table 2. Probe parameters

most recent SOTA on this dataset [24], we keep items without tags in both training and evalution sets.

GTZAN: This dataset addresses the problem of genre classification in a single-label context [35]. We employ the fault-filtered version of this dataset [4].

NSynth: Here we evaluate detecting the pitch (NSynth_P) and instrument (NSynth_I) of individual musical notes. Following [2], in the case of NSynth_P we analyze the average of embeddings from four non-overlapping consecutive snippets of 1 second feature windows, and for NSynth_I we analyze a single embedding for each note produced using a 4 second feature window.

Million Song Dataset: The Million Song Dataset (MSD) contains labels pertaining to era, instrumentation, sonority, genre, mood, origin and activity. Because of the size of this dataset and variation in label quality throughout we adopt several different splits and vocabularies for the dataset. For comparability with the previous SOTA, we adopt the vocabulary of the 50 most common labels, and the splits employed in [15] [4], namely MSDS. We also take advantage of the several cleaned and artist-separated datasets available for this collection [22]—MSD50, MSD100 and MSD500, for which the splits and vocabularies are available publicly [5].

All Music Moods: The All Music Moods dataset (AMM) [36], focuses on mood prediction for the MSD audio data. Because the mood labels are heavily correlated with the artists in the dataset, we find it important to adopt the artist-seperated split [6]. With no previously published result on this split, we additionally provide results for embeddings produced by the MusiCNN model [37].

Jamendo: This dataset contains genre, instrument and mood / theme tags for audio from Jamendo [38]. We evaluate on all tags (Jam-All) and the 50 most common (Jam-50). Because very few of the mood / theme tags are in Jam-50, we also evaluate the mood / theme category (Jam-MT). We use the official splits [7] and full-length audio.

GiantSteps Key: This dataset (GS_Key) concerns major/minor key classification in electronic music—a 24-way classification problem. It combines two datasets: the first, 604 2-minute samples of electronic music tracks collected from beatport.com [39]; the second [8], consists of 1486 tracks from the same source. Consistent with previous work [23, 40], we use the former 604 samples for testing, and the latter for training / validation, selecting high-confidence annotations partitioned into train and validation sets according to [23]. For evaluation we compute a weighted accuracy score common in key classification [9].

EmoMusic: This dataset (Emo) concerns emotion recognition [41], and provides continuous annotations for valence and arousal. Following [23], we consider the static version of this dataset, where target values are averaged for each clip, and use the artist-based train / test partitioning provided in their work. This poses a regression problem—we use the coefficient of determination as the evaluation metric for both valence (Emo_V) and arousal (Emo_A).

MuMu: The Multimodal Music dataset (MuMu) [42], focuses on multilabel genre predictions for the MSD audio data, with genre annotations from the Amazon Reviews dataset. We evaluate using the official splits [10].

4. RESULTS

In order to derive conclusions on the potential performance of supervised models trained using binary labels on music data, we train a supervised model on the complete Musicset dataset, namely *Musicset-Sup*. To compare these results to supervised learning on a large-scale public dataset covering music, environmental, and speech audio, we provide results for a model trained on ≈1.7M items from Audioset, namely *Audioset-Sup*. To compare supervised and unsupervised learning at a similar scale, we provide results for a model trained using the unsupervised methodology discussed in Section 2 on the same Musicset dataset audio data and the Audioset audio data, namely *Musicset-ULarge* and *Audioset-ULarge* using a batch size of 1920 pairs.

In addition, we train two further unsupervised models using a batch-size of 256. One trained on Audioset (*Audioset-USmall*), and one on ≈1.8M randomly sampled 10 second snippets from Musicset, one per content piece (*Musicset-USmall*). The reasoning for this is two-fold—firstly by sampling short snippets from Musicset we mitigate the confounding variable of dataset size when comparing the two, secondly this allows us to investigate the effect of batch size in the unsupervised learning paradigm.

For convenience, we also include results for the recent evaluations in [2, 24], and those for any other previous SOTA, excluding these two evaluations. The results for each of these models is shown in Table 3 for all datasets excluding annotations of MSD, which are shown in Table 4. There, we note that for all multilabel music tagging tasks, the Musicset-Sup model achieves SOTA performance by significant margins. This is encouraging given that the Musicset training dataset was created naively, and the supervised information therein opens the door to improvements such as label-balanced sampling which has been shown to

Models within 0.01 of SOTA are bold. *The previous SOTA for MuMu evaluated artist-level predictions rather than track-level. †The SOTA for Jam-MT is trained on an expanded within-taxonomy set ($\approx$ 16k tracks), here we restrict probe training to Jamendo tracks ($\approx$ 10k).

realize further performance gains [6]. We leave this investigation for future work.

It is also encouraging to see that unsupervised learning on music audio (Musicset-ULarge) achieves SOTA performance compared to previous unsupervised models, in addition to some supervised models (specifically, for models trained on Jam-50 and all MSD datasets).

Comparing to recent transfer learning approaches [2, 24], we see that in all cases either Musicset-Sup or Musicset-ULarge outperform or are on par with these, with the exception of $NSynth_I$. This is a promising result espousing the value of music only audio datasets considering that previously reported results for unsupervised learning on Audioset [2] used more than double the batch size of those in this paper. Wrt. the Jukebox model, models trained for this paper use approximately 1% of the parameters and take less than 1% of the GPU flop hours to train.

We see that the supervised models evaluated demonstrate shortcomings in performance on pitch ($NSynth_P$) and key (GS_{Key}) tasks. This corroborates the findings in [24] that models trained on tags do not perform well in this task, and the findings in [2] that supervised pre-trained models do not generalize as well to novel tasks. We note that there are no pitch or key labels in the Musicset dataset, and in fact, many of the labels employed (e.g., genre, mood, etc.) require the model to be somewhat agnostic to such information. It is yet to be seen whether including such information in the labels of a pre-training dataset would improve the generalizability of such models, though this is outside of the scope of the current work. Interestingly, we see that unsupervised models trained specifically on music data show significant improvements in key estimation.

When comparing the domain of the pre-training dataset features in the models of Musicset-USmall and Audioset-USmall we see that in all cases, in-domain data (music) results in a better performing model. We conjecture that this may be due to (a) increasing the chances of non-trivial negative examples within each batch relative to each positive pair, due to the homogeneity of the dataset, and (b) music is more spectrally dense and correlated than other common noise sources employed in mixup augmentation, such as speech or various environmental noises.

5. CONCLUSIONS

In this work we investigated both unsupervised and supervised learning strategies, to produce compact audio representations that may be deployed across industry-scale audio catalogs for a range of downstream use cases. We observed that supervised training on large scale expert-annotated music data achieves SOTA results in music tagging. We see that unsupervised learning on datasets of the same scale also achieves excellent performance, across a wider range of tasks than supervised learning, particularly on those that involve information not represented in the supervised dataset. Finally, we see that for unsupervised learning, restricting the domain of the pre-training dataset to music results in improvements in model performance.

6. ACKNOWLEDGEMENTS

The authors would like to thank the Pandora music analyst team for their years of dedicated and careful work that enables us to investigate supervised machine learning systems at modern levels of quality and scale.

ABSTRACT

Creating a complex work of art like music necessitates profound creativity. With recent advancements in deep learning and powerful models such as transformers, there has been huge progress in automatic music generation. In an accompaniment generation context, creating a coherent drum pattern with apposite fills and improvisations at proper locations in a song is a challenging task even for an experienced drummer. Drum beats tend to follow a repetitive pattern through stanzas with fills/improvisation at section boundaries. In this work, we tackle the task of drum pattern generation conditioned on the accompanying music played by four melodic instruments – Piano, Guitar, Bass, and Strings. We use the transformer sequence to sequence model to generate a basic drum pattern conditioned on the melodic accompaniment to find that improvisation is largely absent, attributed possibly to its expectedly relatively low representation in the training data. We propose a novelty function to capture the extent of improvisation in a bar relative to its neighbors. We train a model to predict improvisation locations from the melodic accompaniment tracks. Finally, we use a novel BERT-inspired in-filling architecture, to learn the structure of both the drums and melody to in-fill elements of improvised music.

1. INTRODUCTION

Songs in popular music genres like rock are typically split into different sections such as the verse, bridge, and chorus. While the primary task of a drummer is to play in time, it is also important for the drummer to be consistent with the song structure. Traditionally fills, or short groups of notes, are played as the song transitions from one section to another (say, verse to chorus). Thus, it can serve as an indicator to the audience as well as the band, of an upcoming transition in the song. The duration of fills generally tends to be only a few beats long, no more than the length of a bar. Even though they are rare events in a drum track, fills are an important part of the overall aesthetics. Beyond signaling transitions, drum fills can also be played in sections where the accompanying instrumentation is sparse.

Motivated by the above, we improve the quality of the generated drum tracks from seq-to-seq models by incorporating fills/improvisations towards our overall goal of accompaniment generation. This is achieved via the following three distinct stages:

1. **Basic Drum Pattern Generation:** Using a seq-to-seq model to generate a drumbeat as the accompaniment to given melodic instrument tracks of guitar, bass, strings, and piano (i.e. the Melodic Accompaniment - MA).

2. **Improvisation Location Detection:** Detecting explicitly the position of improvisation from the MA using a self-similarity function and mini BERT model.

3. **Generating Improvised Bars:** Generating the fills in the previously detected bars.

Our main contributions are: (i) We show that traditional attention-based transformer architectures fail to capture the "improvisation" due to implicit data imbalance. (ii) We also show that the sampling-based approaches fail to produce a variation of pattern at the right location. To mitigate this, we learn to predict where to improvise directly from the melody tracks using powerful self-attention-based architectures. (iii) We propose a novel in-filling approach, inspired by BERT that can look at the context of drums and the context of melody and use it to generate the improvised bars. (iv) We demonstrate an MLP-based synthesis module for drum improvisation generation from a latent code. For simplicity we have ignored the dynamic (velocities) in the generated drum patterns of this work.

2. RELATED WORKS

Since the introduction of the Transformer architecture [1], there has been a growing interest in this model for sequential task modeling like in NLP and music generation. The architecture uses an attention mechanism to learn long-term patterns and can easily surpass dilated convolutional-based methods such as WaveNet [2]. They achieve state-of-the-art performance in a variety of natural language problems [3], music/audio understanding [4] and generation tasks [5, 6]. However, for generative models, the decoding strategy still remains an open question. Even though high-quality models can be obtained by the use of likelihood as the training objective, likelihood maximiza-

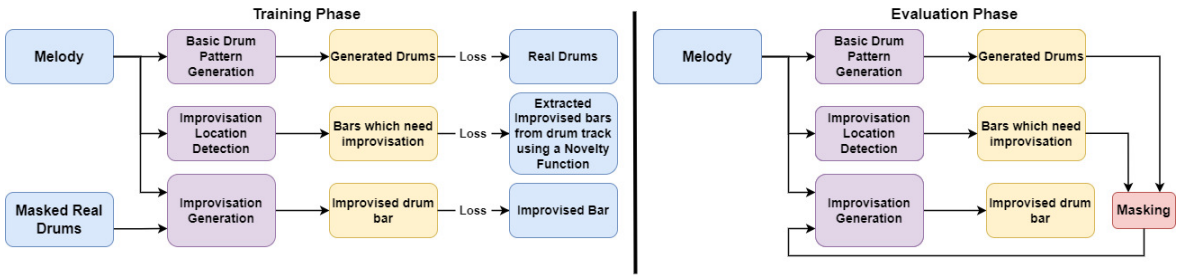

Figure 1. System Overview - Pipeline used for training (left half) of each individual module; combined pipeline (right half) for the evaluation phase.

tion methods like beam search lead to degeneration [7]. To solve this issue, many researchers use sampling-based methods like temperature sampling, top-k sampling, and nucleus sampling [7–9]. Despite all of the success of sequential modeling recently, there still exist many issues that are relevant to our current work such as understanding rare words or sparsely occurring events of interest [10]. Another major problem is the presence of biases in the generated output, as they mimic the distribution present in the training datasets [11]. These issues are ubiquitous across datasets and modalities and are implicit in our task due to the low representation of improvised bars. We here show how these constraints and biases affect the quality of drum generation, and the steps we take to mitigate them.

Conditioned drum beat generation is an important subtask of music generation. Wei et al. [12] observed that the polyphonic melody self-similarity matrix (SSM) is structurally similar to the drum SSM. They used this to predict the drum SSM from the melody SSM and used this intermediate representation to generate the drumbeat. While they used the audio form of the melody as the input, the symbolic domain also offers opportunities for similar research. An example is the work of [13] using symbolic representation of the drum track to predict locations and generate improvisations for the drum track. In this work, we address drum generation conditioned on a melodic accompaniment track, bringing considerably more complexity to the problem.

In the symbolic domain, systems use a discretized representation such as MIDI tag and pianoroll representations that capture the essential information at the semantic level. Pianoroll is a score-like matrix representing a piece of music. Note pitch and time are represented by the vertical and horizontal axes, respectively. The velocities of the notes are represented by the values. The time is generally quantized on a sub-beat level and each instrument track is represented by a separate pianoroll matrix. Dong et al. [14] used this representation along with CNN-based GAN model for music generation. Another popular symbolic domain representation is the MIDI tag representation which we refer to as the "serialized grid representation". In this method, the input is represented by a sequence of MIDI-like tags. Huang et al. [6] used this MIDI tag representation with modified transformer architecture to generate long-duration piano music. Several modifications have also been proposed to this representation. Huang et al. [15] proposed a revamped MIDI (REMI) which introduced `DURATION`, `BAR` and `POSITION` tags to improve the quaity of generated music. Ren et al. [16] further modified this representation to include multi-track representation by introducing `TRACK` tag and used the Transformer-XL model to generate multitrack songs. Nuttall et al. [17] modified the MIDI tags of nine percussion instruments to represent notes being played by a triplet of pitch, velocity, and start time, and used it with the Transformer-XL model to sequentially generate the drum pattern. Thorn et al. [18] demonstrated three experiments with the Transformer-XL model with varying input and output representation and control. In two of the experiments, they tried to control the drum machine while in the third experiment they tried to generate the drum pattern directly.

While the Transformer-XL model facilitates the generation of longer duration (musical) sequences, they still suffer from the same issues of biases in dealing with the implicit data-imbalance that exists in the training dataset [19, 20]. As the specific focus of this work is to find ways to capture the rare events in the generated output, i.e., fills and improvisations, we consider only the necessary context for an improvised bar in the form of 11 bar segments of the songs.

3. DATASET

In this work, we use the Lakh Pianoroll Dataset (LPD-5 cleansed) [14], derived from the Lakh Midi Dataset [21] which is a collection of 21,425 multitrack pianorolls files consisting of following tracks: Piano, Guitar, Bass, Strings and Percussion. All the songs in this dataset are of 4/4-time signature i.e., all the songs contain 4 beats in a bar and the dimensionality of each bar in this dataset is 128 (pitch) x 96 (time steps) i.e. each beat is divided into 24 parts. Our input, which we call melodic accompaniment (MA), consists of notes played by the 4 melodic instruments and output is a percussion instrument pattern conditioned on the input which we call the percussion accompaniment (PA).

Evaluation of generative music systems faces harder challenges than that of image generation systems [22]. We expect our system to replicate the rhythmic consistency and diversity of the dataset. Any drum beat generation system must have correct onset locations in a beat. If the onsets are not properly matched, it appears as if the drums are lagging/leading the melody. We show that our model is able learn this by capturing the onset location distribution.

To compare generated samples with original drums in the dataset, we use the following metric: Instrument Count - Number of distinct percussion instruments used in a bar. To evaluate our outputs in terms of rhythmic consistency, we use the following objective metric: Percussion pattern consistency in consecutive bars.

4. METHOD

The overview of the proposed system is shown in Figure 1. Details of each of the models are provided in subsequent sections. Our models are trained for 300 epochs with Adam optimization [23] starting with a learning rate of 1e-4 and decaying it till 1e-6. All the setup was carried out using the Tensorflow [24] framework. The following two modules are being used in all the models:

1. **Embedding Module:** As the pianoroll matrices are highly sparse, we pass them through 2 layers with 1024 and 128 ReLU [25] activated dense layers to capture the inter instrument and inter pitch dependencies. For the decoder branch of Basic Drum Pattern Generation model, we use 128 dimensional token embedding layer.

2. **Position Encoder:** We concatenate the sinusoidal positional representations [1] with the 128 dimensional vectors and use a dense layer to project them back in 128 dimension space.

4.1 Data Processing & Representation

To compress the input and output representation in our work, we perform the following preprocessing steps: (i) trim the track for start and end silence bars; (ii) resample the beats to 8 parts per beat, making each bar 32 timesteps long; (iii) keep only active MIDI pitches in all melodic instruments, i.e. MIDI 21 to MIDI 83 (notes A0 to B5); (iv) combine similar instruments in the MIDI representation of the percussion track. For example, under the snare drum, MIDI 38, which corresponds to acoustic snare, and MIDI 40, which corresponds to electric snare, are clubbed together; (v) choose only 16 percussion instruments as they capture 85.3% of all the percussion instrument strokes: snare drum, open hi-hat, close hi-hat, kick drum, ride cymbal, crash cymbal, low-floor tom, high-floor tom, high tom, hi-mid tom, low tom, cowbell, pedal hi-hat, tambourine, cabasa, and maracas; (vi) to decrease the amount of training parameters, we binarize the percussion track for seq-2-seq models and exclude velocities; (vii) split the song in non-overlapping contiguous 11 bar samples. The finer grids are superior for representing drum audio and fills [26]. We however opt for a quantized representation, capturing most of the significant musical events, allowing us to model longer duration dependencies by the compressed representation. It will be interesting to compare various representations as a future work.

We use a modified version of pianoroll representation for MA representation. We concatenate the pianorolls (Figure 2a) of different instruments instead of adding them to different channels [14]. As our input is quantized to 8 parts per beat, we represent each $\frac{1}{8}^{th}$ part of the beat by a 256-dimensional vector split amongst the 4 melodic instruments. The first dimension of this 64-dimension vector is the silence state. This is a binary state representing if the instrument under consideration is silent. The rest of the 63 dimensions contain the velocities of the MIDI notes 21-83 being played.

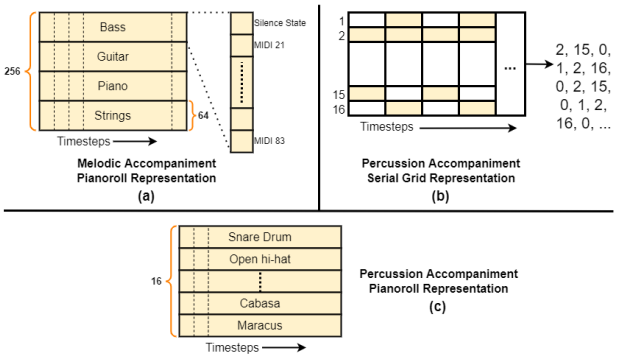

Figure 2. Data representation methods used in this work

For the PA, we adopt a mixed representation. For our Basic Drum Pattern Generation model, which is a transformer seq-2-seq model, we take advantage of the language modeling tasks and use a serialized grid representation (Figure 2b). In this representation, only the active percussion instruments which are being played are unfolded into a sequence of tokens. We add a silence state token and shift by one token making a total of 18 tokens for the percussion track. For the final model, the improvisation generation model, we give the MA and masked basic PA pattern as the inputs. We use the pianoroll representation for the PA representation for this model (Figure 2c) as only a fixed number of timesteps needs to be masked in this representation.

4.2 Train-Test Splits and Data Augmentation

We split the 21,425 songs in LPD-5 into 16,832 songs for training and 4,593 songs for the validation set. As the number of songs is limited, we use the validation set as the test set. We apply the following data augmentation strategies (inspired by sensor dropout methods in robotics [27]) to all of our models' inputs to increase the robustness in the training process:

1. **Random instrument masking:** We randomly mask one of the instruments in MA for 40% of the samples in every epoch. This 40% is equally split between the four melodic instruments. Musically this implies that one of the instruments has stopped playing. This encourages the model to consider all the instruments in the MA while making a prediction.

2. **Random timestep masking:** We randomly mask 20% of the timesteps in every sample. Musically this leads to a small disruption in the rhythm of the song which helps in better generalization of the model.

For the improvised bar generation model, which takes in the MA and masked PA as inputs, (section 4.5), we use the following additional augmentation methods:

1. **Input masking:** We randomly drop one of the inputs (MA or PA) to the model in 20% of the input samples. This

ensures that the model is not dependent on only one input for improvisation generation.

2. **Drum noise:** In the evaluation phase, the drum inputs are taken from the output of the basic drum pattern generation model. As this process could be prone to errors, we simulate this by adding the random noise to the drum samples while training. The random noise can either add new drum strokes or remove some old strokes. Our analysis showed that the PA has a very low density in the pianoroll format (average $\approx$ 5%). Hence we perturb the PA density by a maximum of 1%

4.3 Basic Drum Pattern Generation

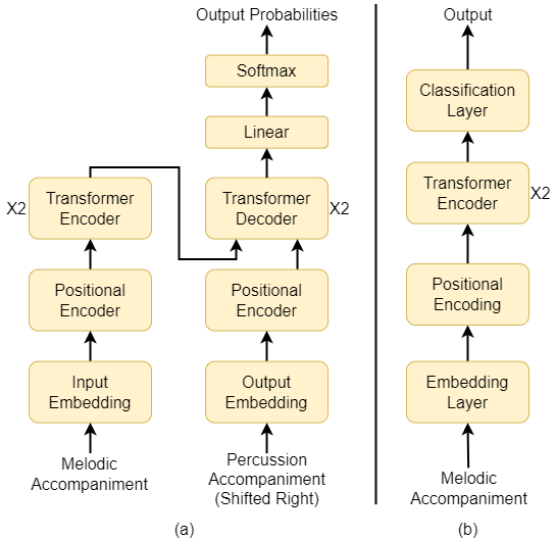

Figure 3. (a) Sequence to sequence model, used for basic drum pattern generation; (b) Improvisation Location Detection Model

We use the Transformer encoder-decoder model [1] to generate a basic drum pattern (Figure 3a). This is done by giving the MA as the input to the encoder and the shifted PA tokens to the decoder branch. Both the inputs are first passed through the embedding module followed by the position encoder. The embedded inputs are passed through 2 layers of encoder/decoder module with 128 dimensional latent space and 8 attention heads. At the output, we have 18 neurons corresponding to the 16 drum instruments, silence token, and shift token.

4.3.1 Sub-module Evaluation

We evaluate the above model with the negative log-likelihood (NLL) values over the train and the validation set. As the model outputs a distribution over the 18 output tokens, there are multiple ways to decode it. We test the greedy method of decoding, where the token with the maximum probability is selected at every step and simple sampling method. The model is trained using categorical cross-entropy loss, achieved a NLL of 0.108 and 0.112 on the train and validation split, respectively.

4.4 Improvisation Location Detection

4.4.1 Novelty Function

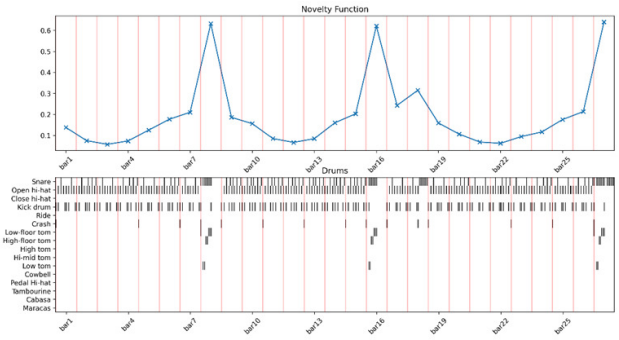

Figure 4. Novelty Function plot for a given drum track

In order to extract locations in the MA that warrant a fill, we propose the following method:

1. We use a 11-bar drum sample to calculate the Novelty value of center bar. The 5 bars on it's left and right are the context bar. The novelty value of a bar is calculated as the average weighted dissimilarity over all the context bars. We use the following equation to calculate the dissimilarity between 2 bars:

$$\frac{||bar_i - bar_j||_1 \times k}{||bar_i||_1 + ||bar_j||_1} \quad (1)$$

We utilize the hanning window to represent the weighting parameter k.

2. This calculation is done for all the bars across a track, except the first and the last 5 bars due to the lack of context bars. From Figure 4 it can be seen that the novelty function peaks at the bar with a drum fill. These bars are then extracted using a peak picking mechanism.

3. To generate the dataset for our task, we pick the bars with a local maxima as the positive samples. To filter out minor deviations, e.g., bar 18 in Figure 4, we put a threshold of 0.1 on the peaks height difference from its neighbours. Maximum of 10% of total bars in a song with these characteristics are selected as the positive samples. Same number of bars from the rest of the non peak regions are selected as negative samples.

4.4.2 Model Architecture

We use a 2 layer BERT [28] (Figure 3b) to detect the location of improvisations. The input to this model is an 11-bar MA and the prediction is done for the middle bar. The MA is passed through an embedding layer followed by the positional encoder. The embedded inputs are then passed through 2 layers of transformer encoder with 64 dimension latent space and 12 attention heads, followed by 1024 neurons. These are finally passed to a 2 dimensional softmax activated dense layer which acts as a classification module. The above model is trained using Huber loss [29], as it is robust to outliers and less sensitive to noise.

4.4.3 Sub-module Evaluation

We monitored the accuracy, precision, and recall of the model in terms of detecting the improvised bars where the

target is the original drum track. The final results can be found in Table 1. As the dataset is split equally between positive and negative samples, we have balanced precision and recall values.

	Precision	Recall	Accuracy	F1 Score
Train	92.3	92.3	92.3	92.3
Val	79.1	79.4	79.3	79.2

Table 1. Performance of the Improvisation Location Detection model. All the values are in %.

4.5 Improvisation Generation

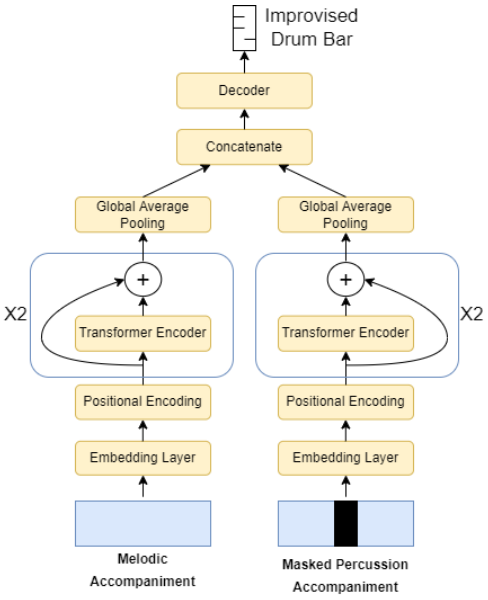

Figure 5. Improvised Bar Generation Model

The final step in our system is the generation of improvised bars. To achieve this we use the architecture shown in Figure 5. We provide 11 bar MA and PA as the input to the model. During the training phase, the PA is the original percussion track, whereas, during the evaluation/generation phase, the percussion track generated by our first stage model (section 4.3) is used. The 6th bar in the percussion sample (middle bar) is the target bar and is masked while giving as the input.

We generate a summary vector of both the MA and the PA inputs. Both are first passed through an embedding layer followed by a position encoder module. This is then passed through 2 layers of transformer encoders with 128 dimensional latent space and 8 attention heads. Even though larger/bigger models could potentially lead to better results, we have used the resources at our disposal. We note that any further improved performance will only apply to in-fill detection and synthesis.

We add skip connections to ease the flow of gradients [30]. To generate the summary vector for each input, we use a global averaging technique. These two vectors are concatenated and passed through a decoder structure which looks at the concatenated vector to generate the improvised drum bar. We test the following decoder architectures with our model:

1. **MLP:** A 3-layer dense network with 2048-2048-512 neurons is used. The final layer is sigmoid activated. The outputs are reshaped to 32 (timesteps) $\times$ 16 (percussion instruments) to get the improvised bar.

2. **MLP mixer:** MLP mixers [31] are simple alternatives to convolution and self-attention. They are based on multi-layered perceptrons applied across either temporal dimension or feature dimension.

3. **Conv1d:** A simple conv1d architecture with blocks of 2 layers of conv1d followed by upsampling.

We did not opt for an auto-regressive architecture, as this work does not assume causality, and we incorporate the right context as well as melody for the fill synthesis. There have been other works for improvisation synthesis, e.g. [32], also using the left and right context, even if only using drums

4.5.1 Sub-module Evaluation

We treat the prediction of the improvised bars as a regression problem. We similarly train it with Huber loss as it is less sensitive to outliers. We do not use cross-entropy loss for generation firstly purely as a design choice, and intuitively each of the time step token in the prediction within a bar lack probabilistic interpretation. We monitor and report the accuracy, precision, and recall of the models. As the distribution of 0s and 1s is not uniform in the predicted sample, F1 score provides a better insight in the performance of the models. From Table 2 it can be seen that a simple 3 layered MLP decoder is able to perform better than the complex MLP mixer and Conv1D architecture.

		Precision	Recall	Accuracy	F1 Score
MLP	Train	98.8	93.2	86.3	95.9
	Val	82.9	**70.3**	79.0	**76.0**
MLP Mixer	Train	97.5	45.0	88.7	61.6
	Val	**83.5**	42.1	**86.0**	56.0
Conv1D	Train	55.2	70.6	86.2	61.7
	Val	53.1	70.3	86.1	60.5

Table 2. Results for various decoders used in the Improvised Bar Generation model (all the values are in %)

5. EVALUATION

To evaluate the quality of the generated PA pattern of the proposed system, we conduct both objective and subjective tests [1] with: **O:** Original MIDI drum patterns from the dataset; **P1:** The basic drum pattern generated by our Basic Drum Pattern Generation model (section 4.3); **P2:** The final drum pattern with fills and improvisations generated by the complete system.

We screen the generated samples to eliminate those with more than 4 silent bars and those where the variation of bar density is high as measured by the standard deviation of the bar density. After applying the mentioned filtering to 8192 P1 drum samples generated by simple sampling method, we are left with 3762 samples for further evaluation.

[1] Note:Additional objective evaluation methods are reported in the supplementary document `https://bit.ly/2022ismirsupp`

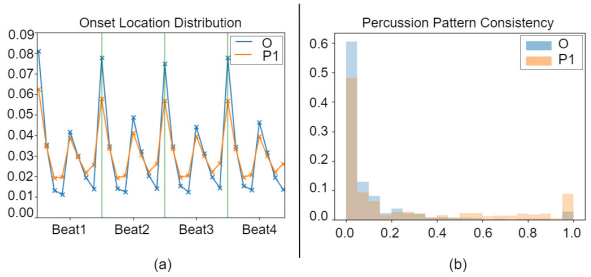

Figure 6. (a) Distribution of onset position in a bar (b) Distribution of Percussion Pattern Consistency

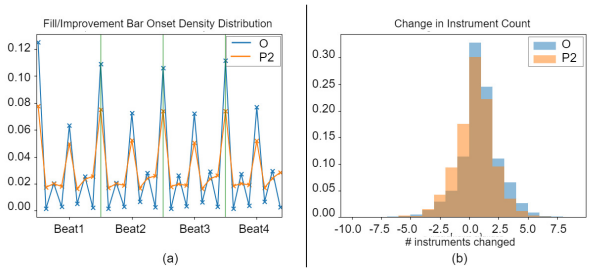

Figure 7. Improvised bars: Distribution of (a) onset location (b) change in instrument count (w.r.t. previous bar)

A basic requirement that any drum pattern generation system must fulfill is the rhythmic positioning of onsets. Generally, in a bar of rock music, the first beat (downbeat) and the third beat have similar instrumentation, featuring a hi-hat and kick drum onset. Beats 2 and 4, commonly referred to as the backbeat, include a hi-hat and snare drum onset. While the quarter notes are accented across the bar, 8^{th} notes are accented within the beat interval. Figure 6a shows the onset distribution present in the bar of both O and P1 samples. We can observe that most of the drum patterns are 8^{th} note patterns and we find a larger proportion of onsets at the accented locations within a beat interval. This is particularly intriguing because the model is given no explicit downbeat or subdivision information yet is still able to emphasis the subdivisions required for an 8^{th} note pattern.

We also do a one-to-one comparison of the P1 outputs against their target drum pattern to understand how closely the patterns match with the original drum sample based on the following metric:

Instrument Count (IC) is defined as the total number of distinct instruments used in a bar. To see whether our model is able to replicate the behavior of multi-instrument dependency, we calculate the deviation of IC in the generated sample with reference to the original target drum track for the same MA. We observe that in 75.8% of the drum bars, we are able to replicate the IC, while in 99.3% of the bars our model was off by at most 1 instrument.

Another important aspect that needs to be considered while generating drum patterns is to have a rhythmic (pattern) consistency across bars. We evaluate this aspects of the generated drum pattern using the following metric:

Pattern Consistency: For consecutive bar pair, we calculate the distance between the drum patterns using (1) keeping $k = 1$. The distribution of the bar distances is shown in Figure 6b. We can see that the generated drum bars are more or less similar to each other with some minor deviations due to the sampling decoding method. The overlapping area of the two distributions is 80.4%.

Next, on the improvised O and P2 bars, we used the following evaluation methods to see how well our models captured the fills/improvisations:

Onset Position: Figure 7a shows the distribution of onset location of percussion instruments across the improvised bars. We observe a slightly higher proportion of 16^{th} note patterns in the improvised O bars as compared to onset distribution across the non-improvised bars seen in Figure 6a. We can see that P2 system is largely able to capture this behavior as well.

Instrument Count (IC) Change: Generally during a fill/improvisation, some additional instrument are being introduced. IC change is measures as the change in IC of improvised bar compared to its previous bar. Figure 7b shows the distribution of IC change. The overlapping area of the two distributions is 87.9%, This shows that our model was able to capture the general trend of IC change.

Additionally, to evaluate the perceptual quality of the generated outputs, we present the generated samples to trained musicians. We created 3 pairs i.e. O & P1; P1 & P2; O & P2 for each MA-PA track and presented them to two guitarists and a multi-instrumentalist with experience ranging from 5 to 10 years. They were asked to provide detailed comments on the drum pattern in terms of timing, appropriateness of fills and coherence of the PA with MA. A common comment from the musicians was regarding the monotonicity in P1 track. As a result when the O & P1 pair was presented, majority of the times O was preferred, but when P1 & P2 were presented, musicians were found to appreciate the fills as it provided a lively feel to the PA.

6. CONCLUSION AND FUTURE WORK

We have successfully shown a method to produce coherent drums accompaniment with improvised bars by conditioning on a given melodic accompaniment. A novel BERT inspired infilling architecture is proposed, along with self-supervised improvisation locator. By learning, where and how to improvise, our evaluations indicate improved generation quality. Thus with a two step approach, we mitigate the biases intrinsic with data-imbalance, and shortcomings that exists with current machine learning architectures. The system can further be improved by learning optimal sampling techniques, which still remains an open problem. As a future work, we could improve the detection performance by employing larger and deeper architectures. This work highlights a serious drawback of traditional language-based generators, which have shown promise in a lot of different fields, yet they fail to capture subtle musical signals, where they are often sparsely occurring in otherwise repetitive and common patterns.

ABSTRACT

Although audio to score alignment is a classic Music Information Retrieval problem, it has not been defined uniquely with the scope of musical scenarios representing its core. The absence of a unified vision makes it difficult to pinpoint its state-of-the-art and determine directions for improvement. To get past this bottleneck, it is necessary to consolidate datasets and evaluation methodologies to allow comprehensive benchmarking. In our review of prior work, we demonstrate the extent of variation in problem scope, datasets, and evaluation practices across audio to score alignment research. To circumvent the high cost of creating large-scale datasets with various instruments, styles, performance conditions, and musician proficiency levels from scratch, the research community could generate ground truth approximations from non-audio to score alignment datasets which include a temporal mapping between a music score and its corresponding audio. We show a methodology for adapting the Aligned Scores and Performances dataset, created originally for beat tracking and music transcription. We filter the dataset semi-automatically by applying a set of Dynamic Time Warping based Audio to Score Alignment methods using out-of-the-box Chroma and Constant-Q Transform extraction algorithms, suitable for the characteristics of the piano performances of the dataset. We use the results to discuss the limitations of the generated ground truths and data adaptation method. While the adapted dataset does not provide the necessary diversity for solving the initial problem, we conclude with ideas for expansion, and identify future directions for curating more comprehensive datasets through data adaptation, or synthesis.

1. INTRODUCTION

Audio to Score Alignment (ASA) is a longstanding Music Information Retrieval (MIR) problem which aims to synchronize a musical score with its audio performance to map between each instant in a recording and a position in the score. When conducted in an online (real-time) fashion, it is often referred to as Score Following, in which the music stream to be aligned (MIDI or audio) must be processed as it is received. When conducted in an offline (non-realtime) fashion, it is often referred to as simply ASA, in which the music stream can be processed after it is fully received. This allows the advantage of looking forward and backward into the input stream [1] before returning the alignment result of each fragment.

Often, ASA problems are solved with methods previously used in audio to audio alignment problems, where the task becomes aligning the performance audio to a synthesized version of the music score [2–5]. In such methods, the alignment is conducted by comparing the same features computed from the synthesized score and the performance audio. Nevertheless, alignment is sometimes performed in the symbolic modality by first transcribing the audio then aligning it with the MIDI score [6–8], and recently alignments were conducted between audio and sheet music images directly through devising intermediate representations allowing both modalities to be compared [9, 10]. The most prevalent approaches through which ASA has been addressed are Dynamic Time Warping (DTW) [1, 2, 4, 7], and Hidden Markov Models (HMM) [6, 8, 11–13], with the former being a popular choice for alignments conducted audio to audio.

ASA research usually begins by defining the scope of the problem and accordingly proposing a system. The characteristics of the target music (i.e. the instruments, recording conditions, musician proficiency, and performance conventions) affect the scope, so ideally, researchers should find annotated data representative of such music. Very often this is not possible, as the datasets available are small and do not cover a variety of musical scenarios. This complicates benchmarking and evaluation because as a result, researchers tend to vary in their choice of data, which we believe hinders the movement of ASA research beyond the typical use-cases. Researchers have sometimes relied on synthetic data as a low-cost and practical way to generate relevant alignment data with properties not found in other datasets. This was done to curate evaluation data [2, 10], to create ground truth for HMM training [8], or to induce temporal mismatches and file corruptions [14].

In our review of prior research (Section 2), we cover several variants of the family of ASA methods comprised of audio representation plus DTW, thus showing how each

Serra, "Bottlenecks and Solutions for Audio to Score Alignment Research", in *Proc. of the 23rd Int. Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

alignment scenario is often addressed in an isolated manner. We believe it would be useful to unify such scenarios under one vision, allowing us to expand the definition of ASA and set clear benchmarking and evaluation strategies representing each of the scenarios formerly addressed in isolation. This would enable researchers to compare between systems and identify directions for improvement, but cannot be achieved without enough varied data to support the development and evaluation of such ASA systems. Since creating datasets is costly, especially at a larger scale, we believe that first we must exhaust the ability to leverage datasets created for tasks other than ASA whenever possible and then synthesize more data as a compliment. This paper demonstrates an example by reusing the Aligned Scores and Performances (ASAP) dataset [15] to generate approximated ground truths for ASA, since it provides 520 classical solo piano performances (audio and MIDI) beat aligned with their symbolic MIDI scores. We thoroughly describe this process in Section 3. In Section 4, we describe the methodology for validating the generated data and discuss their potential problems and aptness for ASA, which involves the application of several DTW-based systems to conduct offline ASA (which, from now onward, we refer to as just ASA). In Section 5, we explain how we use the obtained results to filter data for problems and highlight some limitations of our methods. Although the adapted dataset alone is not a solution to the aforementioned bottleneck, especially since it does not possess the necessary diversity to cover a variety of ASA scenarios, we conclude in Section 6 with ideas for expansion, to support the creation of a unified benchmark and the development of new ideas for ASA research.

2. RELATED WORK

Although this paper concerns ASA, contextualizing its developments requires references to Score Following, which has received more attention over the years. Dixon [16] and Arzt et al. [17] use online versions of DTW suitable for the real-time nature of Score Following. In later years we find the work of Duan et al. [11] and Nakamura et al. [8], both of which propose HMM systems for the same task. Henkel [27] et al. introduce a different paradigm for Score Following, where audio is aligned to score images end-to-end using reinforcement learning. For ASA, recent DTW-based approaches include [2–4, 7]. Table 1 summarizes the datasets used in some of the works above, highlighting the variation among researchers in their choices. The same datasets can be used for the training and evaluation of Score Following and ASA. Although currently inactive, there was a Music Information Retrieval Exchange (MIREX) [1] entry for Score Following which can be used for benchmarking, and it includes several of the datasets shown in Table 1. But the MIREX datasets are small and do not represent a wide variety of scenarios. Moreover, there is no MIREX challenge for ASA.

[1] https://www.music-ir.org/mirex/wiki/2021:Real-time_Audio_to_Score_Alignment_(a.k.a_Score_Following)

2.1 DTW-based Methods

Given two time series $U = u_1, ..., u_n$ and $V = v_1, ..., v_m$, the goal of DTW is to find a minimum cost path $W = w_1, ..., w_n$ where every element in W is an ordered pair (i, j) indicating that the elements u_i and v_j have been aligned. Over the years, researchers have introduced different variants of DTW depending on the specifics of their target problem. For example, FastDTW [28] is a popular, more efficient variant of the algorithm. Moreover, there is the Memory Restricted Multi-Scale DTW (mrmsDTW) [29], which caps the memory requirements of the DTW algorithms for large audio files, for which a python implementation was recently made available in [30]. To the best of our knowledge, there has not been a thorough comparison of all the DTW methods for ASA, although Agrawal et al. [3] compare the results of their proposed system with JumpDTW [31], NWTW [32], and MATCH [16] based on their ability to handle structural variations in the audio compared to the score it is to be aligned with. Moreover, Shan and Tsai [10] compare the alignment results of their proposed Hierarchical DTW with those of JumpDTW and subsequenceDTW [33], where they use intermediate representations [9, 10] allowing the computation of distances between audio and score images. In addition to the variants described above, it is important to note that even within single DTW variant, performance can vary based on system choices such as normalization, the chosen time scales of the feature sequences, and the use of penalties and path constraints [14].

2.2 Audio to Score Alignment Features

Classic features used for ASA are Semitone Energy based features such as Constant-Q Transforms (CQTs) and Pitch Class Profile based features, more commonly known as Chroma representations. In a parameter search by Raffel and Ellis [14] the best alignments were attained with a log-magnitude based CQT. Ewert et al. [21] develop the DLNCO representation, which balances the tradeoff between chroma robustness and time resolution. More recent approaches explore the realm of using learned features [2, 9], or learned distance measures [3]. In [2], the authors explore the use of transposition invariant features learned in an unsupervised way on ASA, thus diverging from pitch based features. They conduct their experiments on piano and orchestral data, and report a result improvement in both. However, in [4], the authors claim that such pitch invariant features underperform in conditions of large tempo variations. So, in their approach, they use features learnt directly from music at the frame level by using a twin Siamese network each containing a Convolutional Neural Network (CNN), and in addition explore the use of salience representations proposed by [34]. In recent work, Automatic Music Transcription (AMT) has been used to first transcribe the target audio before aligning it to the score notes [6, 7].

2.3 Evaluation

Cont et al. [35] formalize the quantitative performance metrics of Score Following, forming the basis of the MIREX challenge for the task. Only a subset of their metrics are relevant for ASA since there is no expectation of real-time execution. They define the error as $\mathrm{e}_i = \mathrm{t}_i^e - \mathrm{t}_i^r$, where t_i^e is the estimated time in the score for event i, and t_i^r is the actual time of event i in the reference. The alignment corresponding to an event is considered misaligned only if it exceeds a time threshold θ_e, which we call the misalignment threshold, noting that events could be notes or other time references (See Thickstun et al. [5] for a discussion on the difference between temporal and note based metrics). Accordingly, the following metrics are proposed: the Standard Deviation of the e_i of non misaligned events, the Misalignment Rate (MR) (percentage of events with $|\mathrm{e}_i| \geq \theta_e$, and the Average Imprecision (average absolute error of non misaligned events). For system-wide metrics, they propose the Piece-wise Precision Rate (PPR) over a related subset of scores, calculated as the percentage of non misaligned notes, and the overall precision rate (OPR) calculated similarly to the PPR but over the whole database instead. In practice, researchers slightly vary in their evaluation metrics. They mostly capture the Alignment Rate (AR), according to a set of θ_e usually between 50 ms to 300 ms, sometimes using it as an analogue for PPR.

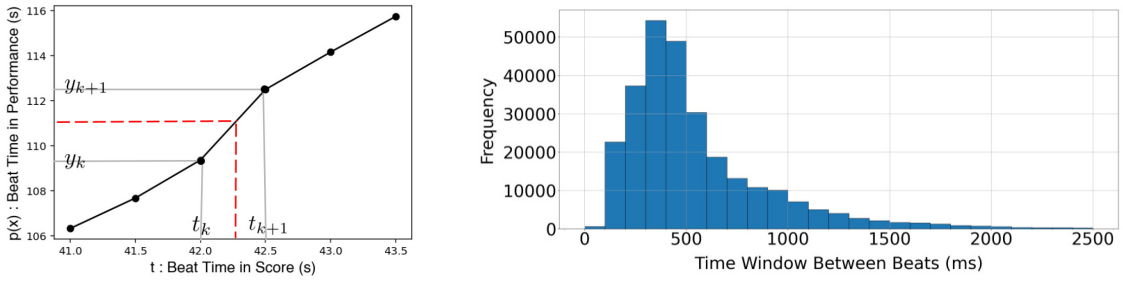
Another commonly used metric is the Average Alignment Error (AAE) defined in [11], which is the average absolute error for each audio frame, distinguishing it from Average Imprecision, which is calculated for non misaligned events only. AAE can be reported in milliseconds or in beats, depending on the end goal in mind [11]. Without using AAE explicitly, Jiang et al. [12] calculate the proportion of misaligned frames by units expressed in beats per measure. A metric with the same essence as AAE is used in [2], where they additionally report the median, 1st, and 3rd quartiles of this difference. In addition to the aforementioned metrics, some authors conduct an extent of qualitative analysis in order to make useful insights about their systems with respect to the scope in which the problem is defined. This has been done to test robustness to performance mistakes [8], for error prone scores [20], to understand the impact of polyphony [11, 19, 20], or the presence of percussion [20], tempo variations [2, 19], or skips [8, 10, 12].

3. GENERATING GROUND TRUTHS FROM ASAP

Reusing the ASAP dataset [15] is a reasonable step to expand the data available for ASA research. First, it offers beat-level aligned audio and music scores for 520 piano performances over various composers and styles. Some pieces are performed by several pianists, and we observe temporal variation in the different interpretations of one piece. In addition, we believe that these alignments could help us create more data by introducing structural variations within a single piece or across different pieces, depending on the scope of the alignment problem we want to consider, which we highlight in Section 6 along with other augmentation ideas to cover a variety of ASA problems. The rest of this section describes how we create ASA ground truth approximations from the beat annotations of ASAP, along with the potential implications and pitfalls of doing so.

3.1 From beat annotations to full alignments

We use the aligned beat annotations of the performance MIDIs and score MIDIs provided by the ASAP dataset to obtain approximated ground truth alignments (performance-aligned scores) for score-performance pairs at a low cost through Piecewise Linear interpolation. Every beat in the score is mapped to a specific time in the performance, yielding an alignment function with which we map each onset time of the MIDI score file to a time in the performance audio. A schematic is shown in Fig 1a. This approach does not give an alignment with a note-to-note resolution. However, we believe it is still usable for evaluating methods outputting temporal alignments that inherently do not provide this level of precision, such as warping paths obtained by DTW alignments, or for training audio to score alignment systems with methods that tolerate weakness in the reference alignments. To understand the extent of the error, we investigate the temporal resolution of the beat annotations (the time distances between consecutive beats) over the chosen subset of the ASAP dataset. As shown in Fig. 1b), the majority of such distances fall between 200 and 1100 ms. Clearly, the faster the tempo of the performance, the less spaced in time consecutive beat annotations are. For context, the distance between two quarter notes in a 120 BPM score is 500 ms.



(a) (b)

Figure 1: (a) Illustrative snippet of the ground truth alignment from the GuoE01M Prelude BMV883 performance. (b) Distributions of the time in between consecutive beats for all files in our chosen subset of the ASAP dataset.

3.2 Error Limits

To understand the limits of the error between the ideal ground truth and the approximated ground truth (ϵ_{gt}) we resort to the definition of Piecewise Linear Interpolation, shown as follows:

$$p(x) = y_k + \frac{y_{k+1} - y_k}{t_{k+1} - t_k}(x - t_k), \text{for } x \in [t_k, t_{k+1}], \quad (1)$$

where x is the time point in the score for which we need to approximate a corresponding time in the performance, t are reference points in the score annotation (in the context of the ASAP dataset, these would be beat times), and y are time reference points in the corresponding performance annotation. This is demonstrated in Fig 1a. In reality, the path between (t_k, y_k) and (t_{k+1}, y_{k+1}) can take any shape as long as it is monotonic (an assumption we can make due to our data). Taking the extreme unrealistic case where $p(x)$ takes on either y_{k+1} or y_k, the ground truth approximation error ϵ_{gt} must be:

$$\epsilon_{gt} = \max(|p(x) - y_k|, |p(x) - y_{k+1}|), x \in [t_k, t_{k+1}]. \quad (2)$$

If x falls on the midpoint of t_k and t_{k+1}, then ϵ_{gt} cannot surpass $\frac{1}{2}(y_k, y_{k+1})$, meaning that even for beats highly spaced apart (1000 ms) the error would be 500ms. Moreover, we would argue that in practice the error would be even less, because of the musical flow. However, the potential of error is a limitation due to which a decision needs to be made on which files to discard. Although not much detail is provided, it is worth noting that Duan and Pardo [19] mention their use of beat annotations to create ground truths, meaning that this process has been accepted in past studies, although it was not discussed elaborately.

4. DATA VALIDATION

The approximated ground truths of our interpolated dataset can have two problem sources: 1) misalignments within the generated annotations due to the low resolution of the score or performance beat annotations (as discussed in Section 3.2), and 2) annotation problems from the original dataset. These need investigation before using the dataset, whether for evaluation or training. We create test audio for every generated annotation file, where the left channel includes the performance-aligned score (the approximated ground truth) and the performance audio on the right channel. Therefore, by listening to all such test audios, it is possible to get a sense of both problems above. However, due to the size of the ASAP subset we reuse, it was not feasible to listen to all the hours of audio. So, we conduct a typical ASA experiment to help give clues as to which files most likely could contain errors and therefore would need to be examined. The rationale of this selective investigation is that files with low misalignment rates have passed an implicit check. Suppose a music score has been aligned with the performance audio using a process different from that with which the ASAP dataset was created. If this result matched the interpolated ground truth, then it is improbable that there is a problem with its beat alignment. Otherwise, there would have been a difference between the alignment result and the ground truth. Moreover, to determine whether we should discard files with large time windows between beats, we listened to a selection of the files with intra-beat annotation time differences of $\approx$ 1500 ms. They sounded correct for several performances, especially for files performed without much temporal variation (such as the Fugue BMV 874 and Prelude BMV 863 performances by Kurz and Shyc, respectively). We decided to keep all such files and only discard them based on the results of the alignment experiment.

4.1 Alignment Experiment

To align a performance and its symbolic score, we sonify the latter using the fluidsynth [2] and conduct DTW-based audio to audio alignment between the synthesized score and the audio performance. We use the librosa [3] [36] DTW implementation, and the distance matrix is computed by applying the Euclidean distance between the feature vectors.

[2] https://www.fluidsynth.org/
[3] https://librosa.org/doc/main/generated/librosa.sequence.dtw.html

4.1.1 Features

We use the CQT and 5 of the chroma representations compared in [37], which are: a Connectionist Temporal Classification loss trained chroma extractor (CTC-Chroma) explained in [38]; Non Negative Least Squares (NNLS) chroma [39]; the Harmonic Pitch Class Profile (HPCP) [40]; the Deep Chroma Extractor (DCE) [41]; and the classic Chroma algorithm implemented in [36]. All these algorithms are easily usable out of the box, and we believe are appropriate to use for piano data. Details on the parameters of each algorithm can be found in the accompanying repository [4] .

4.1.2 Quantitative Results

Since our focus is on filtering files, we report file-based metrics rather than global metrics for each DTW system. Therefore we omit reporting the Overall Alignment Rate (OAR), the system-wide AR considering the notes over all scores (or all temporal units). We use the Average Absolute Error (AAE) for each file in the dataset, shown in the box and whisker plots of Fig. 2 indicating the 1st, median, and 3rd quartiles per each DTW system. We also maintain the AR and the Absolute Errors (AE) for each file. We use these metrics to identify 1) suspects of files with beat alignments that are not highly accurate, which should be discarded, or 2) files for which our ground truth approximation approach yielded a high ϵ_{gt} for annotations within the beats. Those might still be relevant to keep depending on how they will be used. We explain this process in Section 5. However, we must be careful before discarding any files based on performance metrics to avoid cherry-picking only the files for which our ASA systems perform well. This is why we use a variety of audio representations, knowing that some might not be perfectly suitable for audio to score alignment, and no files are discarded unless they performed badly using all DTW systems.

5. RESULT INFORMED DATA FILTERING

Although not the core of our work, we observe that the DTW systems using CQT, HPCP, and Chroma perform better than the rest. This can be seen from Fig. 2 from the lower AAE time windows and the compactness of their distribution, and although we do not show a plot for OAR, these three systems reach very high OARs within the 0 - 60ms error thresholds. In fairness, the CQT system with the best performance is the gold standard obtained by the Bayesian Optimization of [14], suggesting that before making any absolute statements about the superiority of any of the DTW systems, their parameters should be optimized similarly. Besides, comparing such systems or finding the best performing ASA system is not the goal of this paper, and as we argue earlier, ASA is still missing a clear methodology and varied data with which qualitative evaluation can be conducted. This hinders the ability to compare between systems. The ASA results shown are just a means to an end, which is validating the interpolated dataset as described in Section 4, and helping us pinpoint problems and the potential need to filter some files, as shown in Sections 5.1 and 5.2.

5.1 AAE based investigation

Without discarding any generated alignments yet, we start by observing the box-and-whisker plots showing the AAE for all the 520 usable files of ASAP evaluated over the interpolated ground truth references, shown in Fig. 2a. We observe files with very high AAEs, most likely signalling either an annotation or calculation error since they represent alignment error values that are unreasonably high. Drawing a threshold at an AAE of 6000 ms (the red line) allows us to filter those clear outliers, thus arriving at the second plot shown in Fig. 2b. Then, we decide to conduct further filtering at a threshold at an AAE of 1000, arriving at Fig. 2c. We can keep setting lower AAE threshold and filtering more files for as long as needed. But the idea is to listen to the test audio described in Section 4 and to observe the annotations before discarding a file, to make sure that we are not filtering good ground truth approximations.

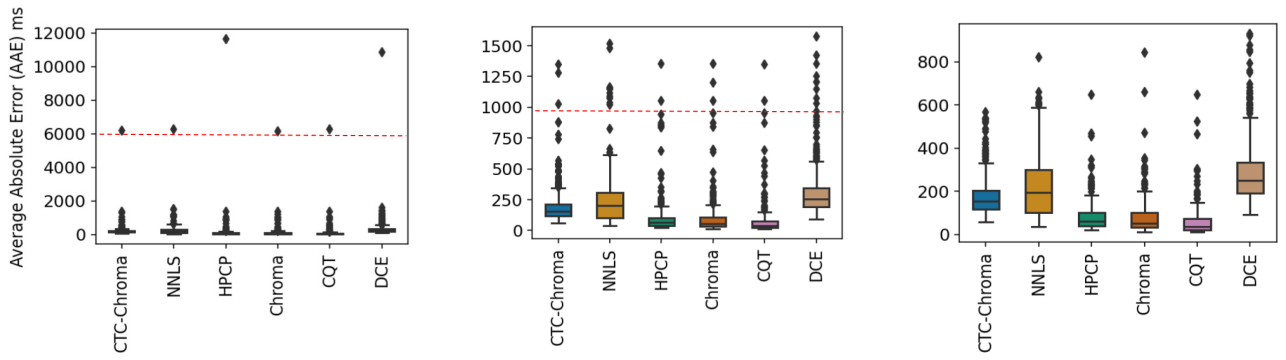
5.2 AR based investigation

Files for which the AR is very low (approx 10%) at θ_e thresholds between 50 and 100 ms signal the need for further investigation. In Section 4 we referred to two problems: 1) the possibility of a temporal offset in the ground truth annotation of the original ASAP dataset, and 2) the possibility of the generated labels being misaligned due to large temporal distances between consecutive beat annotations. If for a file we observe that the 1st quartile, median, and 3rd quartiles do not progress ascendingly as expected a (eg. if the 3 values are nearly equal) and are higher than usual, then this could indicate a temporal offset in the ground truth annotation. Through the listening verification we describe in Section 3, we found that this is the case for at least 6 score-performance pairs. As for the latter problem, if we find that if a file has a low AR, and the 1st, median, and 3rd quartiles of the AE move ascendingly (as expected), then it is a suspect of the low resolution problem. Examples of such files are the 2 performances of Prelude BMV 846, and Prelude BMV 867, where it is clear upon listening that there is a high temporal variation at a phrase level. When coupled with an insufficient resolution of the beat annotations, this would certainly cause ground truth errors. Files of the first category should always be discarded, but files of the second category could be kept, depending on the extent of the misalignment introduced through the ground truth approximation, and the tolerance allowable by the expected use.

5.3 Limitations

A legitimate criticism of our work would be that ground truths generated from the ASAP dataset do not live up to the ambition driving the paper, which is to create a large benchmark for ASA research covering a variety of musical use-cases. Although we do not fully dispute this because

[4] https://github.com/Alia-morsi/asa_benchmarks



(a) Alignment results for all MIDI score-audio pairs. Next cutoff threshold = AAE 6000 ms.

(b) Alignment results for MIDI score-audio pairs with AAE < 6000 ms. Next cutoff threshold = 1000 ms.

(c) Alignment results for MIDI score-audio pairs with AAE < 1000 ms. We do not apply further filtering

Figure 2: Box and Whisker plots showing the Average Alignment Error (AAE) results of the DTW systems using each of the chroma extraction algorithms, calculated using the approximated ground truths. Lower results are better. The red horizontal line of a figure indicates the cutoff threshold to be applied for generating the figure to its right.

all the scores of the ASAP dataset are monotonically increasing classical solo piano performances which highly adhere to their music scores in the performance, our point is that neither the ASAP dataset nor any other single accessible dataset would possess the level of diversity needed to move past the bottleneck. The goal is to start accumulating adapted datasets to eventually arrive at a bigger benchmark. For example, a similar process could be applied to the MazurkaBL dataset [42], and perhaps several others too, although the data preparation methodology and corresponding discussion are coupled with the specifics of the chosen dataset. Moreover, as we better explain in Section 6, even with the generated ground truth approximations from ASAP alone, there is room to create interesting data extensions with the approximated beat alignments. Another drawback of our work could be that the results informed data investigation described in Section 5 is not enough, and there should be a more rigorous manual verification process of the derived ground truths. We agree that manual verification of the whole datatset would be ideal, but we also defend that finding compromises for practical benefit should not be disregarded while being very clear on where these datasets fail. Moreover, perhaps a confidence measure can be created based on comparing the correlation of onsets between the left and right channels of the test audio described in Section 4. Further limitations of this work are that we do not discuss the computational complexity of most ASA methods, and rather constrain the use of the term bottleneck to conceptual hindrances facing ASA.

6. CONCLUSIONS AND FUTURE WORK

In this paper, we argue that ASA research has reached glass ceiling, and a crucial way to get past it is to unify what would be considered core to the problem definition in terms of musical scenarios. For example, what kinds of structural variations between the audio and score should be considered, what kinds of instruments should be supported, what recording quality is expected, etc. We believe this would not be possible without developing benchmarks covering such scenarios, which would support a paradigm shift in how ASA is approached, and would allow us to compare between the performance of ASA systems developed by different researchers. To take a first step towards increasing the size and variety of data, we demonstrate the reuse of the 520 scores of ASAP dataset for which beat aligned scores and performance audio pairs are available. We argue that despite its creation with other MIR research topics in mind, it still can be a very useful resource for researchers interested in ASA for classical piano music. We conduct several data validation steps informed by the AAE and AR from results from a classic DTW pipeline, allowing a selective investigation and filtering of the dataset.

6.1 Future Directions

In addition to adapting more related datasets, we would like to build on this work by artificially extending the data to improve its balance. We need to include cases where the audio performance does not adhere well to the music score, whether through skips, repeats, or performance mistakes. Starting from the generated alignment ground truths (or alignment references from other datasets) we could create semi-artificial data where we shuffle parts of the score, and concatenate the audio from the real performance to match this modified score. To avoid these modifications sounding unnatural, we could try and choose realistic parts of the piece, referring to works on music structure analysis to introduce structural repetitions with more musical sense. Datasets with structural variations would be interesting especially to improve the ability of ASA systems to recover when lost, which is relevant for real-time audio to score alignment. Nevertheless, covering a wider range of instruments still poses a challenge, but this is expected to become easier as synthesis technologies develop further. Finally, we conclude with our hope that ASA approaches would find more inspiration from recent advances in Cover Song Detection and Natural Language Processing.

7. ACKNOWLEDGEMENTS

This research was carried out under the project Musical AI - PID2019-111403GB-I00/AEI/10.13039/501100011033, funded by the Spanish Ministerio de Ciencia e Innovación and the Agencia Estatal de Investigación.

ABSTRACT

Work on musical gesture and embodied cognition suggests a rich complementarity between audio and movement information in musical performance. Pose estimation algorithms now make it possible (in contrast to traditional Motion Capture) to collect rich movement information from unconstrained performances of indefinite length. Vocal performances of Indian art music offer the opportunity to carry out multimodal analysis using this information, combining musician's body movements (i.e. pose and gesture data) with audio features. In this work we investigate raga identification from 12 s excerpts from a dataset of 3 singers and 9 ragas using the combination of audio and visual representations that are each semantically salient on their own. While gesture based classification is relatively weak by itself, we show that combining latent representations from the pre-trained unimodal networks can surpass the already high performance obtained by audio features.

1. INTRODUCTION

In this article we explore the potential for multimodal analysis of Hindustani classical vocal performance. It is well known that Hindustani vocalists use a wide range of manual gestures to accompany their singing: the relationship between their hand movements and the acoustic content of their music has been compared to that between gesture and speech [1–5]. Empirical studies have related gesture to perceived effort and apparent manipulation of imagined objects by singers [6], and have demonstrated the increase of coordinated head movement between soloists and accompanists at cadential moments [7]. The sound-gesture relationship has also been explored in the related Carnatic (South Indian) music tradition [8, 9]. These studies have been based on both empirical analysis and observation of gestures, together with the ethnographic enquiry: empirical study of movement is made possible by various combinations of motion-capture and video-based tracking of individual body parts.

Figure 1. Video stills of singers, from left to right: Apoorva Gokhale (AG), Chiranjeeb Chakraborty (CC), and Sudokshina Chatterjee (SCh).

With raga serving as the melodic framework in Indian art music, raga characteristics have been extensively explored via melodic features computed from the predominant pitch contour extracted from performance audio [10, 11]. There has not been any work that has similarly employed the visual data of performances, let alone the combination. In their survey paper [12], Duan et al. reviewed past research categorised by type of instrument and analysis task; no work was found on audiovisual analysis for singing. The nearest instrument task they reviewed was automatic transcription aided by visual analysis such as hand and finger tracking, helping play/non-play detection and note onset localization [13].

In the case of motion capture, the difficulty of data collection, particularly in natural contexts, limits the scope of research. Capture of full-body position information from video, such as is now possible using pose estimation algorithms, significantly increases the potential scope of multimodal analysis, with the possibility of collecting movement data from natural performance contexts extending over long durations. This makes it possible to explore sound-movement relationships of many kinds. Many different aspects of hand movement have been linked to musical sound and structure: for example, the tapping or beating of hands against knees may indicate the tempo and serve to instruct and coordinate performers; continuous hand movements seem to match aspects of the flow and organisation of sung phrases; some gestures seem to indicate analogies with the manipulation of physical objects such as elastic bands, or to describe dimensions of the sound (an open hand shape is understood to be linked to an open-throated voice production; hands gradually moving apart match an increase in volume). Gesture is observed

Raga	Bag	Marwa	Bahar	Kedar	Shree	Nand	MM	Jaun	Bilas	**Sum**

to be idiosyncratic, and yet there may be common features of the sound-movement relationship: Leante argued that specific gestures such as the deliberate vertical raising of a hand linked melodic aspects to visual imagery in Shree Rag [2]. Each of these possibilities suggests different empirical multimodal studies. The study presented here investigates the possibility that manual gesture is sufficiently closely related to the melodic movement of Hindustani ragas (melodic modes) that movement data may be used to help predict the identity of the raga being sung. We achieve this with suitable deep learning models applied to pose data and, further, to the audio and combined audio and visual streams.

In the next section, we present the data set. This is followed by a description of the audio, visual and combined-modality methods explored in this work. Experiments that compare the distinct approaches in terms of raga prediction performance for two different training conditions are discussed next, followed by the presentation of the results and key insights.

2. DATASET AND PROCESSING

We exploit a dataset comprising solo recordings of a common set of 9 Hindustani ragas recorded by 3 Hindustani singers [14]. For each singer and raga, we have 2 distinct takes of alap singing (duration of a take ranges from 165-221 s, with a median duration of 187 s) for 55 recordings in all (for one combination we have only one take, and for two combinations we have three takes). An alap is the improvised opening section of a concert and introduces the raga. We also have a set of 31 pakad (catch phrases) recordings (duration ranging from 18-96 s with a median duration of 19 s). Table 1 shows the raga distribution of the 86 pieces across the 3 singers combined. The ragas, as listed in Table 2, offer a cross-section of raga features in aspects such as the mood or character with which they are associated (serious, joyful, etc.), typical speed and complexity of melodic movement, and predominant melodic range (i.e. favouring the upper or lower tetrachord). The singers, as captured in Figure 1 are all professional performers, two female (Apoorva Gokhale and Sudokshina Chatterjee, here abbreviated AG and SCh) and one male (Chiranjeeb Chakraborty, CC). The pose of the singer's upper body skeleton is estimated for each frame in the corpus using the OpenPose system [15] for skeleton extraction from the video at 25 frames per second. The selected 11 key-points are from the upper body as shown as video input in Figure 2.

Raga	**Scale**
Bageshree (Bag)	S R g m P D n
Bahar	S R g m P D n N
Bilaskhani Todi (Bilas)	S r g m P d n
Jaunpuri (Jaun)	S R g m P d n
Kedar	S R G m M P D N
Marwa	S r G M D N
Miyan ki Malhar (MM)	S R g m P D n N
Nand	S R G m M P D N
Shree	S r G M P d N

Table 2. The pitch sets employed by the nine ragas. Lower case letters refer to the lower (flatter) alternative and upper case to the higher (sharper) pitch in each case.

The recordings are split into clips of 12 s each with starting times separated by a randomly chosen value in the interval [0.8, 2.4] s. The 12 s duration was set in order to encompass the typical duration of vocal phrases in this music. We then investigate the task of raga identification for each clip – first with each modality separately and then with combining the audio and video modalities using different methods to test whether this can enhance overall classification accuracy. This task is attempted under two conditions. In the first (termed 'seen singer'), each singer contributes to both the training and test data, as explained later; in the second (termed 'unseen singer'), we attempt classification of one singer's clips based purely on training using the other singers' clips. Table 3 summarises the number of examples (clips) in the training and validation sets which are distributed almost equally across the 9 ragas for each singer.

3. METHODS

Figure 2 depicts our overall system for raga classification from the audiovisual data. As discussed next, each of the multiple pathways from the input data to the final prediction represent distinct approaches that differ in which modality is exploited or in how the two are brought together.

3.1 Audio Features

Melodic aspects that distinguish ragas include the tonal material, the hierarchy of notes and their sequences leading to characteristic phrases [10]. Phrases and motifs are recognised by their melodic shape which can be represented by the computed pitch contour. Melodic phrases cannot be regarded simply as sequences of the distinct pitch classes, since raga also helps determine features such as oscillations around certain pitches and distinctive pitch transitions (i.e. slides): thus, the pitch contours contain rich information. Our dataset of alap and pakad pieces comprises solo singing with drone. We apply source separation [16] followed by pitch and voicing detection at 10 ms intervals using short-time autocorrelation analysis

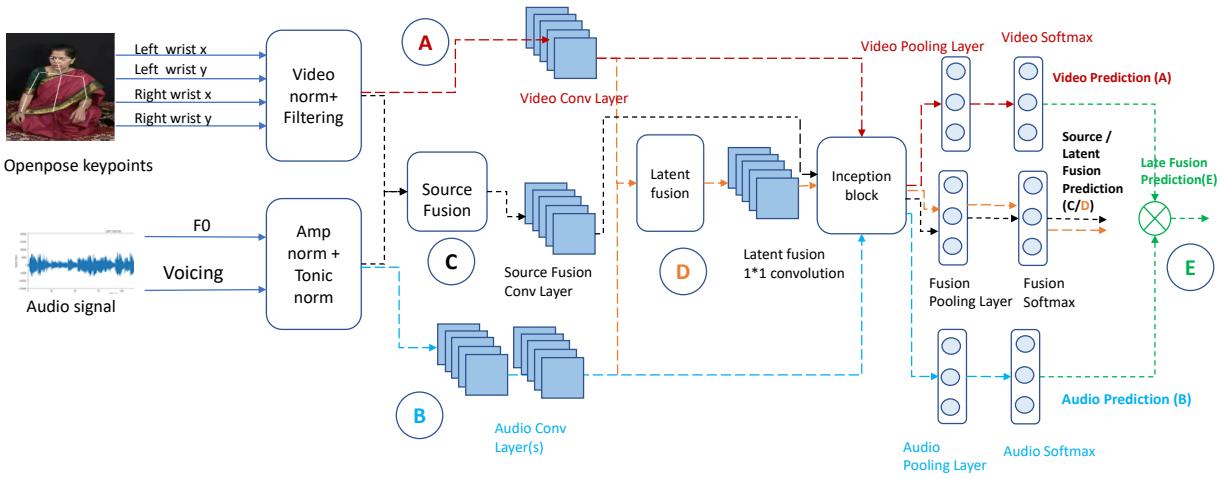

Figure 2. Proposed system for multimodal classification from pose and audio time series extracted from 12s video examples. This diagram shows 5 such configurations. A and B represent unimodal classification for video and audio streams respectively. C and D represent multimodal classification using data fusion at different layers. E represents model fusion using unimodal classification results.

[17, 18]. An important analysis parameter (that also dictates the window size) is the pitch search range, limiting which can help minimize octave errors. The tonic, automatically detected and manually verified [19, 20], was obtained for each performance and used to achieve the needed tonic-normalization of the extracted pitch contours. The detected tonic is also used to define the expected 2 octave pitch range for each piece. The voicing is a binary variable per frame that is set to zero in detected silence frames corresponding to singing pauses. Brief unvoiced regions (less than 500 ms) arising from short silences and consonant utterances are filled in via cubic spline interpolation to obtain the continuous pitch contours associated with melodic movements. The resulting time series from each clip thus comprises of 1200 samples (12s x 100/s).

3.2 Video Features

Real-time skeleton data, such as that obtained via OpenPose, can be handled by a graph model such as Graph CNN. We treat it instead as multivariate time-series data, each time series corresponding to one of the position coordinates of a tracked joint, similar to the processing of data from body-worn sensors in human activity recognition tasks. The 2D positions of the 11 keypoints of the upper body (eyes, nose, neck, shoulders, mid-hip, elbows and wrists) are recorded and used to obtain normalised (x,y) coordinates for each of the two wrists at the frame rate of 25/s. The position data for the singer's two wrists alone is retained for the analysis since (a) these points are more reliably estimated by OpenPose than others such as the elbows or shoulders, and (b) hand gestures most clearly relate to raga expression, and this data is most likely to contribute to raga classification. We thus have 4 time-series representing the x,y positions of each wrist. Any missing data are interpolated and each of the wrist position time series is low-pass filtered to remove any jitter. The length of each of the time series is 300 samples (12s x 25 fps).

3.3 Network Architectures and Hyperparameters

Given that our music audio and video time series data embed information at multiple time scales, we choose an inception network for its multiple kernel sized filters [21,22]. Inception networks have been previously used for multivariate time series classification [23, 24]. We empirically observed that preceding the inception block with two convolutional layers led to superior audio performances while a single convolutional layer worked best for the video input. The relatively high frame rate of audio also necessitated greater stride choices through the convolutional layers that helped reduce the time series dimension to 200 at the input to the inception block. The convolutional layers help in learning audio features which may be relevant for processing via the inception network which further has a range of receptive fields for the convolution. A similar approach to use prior convolution layers with inception blocks was adopted in the original work introducing the inception network for image classification [21]. We further exploit these prior convolutional layers learned for the individual unimodal (audio and video) channels in our latent representation fusion model described in the following section. The inception block is followed by pooling and softmax layers.

Figure 3 shows the architecture of the inception block. Overall, the hyperparameters tuned include the kernel size and number of filters in the convolution layers, the common kernel size, number of filters, pool size and pool type in the inception block and the pool type in the final pooling layer. Hyperparameter tuning was carried out with sweeping across the chosen ranges using Bayesian optimization [25, 26].

3.4 Multimodal Analysis

It is widely believed that integrating features from multiple modalities can lead to more robust classification due

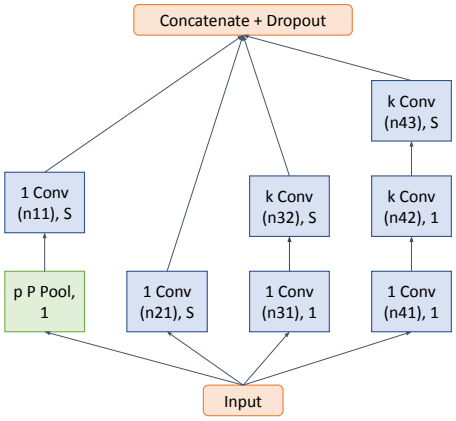

Figure 3. Structure of the inception block. 'k Conv (n), S' indicates a convolution layer with n k-sized kernels and a stride S. 'p' indicates the pooling size of the pool layer and 'P' the type of pooling. k, p, P and the number of filters were determined by hyperparameter tuning. S=1 for the video and combined models and S=2 for the audio model.

to potentially complementary information across the different modalities, all observing the same phenomenon. Multimodal classification has been an active research area in machine learning [27] where the precise approaches to combining information have been broadly categorised as early (feature-based), late (decision-based) and hybrid (their combination). While late fusion builds on combining the decisions of the individual unimodal predictors, early fusion can potentially exploit the low-level correlations between features across modalities. In our task, we have audio and video time series that actually co-vary as the singer makes continuous movements with her hands while singing. This relationship between melodic pitch variation and wrist movements makes it attractive to investigate the combination of the time series for classification.

In Figure 2, the flow-graphs labeled A and B depict the individual video and audio classification paths respectively. While the basic audio-only and video-only models differ only in the number of convolutional layers employed before the inception block, the hyperparameters assume values that are influenced by the time resolution of the corresponding time series with their different sampling rates. Early fusion is then obtained by first downsampling the pitch and voicing time series to the lower rate of 50/s and interpolating the wrist position data from its original 25/s to 50/s. The six time series form a 6-channel input to the convolutional layers thus realizing a form of source fusion. This is shown in position C in Figure 2 and a separate convolutional layer is used to learn the joint features before passing them onto the inception block.

Late fusion is achieved at the point labeled E (decision stage) in Figure 2 by combining the softmax outputs of the ensemble of the best model for each modality. We use soft voting [28] between the two classifiers by averaging the softmax outputs and then choosing the class with the maximum average as the predicted class. In addition, we learn

Data split	**Seen split**			**Unseen split**		
	AG	**CC**	**SCh**	**AG**	**CC**	**SCh**
Train	5590	5487	5588	4715	4105	4304
Validation	972	1075	974	1847	2457	2258

Table 3. Number of 12 s duration examples in each singer's train-validation data split

classifiers using the concatenated softmax outputs of the best models of each modality. This is a common approach in model stacking [29,30] and has been used in multimodal fusion earlier [27,31]. We try multiple models for stacking viz. Random Forests [32, 33] and logistic regression [34] and hyperparameter tune each of them using scikit-learn's GridSearchCV routine [35].

While decision fusion is the most straightforward approach to combining modalities, we also consider fusion at an intermediate stage given that the dynamic correspondence between the movement in the video and the aligned audio is expected to persist in the ealier convolutional layers. We achieve this by fusing the latent representations from each of the subnetworks where each has been optimised for a simpler task, viz. audio-only or video-only classification. Here we use the pre-trained weights of the convolutional layers of the best models of each modality and freeze the weights. This ensures that the features learnt for the individual modalities are maintained and the following inception block is tuned to amplify the interrelations between the two modalities. We call this novel method of fusion as latent fusion and depict it by D in Figure 2. Given that the input audio and video streams are at different effective temporal rates (lengths of 200 and 300 respectively) due to their original sampling and/or the different convolutional layer strides, we need to do a pooling on each individual modality convolutional output to bring the number of steps in the output sequence of the frozen models in sync. In addition, post the fusion we apply a convolution with filter size of 1 and learn the number of required filters via hyperparameter tuning thus letting the model learn the number of channels needed for the inception network.

4. EXPERIMENTS AND RESULTS

The training and validation sets are designed separately for the two tasks. We report experimental results for different model architectures (including one or both modalities) for each singer. In the seen singer task, we create training and validation data splits for each singer. Raga classification accuracies are reported for each method on the validation dataset of each singer and also averaged across the singers. For a given singer, the validation set comprises the set of examples from one of the singer's alap takes for each raga. The corresponding training dataset is then all the *remaining* pieces by the singer plus all the pieces of the other 2 singers. We have thus a validation and train set for each of the 3 singers. The similar exercise is carried out for the unseen singer task. Here, all the pieces by a given singer

are placed in the validation set and the pieces sung by the other two singers in the training set. Table 3 summarises the number of 12 s examples in each split as used in the experiments presented next.

For each task, we carry out model hyperparameter tuning on each individual singer's train-val dataset to obtain 3 sets of hyperparameters in all. These 3 hyperparameter-tuned models next have their weights recomputed on the training data of a given singer (say, AG) to obtain 3 trained models. Finally, the evaluation of Singer AG validation data is obtained via the ensemble of the three models. Similarly, we obtain the ensembled models for each of the singers CC and SCh and evaluate the methods on their respective validation datasets.

Our first set of experiments tests separately the performances of the audio modality and the video modality for the seen and unseen singer raga classification tasks. Table 4 presents the obtained validation accuracies. We observe that the unseen singer task is more challenging as expected. The audio based accuracies are significantly higher than those from video data on both tasks. The video based accuracies in the unseen singer task are close to chance (in the 9-way raga classification) indicating that the association between raga identity and gesture is highly singer dependent.

Our next set of experiments involve different approaches to multimodal classification. Given the non-informative nature of video cues in the unseen singer task, we restrict our attention here to the seen singer task. Table 5 presents the obtained validation accuracies across the different classification methods for each singer and the resulting mean across singers. We observe that early fusion is on the average at the performance level of the weaker modality. This is similar to the observations of Oramas [36] where the learning over very unequal modalities can be overwhelmed by either one. The results of late fusion appear in the final two rows and we find that they fall slightly short of the audio performances, all pointing to the challenge of actually realizing the benefits of the complementary information.

We look for another opportunity to combine audio and video information streams at the output of the convolutional layers. The latent representations at this stage are generated from convolutional layers that are frozen in pre-trained unimodal classification tasks. Rather than simple concatenation of the two representations, we use pooling to first align the representations along the time axis reducing both audio and video to a length of 100 from 200 and 300 respectively. We obtain a performance that is slightly, but consistently, superior to that from audio alone (D vs B in Table 5) for every one of the 3 singers, indicating that the combination of aligned latent representations successfully exploits the joint information. This is also borne out by the histogram summary provided in Figure 4.

5. DISCUSSION

As expected, prediction accuracy is significantly higher for the audio modality than the video, and higher in the 'seen singer' than the 'unseen singer' condition. Prediction accuracy is increased slightly when audio and video data are combined in comparison with audio data alone (from 82.8 to 85.1 %). It should be noted that some extracts score much more highly than others: SCh's Shree scores highly for prediction accuracy in both modalities; CC's MM is unusual in that video prediction seems more accurate than the audio; some extracts score very poorly on prediction from video only, such as AG's Kedar and SCh's Bahar. Some of the wrong predictions can probably be attributed to lack of data: for example, if the singer is silent for a significant part of the 12 second clip, or their hands do not move significantly. Other mismatches may be explained by features of either the melodic movement or the singers' gestures.

We present confusion matrices for the audio, video and the latent fusion bimodal classification in Figure 5. The video-only matrix has significant off-diagonal dispersion.

Data Split	Seen Singer		Unseen Singer	
	Audio	Video	Audio	Video
AG	92.1	36.3	76.9	14.3
CC	79.4	31.8	60.4	13.8
SCh	77.0	39.2	67.2	10.0

Table 4. Validation accuracy (%) of only audio and only video modalities on seen/unseen singer train-val splits.

Model Type	Model Name	AG	CC	SCh	Mean
A	Video	36.3	31.8	39.2	35.8
B	Audio	92.1	79.4	77.0	82.8
C	Source fusion	30.1	42.4	35.8	36.1
D	Latent fusion	**93.3**	**82.7**	**79.2**	**85.1**
E1	Equal voting	85.9	73.7	67.9	75.8
E2	Stacking classifier – RF	81.9	74.2	76.3	77.5

Table 5. Validation accuracy (%) from each singer's split for different model architectures in the seen singer task.

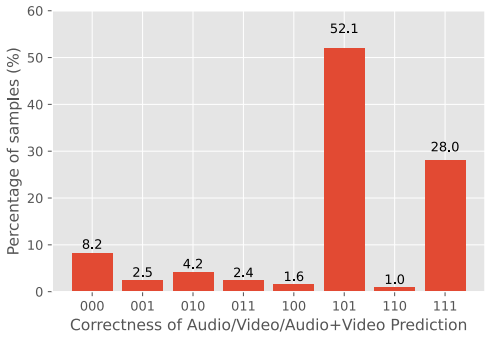

Figure 4. Histogram indicating percentage of the 3021 validation data examples predicted correctly (1) or incorrectly (0) by audio, video and the latent fusion based methods. For example, 011 indicates incorrect prediction by audio but correct predictions by video and bimodal classifiers.

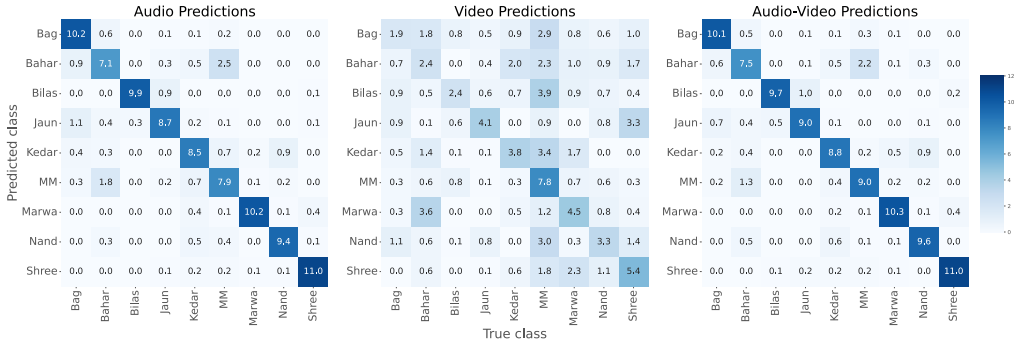

Figure 5. Confusion matrices of predictions made from audio, video and audio-video modalities. Numbers are represented in percentages of the total number of test examples across the three singers combined.

On the other hand, the multimodal matrix visibly improves upon the audio-only by further moving examples into the diagonal. The similar behaviour was noted in the individual singer confusion matrices. We also observe that the most common mis-predictions in the audio modality occur when the scale is the same or similar, and particularly where both pitch material and melodic movements are similar, as is the case between Miyan ki Malhar (MM) and Bahar. The main differences between these two closely-related ragas is that Bahar favours a higher pitch range and faster movement [37]: qualitative review of the prediction results shows that these factors are at play (e.g., in the faster portions of the extracts MM is more likely to be mis-classified as Bahar, at least for the two female singers). Other confusions are observed between Kedar and Nand (same scale), between Bageshree and Bahar (the latter uses one additional note), or between Jaunpuri and Bageshree (one note is different). Relatively few cases occur where the pitch material is very different (e.g. in SCh between MM and Nand or Kedar), which are harder to interpret. Some prediction errors seem to be related to the use of a low pitch (below Pa, the fifth degree, in the lower octave), as for example CC's Shree between 38-53s: this can be explained by the fact that the pitch extraction was constrained to a range of two octaves, with the low Pa as its limit. We find in this case clear instances of video and multimodal predictions doing well.

Confusion matrices for the video prediction are harder to read, given the lower accuracy overall, but some patterns can be observed. The Bahar/MM confusion is also present in the video domain (for the female singers), perhaps related to the fact that these two ragas share not only a scale but also many aspects of their melodic movement. Bahar can sometimes be confused with Nand and Marwa. The Bahar/Nand confusion is not surprising, since both are associated with lively, complex melodic movement and a joyful mood. The confusion between these two ragas and Marwa is less expected, since Marwa's mood contrasts strongly (being serious and often described as unsettled or restless). It may be that there is a similarity in the singers' hand movements between Bahar and Nand's liveliness and Marwa's restlessness. MM, Kedar and Bilaskhani seem to get confused when the singers make rounded, bimanual gestures, as when the hands seem to be moving round each other. These gestures are associated with specific melodic movements, an andolan (slow oscillation) on the Ga (3) in MM and distinctive crooked (vakra) pitch movements in the other two ragas. For SCh, several ragas are wrongly predicted as Shree when she makes a direct upward hand movement, which is often distinctive of this raga [2]. Such qualitative observations suggest that the video prediction system may be classifying the hand movements in meaningful ways even when the predictions are wrong, pointing to similarities between the ways each singer gestures in different ragas.

When we look at the proportion of clips correctly identified in at least one of the two modalities in Figure 4, the most common result is to be correctly classified from the audio but incorrectly classified from the video. The small percentage of clips for which the opposite is true (c. 6.6 %) suggests there is some scope for the video information to improve the prediction accuracy achieved through audio alone, although this seems like a difficult challenge as the audio prediction accuracy is already high. Even so, we note that the 6.6 % where the audio is incorrect but video correct, the multimodal condition actually recovers about a third of this. Further, we have 2.5 % of the total set of clips (75/3021) correctly predicted only in the multimodal condition (i.e. audio and video data are combined using latent fusion). This amounts to a quarter of all clips that were wrongly classified in both audio-only and video-only conditions. It is interesting to note that of the 75 clips correctly predicted only in the multimodal condition, the most common ragas represented were Bahar (19) and MM (14), which as noted above share the same scale and many melodic movements. This study suggests that the combination of coordinated audio and gesture features can improve the classification of ragas from short clips. This approach could be extended to other musicological investigations such as the musical expression of mood or character, melodic phrase segmentation, and interpersonal coordination.

ABSTRACT

Music streaming platforms allow users to enjoy music from all over the globe. Such opportunity speeds up cultural exchange between different countries, a process often associated with globalization. While such an exchange could lead to more diverse music consumption, empirical evidence on its influence on online music consumption is limited. Besides, the extent to which music recommender systems foster exchange or amplify globalization in music remains an understudied problem.

In this paper, we present findings from an empirical study to detect traces of globalization in domestic vs. foreign online music consumption. Besides, we investigate if popular recommendation algorithms, specifically ItemKNN and NeuMF, are prone to amplifying globalization processes. Our experiments on Last.fm listening data show nuanced patterns of globalization in music consumption. We observe a strong position of US music in all considered countries. In countries such as Sweden, Great Britain, or Brazil, US music shows various levels of coexistence with domestic music. We find that Finland is least influenced by US music, while greatly consuming and "exporting" domestic music. With respect to recommendation algorithms, ItemKNN tends to recommend domestic music to users of many countries, while NeuMF contributes to accelerating globalization and shifting balance towards dominance of US music on the market.

1. INTRODUCTION AND RELATED WORK

Globalization can be defined as an *"expanding cultural exchange between countries, which may imply an increasing consumption of foreign cultural goods beside the local ones"* [1]. Among others, previous research proposes two interpretations of globalization: (i) *Cultural Imperialism* [2], i. e., the growing cultural exchange triggered by globalization is mostly profitable for certain dominant western cultures (in particular American culture) and thereby threatens to overwhelm the others; and (ii) *Glocalization* [1, 3], i. e., fostering the development of local cultures through the globalization process, by means of adaptation of global cultural forms and strengthening local identity as a counterbalancing mechanism against global influences. These interpretations imply that globalization exposes local cultures to pressure from global trends, and while some of them adapt and confront the threat, others weaken and decline.

The realizations of these interpretations in various domains have been confirmed by several studies. For instance, Crane [2] shows the dominance of US film industry in most regions of the world, while Chen and Shen [4] display the ability of some cultures to adapt and develop under the pressure of more dominant ones. Approaching globalization, most of the previous works resort to the analysis of various aggregated popular charts representing mainstream consumption trends [1, 5–7]. Specifically, Achterberg [1] show that US music has become increasingly popular in the Netherlands, Germany, and France until the late 1980s', while starting in the 90s', more local music has been produced. The revival of domestic music consumption is also evidenced by Bekhuis et al. [6], who show that popularity of domestic artists is positively correlated with a high sentiment of national pride. Similarly, Verboord and Brandellero [7] conduct a multilevel analysis of popcharts' evolution, showing that the consumption of foreign music has increased in many countries except in the US.

The mentioned studies conduct the analysis on aggregated pop-music charts, neglecting the nuances of music consumption by the consumers with less mainstream tastes. Including less-mainstream listeners in country-specific analyses is particularly important, as listeners in different countries display diverse tendencies towards listening to mainstream music [8], which also gets translated into significant differences in the *performance* of recommendation algorithms [9, 10]. However, to the best of our knowledge, little research has been dedicated to investigate the *influence* of streaming platforms on globalization processes [5]. Furthermore, the extent to which existing globalization processes might be amplified by music rec-

Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

ommender systems has, to the best of our knowledge, not yet been investigated.

To bridge these gaps, we leverage online music listening data, allowing us to analyze globalization patterns based on actual per-user consumption of music from a wider range of countries. In addition, we study potential impacts music recommender systems may have on globalization. To this end, we strive to answer the following three research questions:

- **RQ1**: How prominent is the aspect of US "cultural imperialism" in the sphere of online music consumption? Is its influence uniform across countries?
- **RQ2**: How significant is domestic music consumption in different countries? Are there any signs of "glocalization"?
- **RQ3**: Do music recommender systems influence users' inclination towards music coming from certain countries?

We highlight the importance of RQ3, considering recent research showing that recommender systems can amplify biases from underlying data in their output, as well as inflict additional algorithmic biases. An overview of biases recommender systems are prone to is given in [11,12]. Among them is popularity bias, i. e., the tendency to favor popular items at the expense of niche and less popular items, often leading to dissatisfaction of users [13,14]. We pose RQ3 to investigate possible occurrence of analogous "globalization bias" in recommender systems.

The remainder of the paper is structured as follows. Section 2 describes our methodological approach to the research questions, including data and methods used. We report and analyze our results in Section 3. Section 4 is dedicated to limitations of our study. Finally, we sum up our findings and list potential future directions in Section 5.

2. METHODS AND MATERIALS

In the following, we detail the methodology we adopt to answer the research questions and describe the dataset our analysis is based upon. We first clarify and formally define the terminology we use in the methodological description: A *listening event* (or *interaction*) is a tuple $< u, i >$, indicating that a user u consumed an item i, which is a music track or a song in our case. Each track i has been created or performed by an artist a.[1] Each artist a originates from a country c_a. Each user u is from a country c_u. $\mathcal{I}_{c_u}$ denotes the set of all user–item interactions made by users in country c_u. $\mathcal{I}_{c_a}$ refers to the set of all interactions with items created by artists from country c_a. $\mathcal{I}_{c_a,c_u}$ denotes the set of all interactions with items created by artists from country c_a, listened to by users from country c_u.

2.1 Investigating US Cultural Imperialism

To answer RQ1, we compute, for all users in a given fixed country c_u, their aggregate share of consumed music that has been created by artists from each country under consideration. Since we are interested in this share for local and US music (artists), we define the following function

$$IC_{c_u \to c_a} = \frac{|\mathcal{I}_{c_a,c_u}|}{|\mathcal{I}_{c_u}|}$$

for which we consider three cases:

- *Local:* $c_a = c_u$,
- *US:* $c_a = US$, and
- *Other:* $\sum_{c_a \in C \setminus \{c_u, US\}} IC_{c_u \to c_a}$, where C is the set of all countries considered (sum over all artist countries that are not the local country nor the US).

In simple words, this formal framework can answer how much of the music all users in country c_u consume was created by artists from the same country (local consumption), was created by artists from the US, and was created by artists from other countries (neither local nor the US); all expressed in relative numbers.

2.2 Investigating Traces of Glocalization

To answer RQ2, we consider all listening events of songs by artists from the country under investigation, i. e., we fix c_a. We then define $IC_{c_u \leftarrow c_a}$, analogously to $IC_{c_u \to c_a}$ above, i. e., for a given country c_a, the share of its artists' listening events that originate from users in each country c_u under investigation.

$$IC_{c_u \leftarrow c_a} = \frac{|\mathcal{I}_{c_a,c_u}|}{|\mathcal{I}_{c_a}|}$$

Here we are mostly interested in this share between local and foreign music consumers, and accordingly consider two cases:

- *Local:* $c_u = c_a$, and
- *Other:* $\sum_{c_u \in C \setminus \{c_a\}} IC_{c_u \leftarrow c_a}$, where C is the set of all countries considered (sum over all user countries that are not the local country).

In simple words, this formal framework can answer how much of the music created by artists from c_a is consumed by users in the same country (local consumption of local artists), and how much by users in other countries; all expressed in relative numbers.

2.3 Influence of Recommendation Algorithms on Globalization Patterns

To approach RQ3, we consider two popular recommendation algorithms, a classical ItemKNN [15] and a more recent, deep-learning-based NeuMF [16]. ItemKNN assigns a recommendation score to an item for a given user based on how similar this item is to the items already consumed by the user. Similarity is computed based on the interactions of other users. This algorithm does not learn any special representations for users and items, operating directly on the interaction matrix. On the other hand, NeuMF is a matrix factorization approach. Not only does it learn user and item embeddings, but also a dedicated scoring

[1] Being aware that "artist" in the context of music can refer to different subjects, we adopt a pragmatic definition here. Owed to the type of user-generated data we investigate in our study, we consider both composers and performers as artists.

function, thanks to the multi-layer perceptron constituting a part of the model.

To estimate potential influence of the recommender algorithms on globalization patterns in different countries, we train them on subsamples of the dataset used to answer RQ1 and RQ2, and then analyze the recommendations they produce. To this end, we consider top 10 recommendations provided to each user and then calculate $IC_{c_u \to c_a}$ for $c_u = c_a$ and $c_a = US$ exactly like for RQ1.

Because the dataset under investigation contains a large number of items (see Table 1), we use its subsamples (containing around 100K items each) to run recommendation experiments, thereby avoiding computational limitations. For the subsamples, we enforce the following standard limitations: every track has to be interacted with at least 5 times and every user is required to have at least 5 interactions. To ensure robustness of the results, we conduct the experiment on three such random subsamples and report average recommendation levels.

2.4 Dataset

We conduct our experiments on the LFM-2b dataset [17] of listening events created by users of the online music platform Last.fm. [2] Unlike stand-alone streaming services such as Spotify or Deezer, Last.fm is based on the concept of "scrobbling", meaning that its users can share on the platform which music they are listening to, regardless of the actual service, device, or application they are using for music consumption. Therefore, Last.fm can be regarded as an aggregator that reflects the entire music consumption history of its users. This is desirable for our analysis since we aim at capturing in a more comprehensive way each listener's (and country's) music consumption behavior instead of focusing on one particular streaming platform.

The full LFM-2b dataset contains listening histories of ∼120K users, totaling to ∼2B interactions. Since the dataset's temporal coverages spans 15 years, from 2005 to 2020, and we intentionally leave out aspects of temporal dynamics from our analysis (see future work), we only consider a subset covering the years 2018-2019. Furthermore, we exclude potentially accidental interactions by removing listening events $< u, i >$ that only occurred once. [3]

Since our analysis necessitates country information of both users and artists, we first remove all users for which no such information is available in LFM-2b. We then collect information about artists' country from Musicbrainz [4] and only retain those artists for whom country data could be retrieved. After these steps we end up with a dataset of ∼14,640K interactions triggered by ∼13K users from 143 countries with ∼637K music tracks produced by ∼45K artists from 155 countries.

Finally, to reduce the complexity of the analysis and concentrate on reasonably represented countries, we select for the detailed analyses countries with at least 100 users and only countries whose artists created at least a total of 1,000 tracks. These filtering steps result in 20 countries [5] from all over the world (see Table 1 for basic statistics), which we further analyze. Note that the countries beyond these 20 still contribute to the results mentioned as a part of the aggregation over "other" countries.

3. RESULTS

We illustrate our findings with a series of figures. Figure 1 shows how popular is domestic music, music produced by US artists, and music produced by artists from other countries in every of the 20 investigated countries. In case of DE, a little under 40% of listening events generated by German users are allocated to music produced by US artists (orange bar on the left). Under 20% of listening events generated by them is allocated to domestic music, i. e., produced by German artists (blue bar on the right). Figure 2 indicates the degree to which domestic music of different countries is consumed in the country of origin and outside. For example, BR has most of the listening events allocated to its domestic music coming from Brazilians, showing that it is not as popular in other countries. Figure 4 shows the spread of listening interactions with music from every country across other countries. In other words, this matrix shows how uniform the "export" of domestic music from every country to other countries is. Every row

[2] `https://last.fm`

[3] Since the dataset provides no information about the duration of a listening event, those single user–item interactions are often the result of a recommender engine starting to play a new track to the user, which the user skips after a few seconds. Therefore, we exclude those single interactions to remove this kind of noise.

[4] `https://musicbrainz.org`

[5] Throughout the paper, we use ISO codes to abbreviate countries. US: United States, GB: United Kingdom, DE: Germany, SE: Sweden, CA: Canada, FR: France, AU: Australia, FI: Finland, BR: Brazil, RU: Russia, JP: Japan, NO: Norway, PL: Poland, NL: Netherlands, IT: Italy, ES: Spain, BE: Belgium, MX: Mexico, UA: Ukraine, TR: Turkey

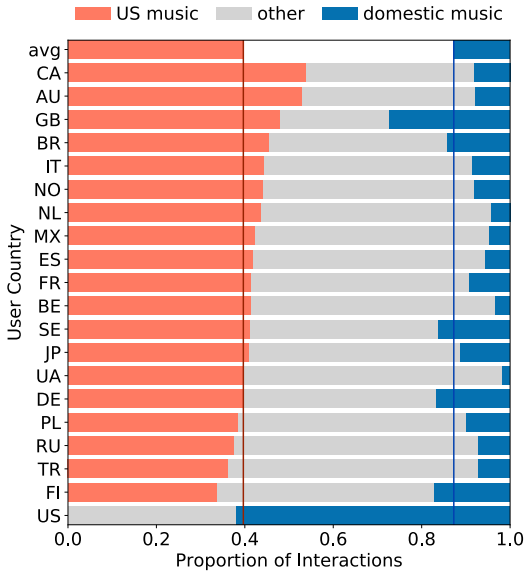

Figure 1: Distribution of listening activity over foreign (US and other) and domestic music. Every row corresponds to listeners of one country. Average proportions of interactions with music produced in the US (orange) and domestically (blue) are shown in the first row.

corresponds to the share, among all listening interactions, of the music produced in a single country. Every cell in the row shows the percentage of listening events coming from listeners of the corresponding country on the x-axis. For example, we can observe that 14.6% of listening interactions with JP music comes from US users (row JP, column US). Figure 3 demonstrates the potential impact two recommendation algorithms, ItemKNN and NeuMF, may have on the consumption balance in different countries. In each of the two subplots, empty bars reflect proportions of music actually consumed by the users (similar to Figure 1): orange bars on the left indicate listening events allocated to US artists, blue bars on the right refer to domestic artists. The filled bars illustrate the same concept applied to items recommended to users of different countries. For example, in Figure 3b, the row corresponding to DE shows that about 50% of items recommended to German users come from US artists, while at the same time only about 40% of their actual listening activity belongs to tracks from US.

We make the following observations answering **RQ1**. First, from the listening activity on Last.fm in 2018-2019, we see that 39.6% of all items interacted with were produced by US artists. Second, as Figure 1 shows, over 60% of listening events generated by US users are allocated to domestic music (bottom row, blue bar). This marks domestic superiority of US music, unmatched by any other country. The runner-up, being GB, shows only about 30% of listening events allocated to the domestic market. Third, on average, listeners of considered countries allocate 40% of their consumption to music produced by US artists (top row and vertical red line), with a maximum of about 50% shown by Australia and Canada. For many countries, above-average consumption of US music is combined with below-average consumption of domestic music, e. g., AU,

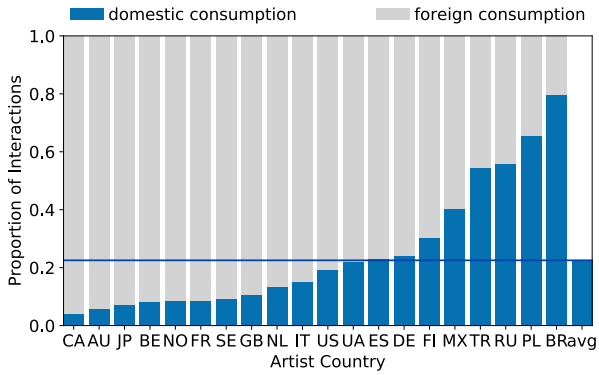

Figure 2: Consumption distribution of music produced in different countries, between local (blue) and international (gray) audiences.

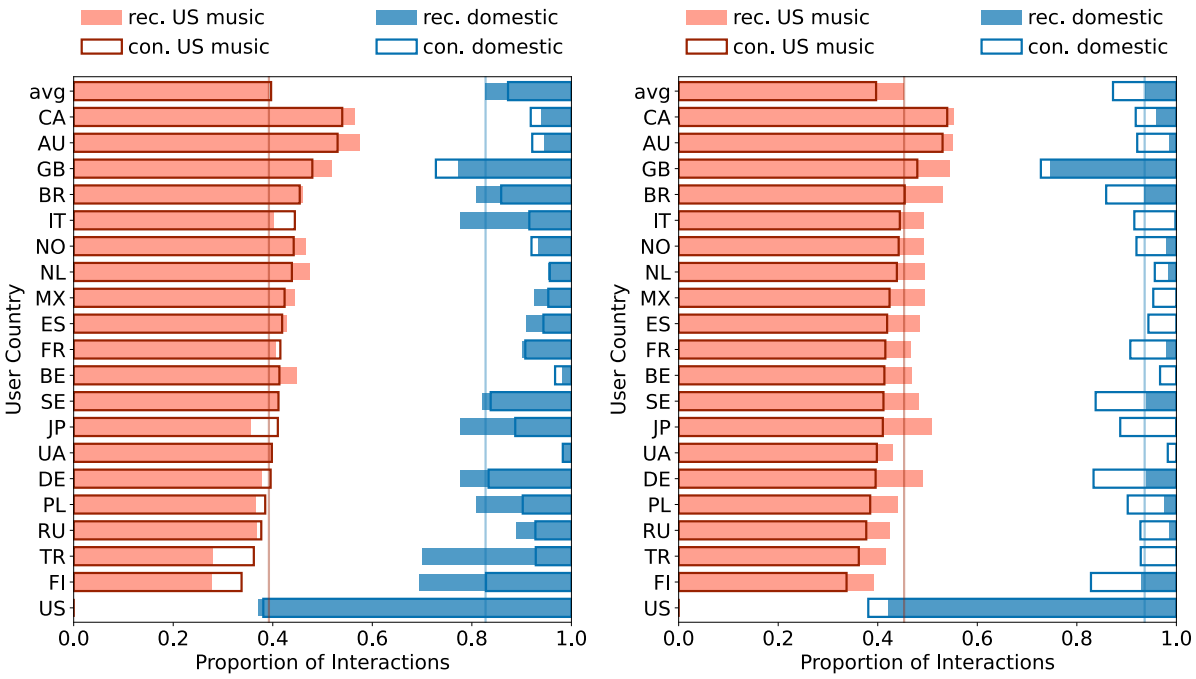
CA, NL, IT, and UA. Forth, some countries such as GB, BR, and SE show above-average consumption of US music combined with also above-average consumption of domestic music. This is an indication of local musical culture comfortably coexisting and possibly interacting with the incoming US culture. Fifth, other countries such as TR, PL, FI, and RU consume below average of US music, remaining more open for music coming from other countries. In addition, FI also displays significant attention to domestic music.

From these observations, we conclude that music produced by US artists maintains strong positions in the considered countries. In particular, it dominates its own domestic market unlike domestic music of other countries. While there are countries combining low consumption of domestic with high consumption of US music, it is hard to call US music globally dominating. Many regions are also comparably influenced by other countries (if combined) and some, like FI or GB, show very strong positions of domestic artists. Thus, we hesitate to call US "cultural imperialism" absolute and homogeneous across countries.

We approach **RQ2** by defining three indicators related to domestic music in every country: *international consumption*, i. e., how big is the proportion of interactions with its domestic music coming from other countries (in other words, how widely exported domestic music is, see Figure 2 and 4); *domestic popularity*, i. e., the proportion of interactions from listeners of the country with domestic music (how popular domestic music is in its home region, see Figure 1); *popularity of US music* (used to detect hints of cultural dialog between US and considered country, see Figure 1). We analyze these indicators in terms of below/above average across considered countries for every particular country.

Using the indicators described above, we identify four patterns in behavior of domestic music scenes. First, glocalization through adaptation. Countries such as SE and GB score above average on all three indicators: their music is appreciated abroad while also being popular locally, and in addition these countries consume above average US music. We interpret this pattern as comfortable coexistence of global and domestic cultures with the latter likely adapt-



(a) Impact of ItemKNN

(b) Impact of NeuMF

Figure 3: Potential impact of recommender algorithms on music consumption balance in different countries. Empty boxes reflect actual consumption (denoted con.) extracted from the data. Filled boxes represent the output the two recommender algorithms produce (denoted rec.). Orange-tinted boxes on the left correspond to consumed / recommended music from US. Blue-tinted on the right - consumed / recommended domestic music.

ing and contributing to the former. Second, heavier adaptation of global trends. Domestic music is popular in BR as well as US music (both indicators above average). Domestic BR music receives most of its interactions from BR and little international attention. This pattern may imply even heavier adaptation of global influences to domestic circumstances. Third, non-US influenced. Countries such as PL, TR, and RU score below average on all three indicators: their music is predominantly consumed on domestic market while being less popular than US-produced music (which in turns enjoys below average popularity in these countries). We interpret this combination in a way that in these countries domestic music competes with a wide array of incoming music and US music is not necessarily the strongest influence there. Fourth, as the sole representative of this pattern, FI demonstrates high popularity of domestic music, combined with decent international consumption and lower popularity of US music. This pattern may express successful adaptation of less mainstream (beyond US) influences as well as strong distinct national culture.

We answer **RQ3** by analyzing results of the recommendation experiment detailed in Section 2.3. As shown in Figure 3b, NeuMF consistently recommends more US-produced items to listeners of every non-US country than these non-US listeners used to consume. This happens at the expense of the share of recommended domestic items. The character of the change implies that the share of recommended items from other countries is also larger than their actual consumption share (for all countries). We conclude that NeuMF amplifies globalization patterns and in particular dominance of an already dominant player, i. e., the US. On the contrary, ItemKNN (see Figure 3a) shows a different and less consistent behavior. Listeners in JP, TR, IT, and FI are recommended a considerably bigger share of domestic tracks than the share of listening events they actually allocate to domestic music. Interestingly, the shares of US music recommended to users in these four countries is lower than the share of US music consumed by them. The average share of recommended US tracks (see top row and red vertical line) is very close to the share of attention US music actually receives. On average, ItemKNN shows less changes than NeuMF. These observations are in line with the results of [14] where ItemKNN shows most calibrated recommendation results in terms of track popularity, especially when compared to methods with a higher number of trainable parameters, such as ALS and Variational Autoencoders. Our experiment shows that music recommendation algorithms can considerably contribute to the process of globalization, and the exact contribution largely depends on the algorithm. Therefore, recommender system designers need to be aware of such potential impacts.

4. LIMITATIONS

While our analysis captures listeners' behavior beyond pop charts, it bears a number of limitations. First, the data we base our analysis upon reflects a particular audience: Last.fm users (likely active internet and social media users), and therefore might not be representative of the population at large. Some countries and social groups are underrepresented on Last.fm (e. g., female users). In some

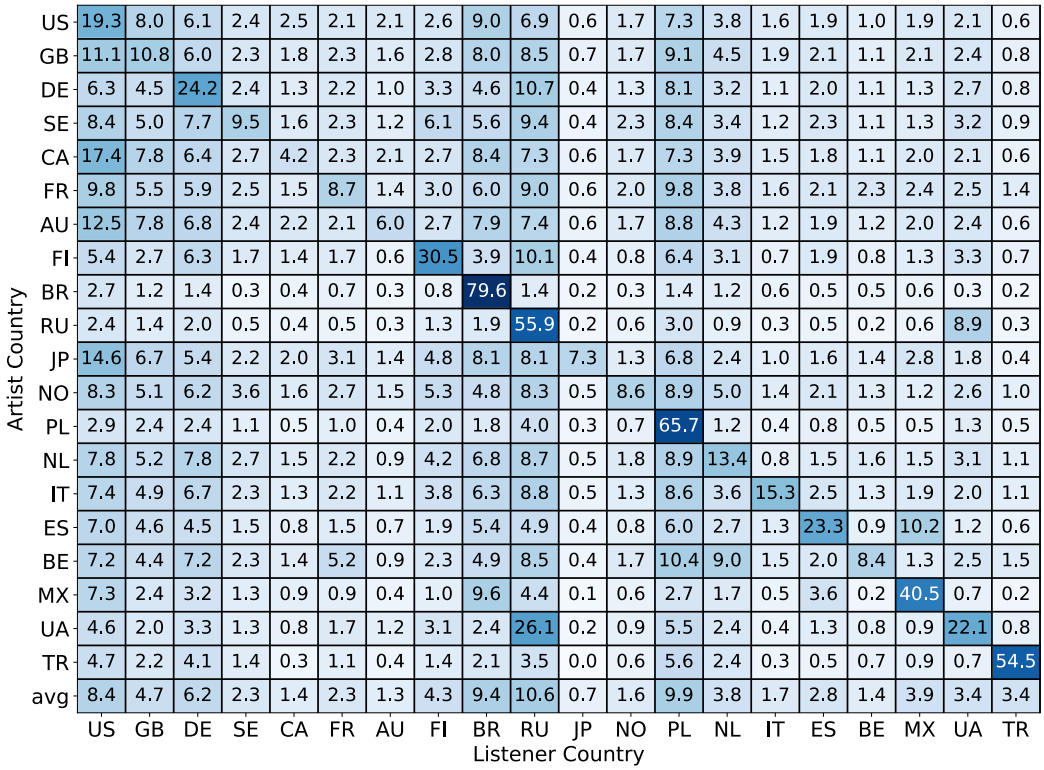


Figure 4: Music export matrix. Every cell shows the proportion of interactions with music from a given artist country allocated to users from a given listener country. For instance, 19.3% of all the music created by US artists is consumed by US listeners, while 14.6% of interactions with the entirety of Japanese music are made by US users.

countries Last.fm is not very popular and their listeners are likely to use different channels of music consumption. Therefore, our dataset may overrepresent listeners who are open to and interested in global culture, in particular in countries where Last.fm is not popular. Furthermore, the data gathered in the LFM-2b dataset are already affected by recommender systems of different platforms users connect to their Last.fm accounts, which means that our insights about "actual music preference" can be, to a certain degree, distorted.

5. CONCLUSION AND FUTURE WORK

We addressed three research questions related to patterns of music consumption on online music platforms. Regarding the dominance of US vs. domestic music (RQ1), we found that the former maintains strong positions in all considered countries. However, the US does not display signs of absolute and homogeneous "cultural imperialism". While it dominates its domestic market, in other countries, US music shows various levels of coexistence with domestic music. While some countries such as Australia and Canada find their domestic music competing with US music, others, such as Great Britain, Brazil, and Sweden, display high consumption levels of both US and domestic music. Countries like Finland and Germany, on the other hand, are open to music both from other countries and domestically created.

Looking for traces of glocalization (RQ2), we distinguish several ways domestic music can behave under the pressure of global cultural trends. Music from countries like Great Britain and Sweden shows signs of adaptation of global cultural trends, with their music coexisting with US music and being greatly listened to outside their domestic markets. Music from Brazil appears to be highly influenced by global trends but mostly consumed locally. Countries like Poland and Turkey also display signs of their music being localized and influenced by global trends, however, to a lesser extent influenced by US music than others. Finland combines competitive "export" of their music with high local consumption and relatively low consumption of US music, showing signs of a strong and distinctive musical culture.

Finally, we show that recommender systems may have a considerable impact on globalization patterns (RQ3). We investigate this for a traditional ItemKNN approach and the deep-learning-based NeuMF algorithm. While the former fosters consumption of local music in most of the considered countries, the latter supports internationalization and, in particular, cultural imperialism of the US.

Directions for future research include temporal analysis of consumption trends over the 15-year-span covered by the LFM-2b dataset, in particular considering possible alterations caused by the global pandemic [18, 19]. Other directions include exploring the link between globalization amplification and popularity bias, and investigating the effectiveness of different mitigation strategies.

ABSTRACT

Anglo-American popular culture has been said to be intricately connected to global popular culture, both shaping and being shaped by popular trends worldwide, yet few research has examined this issue empirically. Our research quantitatively maps the extent of these cultural influences in popular music consumption, by using network analyses to explore cross-cultural popularity in music from 30 countries corresponding to 6 cultural regions (N = 4863 unique songs over six timepoints from 2019-2021). Using Top100 charts from these countries, we constructed a network based on the co-occurrence of songs in charts, and used eigencentrality as an indicator of cross-cultural song popularity. We then compared the country-of-origin of the artists, arousal music features, and socioeconomic indicators. Songs from artists with Anglo-American backgrounds tended to have higher eigencentrality overall, and mixed effects regressions showed that eigencentrality was negatively associated with danceability, and positively associated with spectral energy, and the migrant population of the country (of the charts). Next, using community detection, we observed 11 separate 'communities' in the network. Most communities appeared to be limited by region/culture, but Anglo-American music seemed disproportionally able to transcend cultural boundaries far beyond their geographical borders. We also discuss implications pertaining to cultural hegemony, and the effectiveness of our method in estimating cross-cultural popularity.

1. INTRODUCTION

How do songs become international hits? To some extent, research suggests that one answer is simply being based in America, and singing in English [1]. Numerous studies have documented the prevalence of Anglo-American artists on the charts of 'foreign' countries throughout the 1960s to the 2000s [2, 3]. Yet, at the same time, the 1980s saw a nationalistic increase in the consumption of domestic, and localized artists alongside widely dominant Anglo-American music [1, 4]. However, these papers rely on country-determined charts as indicators of music-popularity, which raises problems of irregularity. For example, the metrics/methods used to determine rankings on national top charts may differ between countries. Moreover, charts may also be defined through radio plays (e.g., Billboard), which biases the consumption pattern towards the distributor of the music, rather than bottom-up listening preferences. The advent of music streaming services in recent years provides a possible solution to both these issues: within a platform, charts are calculated through consistent metrics. Secondly, users choose the songs they want to listen to. While music recommendation systems do provide suggestions on songs for the user, these are still largely based on the users' preferences and listening history [5], and users still retain agency in choosing whether or not to listen to a recommended song. This is a shift away from the music-purchase model [6], allowing for greater flexibility and choice. Accordingly, streaming charts offer increased granularity, whereas music-purchase models only monitor sales. In this regard, country charts from music streaming services may be more representative of bottom-up music consumption.

In assessing the global top charts provided by streaming services, we are unable to decompose the cultural contribution of individual countries in determining overall global popularity, as such information is typically not made public. We thus needed a method to combine music from various country-charts to composite a marker of global popularity. To this end, we constructed a network from Top 100 charts from 30 countries (over 6 cultural regions), and relied on the co-occurence of songs within and across charts to determine its cross-cultural popularity through centrality. Constructing a network would also allow us to quantify the cultural diversity and clusters present across these 30 charts through community detection algorithms. More information on how networks are used in this paper is available in Section 2 (Methods).

Accordingly, our research aims to use network analyses to model the cultural 'Communities' present across these charts, and in doing so, assess the dynamics of cultural influences in music consumption around the world. We identified 11 Communities, most bounded by shared cultures,

with the exception of the largely Anglo-American Community, which was prevalent across charts from all cultural regions.

1.1 Network analyses

Network analyses model the complex relational structures present in a data, and have been used in a diverse range of applications, from web search engines [7], to modeling language evolution [8], and are used widely in the social sciences [9, 10]. They examine relationships between nodes in a network: nodes refer to any entity that is treated as fundamental in the analysis. For example, in a study on social networks, individuals are often treated as nodes. The relationships between nodes are represented by edges. edges may be weighted, to reflect the strength of a connection between two nodes. For example, two individuals (nodes) that frequently interact with each other, may have a higher weight for that relationship (edge), than between two strangers. Accordingly, some nodes may be more strongly connected with other nodes in a network. These nodes exert a greater influence on the network, and are more 'central': centrality refers to the relative importance of a node to all other nodes within the network [11].

In this paper, we rely strongly on the notion of eigencentrality, which additionally accounts for the corresponding centrality of linked nodes in determining the centrality of a given node [12]. For our analysis, we define nodes to be unique songs, and the edge weights as the frequency by which they co-occur on any country's Top 100 charts. Songs with high eigancentrality scores are more influential within the network, which means that they carry a greater presence across the various country-based Top 100 charts used in this analysis, which could be in turn indicative of greater cross-cultural popularity.

1.2 Contextualizing factors

For interpretation, we also compared the eigencentrality of songs on countries' charts with socioeconomic indicators, as well as song-level information on the country-of-origin or residence of its artist, and features of rhythmic and intensity arousal.

1.2.1 Artists' Country-of-residence and origin

While constructing a network of music charts would allow us to visualize and compare the influence of individual songs, we still needed to compare this information to the cultural background of these songs. As such, we obtained the country-of-residence (where possible) or country-of-origin of all artists that were represented on the charts. We then grouped these countries according to their cultural region to facilitate cultural comparison.

1.2.2 Gross Domestic Product (GDP), income inequality, and migration

Going beyond the network, we wanted to examine if economic development, social inequality, and migration could offer explanations for cross-cultural popularity. Past research has identified links between music preferences, and socialeconomic status (SES; [13]), such as social class [14]. At a country-level, Woolhouse and Bansal [15] found a direct relationship between economic development and music consumption patterns. Accordingly, we examined economic development through GDP per capita, and income inequality (Gini coefficient). Finally, we also examined migration statistics, as music has strong functions for identity formation in immigrants (see [16, 17]), who may bring with them differing music consumption patterns into the country they relocate to. Moreover, societies with high openness may be more accepting of immigrants and more open towards foreign cultures [18], and consequently, may be more receptive towards music from beyond their cultural region.

1.2.3 Arousal features in music

Rhythmic (danceability) and intensity (energy) arousal features of songs in national charts has been shown to reflect that country's affordances for high-arousal negative emotional experiences in daily life [19]. Energy, in particular, has been shown to reflect the use of cathartic emotional downregulation of anger experiences [20]. Given that past research has found links between music popularity and arousal features (e.g., [21, 22], we also examined eigencentrality in the context of musical arousal.

1.3 Related work: Network analyses in music research

Networks have long been used to analyze and visualize relationship structures in music. In predicting artist popularity, Matsumoto et al. [23] constructed a context-aware network combining Spotify-based audio features with biographic metadata and 'related artist' lists. South et al. [24] examined a dataset of musical collaborations on Spotify, and used eigencentrality to estimate the influence of artists on that dataset. Zinoviev [25] similarly examined the mobility of individual musicians amongst music groups in the Russian music industry. Finally, Ortega [21] examined music covers to estimate the influence of the original artist. While these projects largely used network analyses to estimate the popularity or influence of an artist or song, our research is unique in using chart co-ocurrence to derive cross-cultural popularity, through accounting for the relative popularity of songs from different regions around the world.

2. METHODS

2.1 Data Acquisition

Our analysis utilized consumption charts of Top 100 songs (by monthly play count on Deezer) from 30 countries (see Table 1: Chart Country) for March 2019, September 2019, March 2020, September 2020, March 2021, and September 2021, for a total $N_{songs} = 16998$ (unique $N_{songs} = 4863$ from $N_{artists} = 1001$).

For each song, we obtained the titles, artists, and ISRC codes from the Deezer Application Program Interface

Cultural Region	Chart Country	Country-of-Origin
African-Islamic	*UAE, Saudi Arabia, Turkey, South Africa	*Bahrain, *Morocco, Lebanon, *UAE, Saudi Arabia, Egypt, *Syria, South Africa, Iraq, Nigeria, Turkey, Algeria, Uzbekistan, Iran, Azerbaijan, *Kazakhstan, *Kuwait, Tunisia, Jordan, Palenstine, *Comoros, *Yemen, *Congo
Catholic-Europe	Croatia, Hungary, Poland, Austria, Belgium, Spain, France, Italy	France, Italy, Belgium, Spain, Austria, Croatia, Slovenia, Hungary, Poland, *Greece, Portugal
Confucian (Asia)	Not Applicable	South Korea, Japan
English-Speaking (Anglo-American)	Australia, Canada, *Ireland, United Kingdom, United States	United Kingdom, United States, Canada, Australia, *New Zealand, *Ireland
Latin America	Argentina, Brazil, Chile, Colombia, Guatemala, Mexico	Colombia, Philippines, *Puerto Rico, Argentina, Uruguay, Chile, *Panama, Venezuela, *Dominican Republic, Peru, *Jamaica, Brazil, Mexico, Guatemala
Orthodox-Europe	Russia, Ukraine	*Lithuania, *Kosovo, Bosnia and Herzegovina, Ukraine, Romania, Serbia, Bosnia, Belarus, Bulgaria, Russia, Armenia
Protestant-Europe	Switzerland, Germany, Denmark, Finland, Netherlands	Netherlands, Sweden, Norway, Germany, Switzerland, Denmark, Iceland, Finland, Estonia
West-South Asia	Not Applicable	Israel, Vietnam, Malaysia

Table 1. List of countries where charts were sampled from (Chart Country) and where sampled artists either resided in or originated from (Country-of-Origin). These were grouped according to Inglehart & Welzel's Cultural Map of the World (Cultural Region), following their macro-level orientation on Traditionalism and Secularity. Countries with '*' were not included in the original Cultural Map, but were categorized following the categories of their geographical neighbours.

(API) [1], and obtained artists' country of residence/origin from the MusicBrainz API [2]. Through this method, we managed to obtain the country or residence for artists from 2942 songs, and manually searched for the country of residence or origin (if country of residence was unavailable) for the artists of the remaining 1921 songs, through a combination of databases from Google, Wikipedia, LastFM, and Popnable. For analyses, we labelled this variable as Country-of-Origin. We also obtained danceability, based on detrended fluctuation analysis [26], and spectral energy scores for each song through the Essentia [27] library.

Country-level indicators of economic development were obtained through Gross Domestic Product (GDP) per capita, percentage of migrants, and income inequality (Gini) from the World Bank Databank [3]. We also categorized countries according to their respective Inglehart-Welzel cultural regions [4]: African-Islamic, Catholic-Europe, Confucian, English-Speaking, Latin-America, Orthodox-Europe, Protestant-Europe, and West-South Asia. If the country was not officially categorized in this system, we approximated the category based on the categorization of its geographical neighbours. Country categorizations are in Table 1, and data is available on our online repository [5].

2.2 Data Handling and Analysis

To construct the networks, we created undirected edge lists for each timepoint, consisting of nodes (song), weight: the number of times any two songs (or nodes) appeared on the same country's charts (denoted by W). In other words, for any given timepoint, we define a network G, where $G = (V, E)$. V refers to the set of unique songs in all charts, and E refers to the set of edges. W is the weighted adjacency matrix of the graph and is defined as follows for any pair of songs (i, j):

$$W_{ij} = \sum_{C_k \in C} Cooccur(C_k, i, j) \quad (1)$$

where $C = \{C_1, C_2, \ldots, C_K\}$ is the set of all considered charts and C_k is a particular chart (for a particular country and month), *i.e.* the set of 100 songs that were most listened in this country during this month. $Cooccur$ is an indicator function which takes the value 1 if and only if song i and song j co-occur in C_k, and 0 otherwise. To assess the centrality of a node, we examined the eigencentrality (x) of a node i, which is written in Equation 2 as:

$$x_i = \frac{1}{\Lambda} \sum_{j \in V} W_{ij} x_j \quad (2)$$

Here, Λ refers to the largest eigenvalue of the matrix W. Centrality of a node (song) x_i takes into account the sum of centralities of its neighbors, which was a reason why we used this measure (as opposed to degree centrality, which relies only on the number of connections). Eigencentrality parameters (e.g., number of iterations) relied on igraph defaults obtained from arpack [28].

For community detection, we used the modularity metric, which identifies nodes with statistically higher numbers of connections (edges) than random chance levels, and partitioning the interconnected nodes according to the boundaries of these 'above random' interconnections [29]. We used Clauset et al's fastgreedy function ('cluster_fast_greedy' [30]) that repeatedly combines lower-level communities to maximize modularity, for a bottom-up determination of the number and structure of communities. These analyses were conducted through the igraph package [31] in R [32].

For statistical analyses, we fitted separate χ^2 tests and ordinary least squares (OLS) or linear mixed effects (LME)

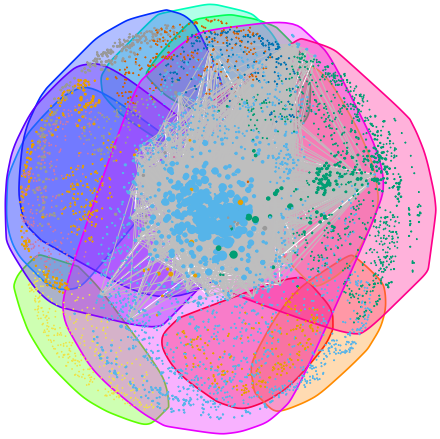

Figure 1. Network visualization using the Kamada-Kawai force-directed algorithm. Songs are represented by nodes, and node size corresponds to eigencentrality. Communities are displayed through colors. A version with node labels (titles and artists) is available on our online repository.

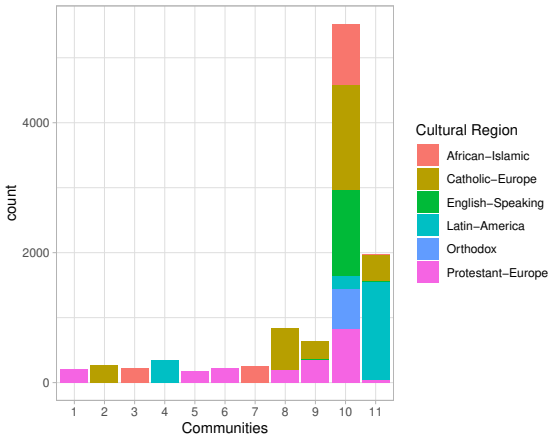

Figure 2. Visualizing culture-of-consumption: the distribution of charts that make up each Community, categorized by cultural region. Community 10 (C10) for example, comprises 5807 songs that are in charts from all 6 cultural regions sampled in this study.

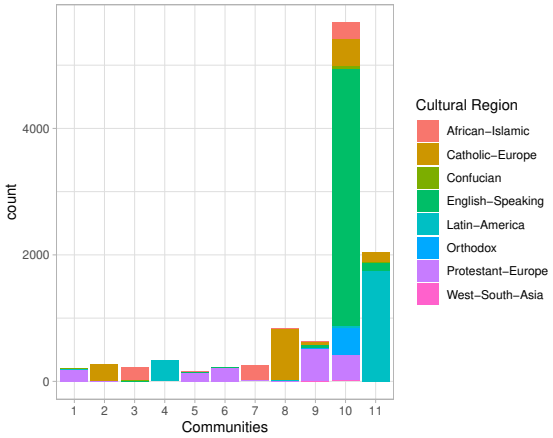

Figure 3. Visualizing culture-of-origin: the distribution of artists' countries for each Community, categorized by cultural region. Community 10 (C10) for example, comprises 5807 songs, of which 4707 are from the English-Speaking (Anglo-American) cultural region.

regression models [33] predicting node (song) eigencentrality from Community (OLS), cultural region (LME), economic development (LME), and danceability/spectral energy features (LME). For LME models, random intercepts were included for country-of-consumption (countries' charts), and random slopes were included for danceability and spectral energy by country where applicable. Degrees of freedom were estimated using Satterthwaite approximation. All categorical variables were deviation coded to examine the relative effect of a specific cultural region against the mean of all regions.

3. RESULTS

3.1 Descriptive statistics of detected Communities

A total of 11 Communities (C1-11) were detected from the network. Of which, Communities 10 (C10) and 11 (C11) had substantial amounts (5807 and 2056 songs respectively), but the other Communities ranged between sizes of 179 (C5) to 832 (C8). Due to space concerns we report only the results on cultural regions in this paper, but contingency tables and lists describing the country-of-consumption of the charts and country-of-origin of the artists' are available on our online repository [6]. Figure 1 displays a visualization of the network using a Kamada-Kawai layout [34].

We then tested the Communities' association with country-of-consumption (that the Top 100 chart was from) and country-of-origin of the artist. These were grouped according to their cultural region, described in Table 1. We observed a significant association between Communities and songs' culture-of-consumption, $\chi^2(50, 10681) = 15433, p < .001$, and between Communities and artists' culture-of-origin, $\chi^2(35, 10459) = 16253, p < .001$. Figures 2 and 3 visualize the cultural make-up by culture-of-consumption and culture-of-origin. For the most part, with the exception of C10, we find the relative consistency between culture-of-consumption and culture-of-origin, suggesting that the artists residing or originating from a specified cultural Community were largely listened to (popular) within the same cultural Community. For example, C1 comprised charts from the Netherlands, and a majority (87.6%) artists were of Dutch origin. Other Communities represented a linguistic cultural sphere over several countries: in C8, French-origin artists comprised 88.7% of the Community, which was largely split amongst Belgian (36.4%), French (39.3%), and Swiss (27.8%) Top100 charts. However, for C10, we observed that Anglo-American artists' formed the majority (70.1%), but consumption was spread out over all cultural regions and all 30 countries.

[6] https://osf.io/uyh6d/

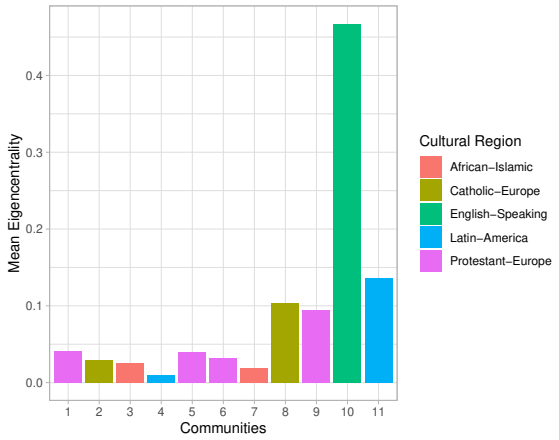

Figure 4. Mean eigencentrality of songs in each Community. Colors denote the most common culture-of-origin for artists in that Community.

3.2 Cross-cultural popularity (eigencentrality)

An OLS model ($R^2 = 0.36, F(10, 11033) = 614, p < .001$) with eigencentrality as the outcome variable, Communities as the predictor, and C1 as the reference level, found that, C2 ($\beta = -0.19, t = -4.15, p < .001$), C3 ($\beta = -0.20, t = -4.01, p < .001$), C4 ($\beta = -0.25, t = -6.10, p < .001$), C5 ($\beta = -0.16, t = -2.87, p = .004$), C6 ($\beta = -0.18, t = -3.69, p < .001$), and C7 ($\beta = -0.19, t = -4.15, p < .001$) showed significantly lower eigencentrality (than the average across Communities), and C10 ($\beta = 1.17, t = 72.08, p < .001$), and C11 ($\beta = 0.14, t = 6.92, p < .001$) showed significantly higher eigencentrality. These suggest that C2-7 had songs with cross-cultural popularity significantly lower than the Grand mean, and C10 and C11 had songs with cross-cultural popularity significantly above the Grand mean. These results are visualized in Fig 4.

Next, we examined the eigencentrality of songs by the culture-of-origin of the artist. As one artist could have several songs across various countries' charts, we used a LME model, with random intercepts for country-of-consumption (Model $R^2_{marginal} = 0.42, R^2_{conditional} = 0.44$). As countries' economic situation may have also influenced their consumption preferences, GDP per capita was added as a control variable. We observed a significant effect of culture-of-origin ($F(7, 6166.9) = 778.73, p < .001$), but not GDP per capita ($F(1, 27.9) = 0.90, p = .350$). With African-Islamic culture as a reference level, we found that songs originating from artists in Catholic-Europe ($b = -0.11, t = -9.31, p < .001$), Latin America ($b = -0.11, t = -8.43, p < .001$), and Orthodox Europe ($b = -0.06, t = -3.73, p < .001$) cultures had eigencentrality significantly below the Grand mean, songs originating from artists in Confucian Asia ($b = 0.12, t = 4.49, p < .001$) and English-Speaking (Anglo-American) cultures ($b = 0.34, t = 34.93, p < .001$) had eigencentrality significantly above the Grand mean. This suggests that songs from Confucian Asian and Anglo-American artists appeared to be more popular cross-culturally.

3.3 Additional analyses

We fitted two LME models exploring possible factors behind cross-culturally song popularity. These include socioeconomic reasons, such as GDP, income inequality, and immigration, and musical reasons, where we focus on danceability and energy as measures of rhythmic and intensity arousal inherent in the song. For the socioeconomic model (Model $R^2_{marginal} = 0.05, R^2_{conditional} = 0.10$), only immigration, measured using 2015 migrant percentages within a country's population, significantly predicted the eigencentrality of the songs on its charts ($b = 0.01, t = 3.83, F(1, 20.1) = 14.67, p = .001$). However, we noted the possibility that Anglo-American cultures, that typically have higher migrant percentages, also have artists with songs that have higher cross-cultural popularity. As such, we repeated the analysis with the exclusion of these countries (USA, UK, Australia, Canada). While still significant, migrant percentages predicted eigencentrality to a smaller extent (Model $R^2_{marginal} = 0.03, R^2_{conditional} = 0.07; b = 0.007, t = 2.21, F(1, 16.9) = 4.90, p = .041$, suggesting that countries with larger migrant populations also consume songs that are more cross-culturally popular.

While both are used as measures of arousal, danceability (rhythmic arousal) and spectral energy (intensity arousal) are only weakly correlated on a song-level ($r = 0.043, p, .001$). The LME model (Model $R^2_{marginal} = 0.02, R^2_{conditional} = 0.12$) showed a significant effect of danceability ($F(1, 30.4) = 12.4, p = .001$) and spectral energy ($F(1, 26.9) = 16.3, p < .001$). Eigencentrality was negatively predicted by danceability ($b = -0.121, t = -3.52, p = .001$), but positively predicted by spectral energy ($b = 2.68, t = 4.04, p < .001$). In sum, after controlling for country-specific effects, the cross-cultural popularity of a song was negatively associated with its danceability but positively associated with energy.

4. DISCUSSION

Our network appears to model the cultural spread of music consumption amongst the 30 countries studied. The 11 Communities detected largely reflect cultural consumption, which to some extent, seems to quantify linguistic boundaries as a common denominator across cultures. C8 for example, comprises French music, and is consumed in countries where French is widely spoken: Belgium, France, and Switzerland. Similarly, C9 comprises German artists, and is most consumed in Austria, Germany, and Switzerland. However, C10 appears unique in that that is largely comprised of songs by Anglo-American artists, yet is common in charts from countries where English is not primarily spoken. This appears to go beyond the nation or language-based consumption patterns of the other Communities. Given the high eigencentrality scores associated with songs from these cultures, our results may thus be indicative of a disproportional popularity of English-medium songs in global music consumption.

This interpretation would be consistent with Bello and Garcia's [4] research on nationalism and cultural diver-

gence in local charts in recent years. Our results show that many charts retain a large amount of songs by local or regional artists, and despite past research suggesting that American cultural hegemony in popular music might have decreased in recent years (see [1]), still contain strong Anglo-American music presences.

In contextualizing cross-cultural popularity in the socioeconomic conditions of a country, we found that migrant population, and not economic development (GDP) or income inequality (Gini coefficient), significantly predicted a country's consumption of cross-cultural popular songs. As many such artists are of Anglo-American origins, and Anglo-American countries typically have large migrant populations, we repeated this analysis after systematically excluding these countries. Despite a smaller observed effect, our findings remained consistent, in suggesting that migrant population is associated with wider consumption of cross-culturally popular songs. We speculate that a larger migrant population could indicate a more diverse population [35, 36]. If so, consumption patterns may be less subject to nationalistic tendencies, and the drive for local music in recent years may not have had as strong an effect in these Communities. One possibility could be that this creates a larger space and demand for music that is popular elsewhere, but caution that these interpretations are speculations, and more research is needed to uncover the antecedents of cross-cultural popularity.

We also examined cross-cultural popularity by analyzing song arousal. Following research by [22, 37] that found popular music comprised high intensity and strong rhythms, we show that intensity arousal appears to be more cross-culturally popular, but rhythmic arousal appeared inversely related to popularity. This suggests a conceptual differentiation between both arousal domains, and more research is needed to identify the distinct functions and qualities of both.

Regarding the high eigencentrality of artists from Confucian Asian cultures, we note however that this could be a result of sampling bias. Given that we did not examine charts from Confucian Asian cultures, the presence of artists with this cultural background would mean that they had to have a level of global visibility to appear in the charts we sampled. In our data, these mainly consisted of South Korean artists, like BTS and Blackpink. Nevertheless, that these artists had songs with larger-than-average eigencentrality, despite our sample not having any East Asian charts (where they would have had a natural advantage), is a testament to the success of the South Korean Hallyu movement. Yet, research has also suggested that this may be due to the hybridization of Korean popular music with American influences and trends [38].

One limitation of our research is in the narrow sample of countries included in the analysis. For validity, we chose only to focus on countries where Deezer occupies a sizeable market share, inevitably under-representing users in Asia. Secondly, some songs may be region-locked, in that users from Country A may not necessarily be able to listen to a song from Country B. However, we think that this affects only a minority of songs, and most songs appear to be accessible from different geographical regions; region specificity may not be a strong-enough limiter in preventing German artists (for example) from being played in the United States.

Next, we did not conceptually distinguish popularity from influence. Cross-cultural popularity (i.e., the consumption of foreign music) may not necessarily suggest cross-cultural influence (i.e., the pervasiveness of foreign aesthetics and values in local culture), and some of our arguments are built on the assumption that popularity reflects a certain amount of influence. A thorough distinction on mechanisms are beyond the scope of the current paper, but is an area that we feel is in need of more research. Finally, we had difficulties in differentiating country-of-origin from country-of-residence for the artists sampled. These issues were often technical, in that the databases we relied on did not necessarily specify these differences. Consequently, some issues on validity remain: an artists originating from Puerto Rico but residing in New York may be coded inconsistently. Nevertheless, we think our data is sufficient in supporting the broad claims on cross-cultural popularity made in this paper, but we defer to ethnomusicologists working in localized geographical areas for greater depth on the role of specific cultural influences within local societies.

5. CONCLUSION

Given that our aim was to empirically quantify the dynamics of cultural influence in music charts, we think that the findings demonstrate a limited usefulness of our method of using song co-occurence on countries' charts for network construction, to empirically examining the extent of a culture's influence. While we focused solely on music consumption and popularity, which at best can be considered just one aspect of influence, we nevertheless found convergence in our findings on Anglo-American musical influence, with evidence from sociological and anthropological literature: Anglo-American dominance remains unmatched in its prevalence around the world. Moving forward, we propose that our method of network construction can also be used to examine the dynamics of regional influences from within the other Communities. For example, C11 comprises songs mostly on Latin American charts, but shows that artists tend to be from Puerto Rico or Colombia, and these artists from these countries may thus have a stronger regional influence within this Community. Thus, even within these regional cultural spheres, artists may be concentrated within industries centered on a small number of countries, and this may be of interest to researchers. All supplementary materials are available on our online OSF repository [7], and we hope that this can be a resource for the music science community in researching the dynamics of cultural products and cross-cultural influence.

ABSTRACT

The Middle Byzantine notation (MBn) is used to capture the plainchant melodies of eastern Orthodox Christian music from the middle of the 12th century until 1814. In the context of this research, we study the evolution of a subgenre of Byzantine music known as Heirmologic. We present three Heirmologic corpora spanning the periods before, during and after the 16th century. We discuss the challenges we faced during the digitisation process, and the steps we took to overcome them. For the analysis of the three corpora, we apply the three methods, namely notational texture, melodic arch similarity, and Jensen-Shannon distances of Markovian models, the second of which is novel and inspired by the idea of melodic arches [1, 2]. Through these methods, we aim at highlighting the differences of the corpora in order to obtain an outline of the evolution of the subgenre. We observe that the post-16th century Heirmologic pieces are more similar to the 16th century ones, while there is a greater difference with the pre-16th century pieces. This indicates that the 16th century constitutes a turning point in the melodic features of the Heirmologic subgenre.

1. INTRODUCTION

Byzantine music has a known history of 2000 years and it constitutes a part of the human world heritage [3]. Roughly, the first millennium is characterised as pre-notational period, while the second as notational period [4]. It was mainly developed in the Eastern Byzantine Empire and up to this day has been influencing the cultures of the Southeast and Eastern Europe, and parts of the Caucasus regions. It has also influenced, among others, the Western and the Slavic music [5, 6].

The Middle Byzantine notation (MBn) is used to capture the plainchant melodies of Byzantine music from the middle of the 12th century until 1814 [7]. At the moment of writing, the cataloged manuscripts of Byzantine music are numbered approximately 10,000, most of them written in MBn [8]. The absence of MBn corpora prevents the computational process of this music genre and makes impossible any cross-cultural research, what is described in [9, 10]. Previous attempts have been made to transcribe Byzantine music into staff notation, but they were rejected due to loss of the information that is rooted in the symbols' orthography [7].

We present three related corpora of MBn scores which are part of the Knowledge Representation presented in [11]. The corpora are available to MBn researchers as well as to the wider musicological community [12]. These corpora are used in a study to outline the evolution of the Heirmologic subgenre of Byzantine music that took place in the 16th century. For this reason, we present a preliminary comparative analysis of the corpora.

This paper is organised as follows. Section 2 introduces the Heirmologic subgenre that the pieces of the corpora belong to, the manuscripts that the corpora consist of, and the reason why we study them. It closes with the discussion on the challenges in the digitisation and how we dealt with them. Section 3 presents the methods we applied for the musicological analysis of the corpora. Section 4 presents the results of the analysis. This paper closes with section 5 which discusses our results.

2. THE THREE CORPORA

Byzantine music consists of three subgenres: Heirmologic, Sticheraric, and Papadic. The subgenre of a Byzantine music piece depends on the poetic form of its lyrics [1]. Generally, Byzantine music compositions of a hymn are influenced by (a) the subgenre that the hymn belongs and (b) the preceding compositions of the same hymn (different melodies using the same lyrics). Regarding point (b), Manuel Chrysaphes (15th century) in his treatise [14, pp. 44–47], states that new compositions of Hymns follow the music of the preceding compositions of these Hymns. Since music can be expressed as a series of viewpoints,

Kalofonos, D. Balageorgos, and C. Anagnostopoulou, "Three related corpora in Middle Byzantine music notation and a preliminary comparative analysis", in *Proc. of the 23rd Int. Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

[1] Specifically, the Heirmologic music pieces (called *Heirmoi*) use lyrics that belong to the poetic form of *Kanon* [7, 13]. At a high level, a *Kanon* consists of a number of stanzas, some of which work as model melodies. These stanzas are called *Heirmoi* (singular: *Heirmos*). The remaining stanzas of *Kanon* follow the melodies of the *Heirmoi* [7]. The book that contains the Heirmoi is called Heirmologion.

we explore this observation and we model the similarity of the corpora through the distances of their respective viewpoints.

In the context of this research, we study the evolution of the Heirmologic subgenre. Using the Knowledge Representation (see section 2.5), we focus our attention on the Heirmologions of 16th century, and specifically the Karykis Heirmologion. This selection is not random. According to the existing historical research, in the 16th century a great change happened to the melodies of the Heirmologion [13, 15, 16]. In order to study the Karykis' Heirmologion and to evaluate its contribution to the tradition, we select the Heirmologions of pre-Karykis, Karykis and post-Karykis.

2.1 A representative sample of Heirmologion of pre-Karykis era

In our research we evaluate the contribution of Karykes' Heirmologion in the context of tradition. As a representative example of the previous tradition, the Heirmologion of manuscript 1101 from the Iveron (mount Athos) library was chosen. This Heirmologion was written somewhere between 1535-1540 by the monk Pachomius Rousanos [17].

There are several reasons for choosing Rousanos' Heirmologion as a representative of the pre-Karykis era: (a) the Rousanos' Heirmologion follows the prevailing tradition of the subgenre, (b) it is dated close to Karykis' era, (c) Rousanos was a well-known lettered monk, who had a good knowledge of both notation and theory, so his manuscripts are considered reliable sources.

2.2 A representative sample of Karykis' Heirmologion

So far, no autograph of Karykis' Heirmologion has been identified. From various copies of the Karykis' Heirmologion, the Iveron 1167 was chosen for these analyses. This manuscript dates to the early 17th century.

2.3 A representative sample of Heirmologion of post-Karykis era

As a representative example of the post-Karykis tradition, we take the Balasis' Heirmologion of Sinai 1433 (Jerusalem). This Heirmologion was written in 1690 by Kosma the Macedonian [18]. In the period between the Balasis' and Karykis' Heirmologions, appeared also some other Heirmologion anthologies. However, based on the number of copies, Balasis' Heirmologion was especially popular among the post-Karykis' Heirmologions. Therefore, the next main tradition of the Heirmologion subgenre is considered to be that of Balasis. Regarding the choice of the copy, Kosmas the Macedonian was a peer of Balasis in music studies and his manuscripts are considered to be a reliable source [19].

2.4 Corpora

Having defined the previous and the next tradition of the Karykis' Heirmologion, it becomes possible to create three corpora that represent these traditions. Specifically, 128 Heirmoi were received from each Heirmologion. The sample is evenly distributed in terms of Echoi (modes): 16 Heirmoi per Echos. The same Heirmoi were taken from each corpus, i.e., the same text (lyrics) composed by different composers. This sample is approximately 25% of the number of Heirmoi contained in each Heirmologion.

2.5 Knowledge Representation

The Knowledge Representation we use is a tree structure capturing the viewpoints [20, 21] of the music piece. In our case, these viewpoints are the *syllable*, *interval*, *pitch*, and *voiced sign*. The *syllable* is the viewpoint that captures in a sequential form the syllables of the lyrics. The *interval* and *pitch* viewpoints capture the information that provides us with the Metrophonia [2] of the piece (i.e., basic melodic line without duration information). The *voiced sign* viewpoint captures the aspect of the notation that provides us with the Metrophonia. Naturally the tree captures the relations of the viewpoints and their sequence in the music piece. Exploiting the structure of the tree, the researcher can then perform a computational analysis of the properties of the music piece. Moreover, the researcher can post-process the tree to highlight specific properties of the music piece by reorganising the connections of the viewpoints. For more information see [11].

2.6 Digitisation challenges

During the process of digitisation of the music pieces, we were faced with a number of challenges. Firstly, notational errors in the manuscripts due to the scribe is a common issue. Such errors are identified through the Metrophonia of the notation and are corrected by comparing these excerpts containing the error with similar excerpts from other manuscripts. For the pre-Karykis Heirmologion (manuscript Iveron 1101), the following manuscripts were used for the corrections: Grottaferrata EgII [22], Sinai 1256 [23] and Iveron 1185 [24]; for Karykis Heirmologion (manuscript Iveron 1167) manuscripts Iveron 1154, Iveron 1155 and Iveron 1231 were used [24]; and for post-Karykis Heirmologion (manuscript Sinai 1433) manuscripts NLG 946, NLG 936 and NLG 967 were used [25]. All the imposed corrections are documented within the corpus (GitHub link).

Secondly, the signs of MBn are grouped into two main categories: Voiced signs and Voiceless signs. One of the uses of the latter is to group the former. Many times it does not seem clear which Voiced signs the Voiceless signs are grouping (e.g., Figure 1). This ambiguity particularly concerns the Heirmologions of Karykis' era and onwards. This problem does not have a unique solution and individual rules may apply. A general principle that we followed in our corpora was that Voiceless signs group all the Voiced signs in a syllable. Also, sometimes we juxtaposed the am-

[2] Although the interpretation of this notation remains an open question, the basic melodic line as evidenced by the signs (called Metrophonia) is unquestionable.

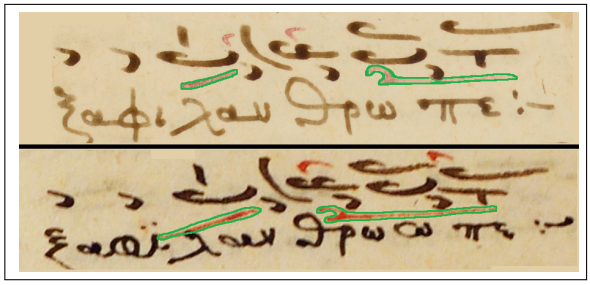

Figure 1. The top excerpt is from the Heirmologion of the manuscript Iveron 1167 f 4r, while the bottom is the same excerpt from the Heimrologion of the manuscript Iveron 1155 f 4r. As can be seen, the same Voiceless sign (red with a green border) spans several Voiced signs (black) in the two manuscripts.

biguous excerpts from corresponding manuscripts to locate a kind of pattern.

Thirdly, at a higher level, the MBn can be understood as a sequence of signs that indicate intervals. The pitches of these intervals are determined by a series of specific signs which are always placed at the beginning of the pieces. This group of signs is called Martyriai. Choosing a pitch as representative of each Martyria is not always straightforward [26]. The choices made in the specific music pieces are such as to facilitate the comparison of the three corpora.

Fourthly, our Knowledge Representation gives us the ability to capture the melodic phrases of each piece. The choice of end points of music phrases is not objective. In order to be consistent with our choices across the corpora, we have created a set of general rules and separation preferences.

Rule 1.1: Phrases are separated in the last syllable of a word. **Rule 1.2:** Phrases are separated in the last syllable of an *Enclisis* group (linguistic term). **Rule 2.1:** The last syllable of the phrase usually contains at least one of the following signs [3] : *Diple Apostrophos*, *Diple*, *Apoderma*, *Kratema* (rarer), *Klasma* (rarer). **Rule 2.2:** The penultimate syllable of the phrase can have the *Koufisma* sign. **Rule 2.3 (intuitive):** The last syllable of the phrase may have one of the following compound signs: *Omalon*, *Piasma*, and *Vareia*. **Rule 3:** There should be a colon and/or a comma in the lyrics of the music text. **Rule 4 (tendency):** Small phrases rather than large ones are preferred. **Rule 5:** The *Martyriai* appearing mid-text usually separate phrases.

3. METHODS OF COMPARISON

In order to draw an outline of the evolution of the Heirmologic subgenre of Byzantine music, we use three methods to capture the differences of some aspects of the corpora: Notational texture (method 1), similarity of the melodic arches (method 2), and distances of Markovian models of the attributes (method 3).

[3] These are the names of the signs of MBn that etymologically come from Greek words [7].

3.1 Method 1: notational texture.

In plainchant music (e.g., Byzantine, Gregorian, Mozarabic etc.) a characteristic of the style of a piece is its average number of notes, time beats, or signs per syllable [27–33]. Based on this characteristic, we can cluster the music pieces into three categories: syllabic, neumatic, and melismatic. In order to eliminate any ambiguities in these categories, we define two types of texture: Notational and Durational texture. *Notational texture* of a corpus is defined as the average number of pitches or of signs on a syllable, while *Durational texture* of a corpus is defined as the average number of durations per syllable. When the average number of the measured quantity (pitch, duration, signs etc.) of a corpus is between 1 and 2, then the texture of the corpus is characterized syllabic, when it is between 2 and 4 then the texture of the corpus is characterized neumatic, and when it is 4 or more then the texture of the corpus is characterized melismatic. Hence, a music corpus in terms of pitch can belong to syllabic style, while in terms of duration can belong to neumatic style. The interpretation of the MBn in terms of the duration of the syllables remains an open question. Consecutively, as the music pieces considered in this research are written in MBn, our measurements cover the notational texture.

All the pieces of our corpora belong to Heirmologic subgenre. This means that the general notational texture of these three corpora is syllabic. Nevertheless, through this measurement we can obtain a more subtle distinction of the notational texture of the syllables as examined by Troelsgard [30]. Specifically, we measure the number of pitches per syllable, $notational\_texture = \frac{|voiced\_units|}{|syllables|}$.

3.2 Method 2: similarity of the melodic arches

As we discussed in section 2, tradition plays an influential role in the composition of a hymn. In this research, we are interested in (a) identifying the areas where the new compositions follow the tradition, (b) the areas where the new compositions diverge from the tradition, and (c) quantify the divergence of the new and prior compositions.

Plotting the melodic lines of the different compositions of the same poetic verses lined up by syllable, we observe that the compositions usually present similar melodic shapes in corresponding areas (Figure 2). Based on this observation and inspired by the idea of melodic arches [1, 2], we create a novel method that, given two melodies of the same number of syllables, returns a percentage of similarity of their melodic arches. The design of this algorithm is driven by (a) the fact that the compositions in Byzantine Music are rooted on the syllables of the lyrics, (b) the duration of the pitches is unknown, and (c) the need for the derivation of a comparison metric instead of a metric for the identification of a dominant melodic arches [1].

The algorithm consists of three phases, (a) the plotting of the pitches (Algorithm 1), (b) the extraction of the arches (Algorithm 2), and (c) the comparison of the arches of the melodic lines (Algorithm 3).

Given two music pieces, the algorithm extracts the pitches, and plots them on a two dimensional grid (Algo-

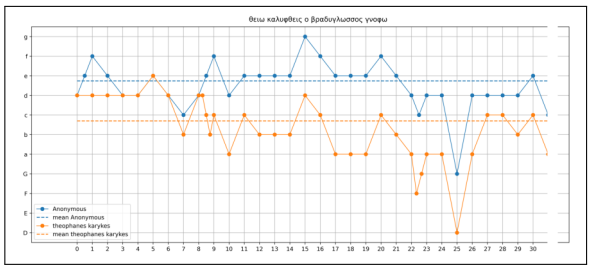

Figure 2. The melodic line of the first 30 syllables of Heirmos 'Theio kalyptheis' by the two compositions (Iveron 1101 and Iveron 1167). The x-axis represents the syllables, where at x=0, the value of y is the Martyria, i.e., the initial pitch (see [11]). The y-axis represents the steps (pitches).

rithm 1). The two pieces are aligned by syllables, and are of equal length. As a result, the pitches give us a view of the shape of the melodic lines, and highlights the similarities and differences of the compositions (Figure 2).

In the next phase the algorithm extracts the arches that are formed by the pitches (Algorithm 2), i.e. shape of the melody. Using these arches, we translate the two melodies into sequences of two types of arches: convex and concave.

In the final phase, the algorithm compares the compositions through their arches (Algorithm 3). When two areas are translated into the same arch type, they are considered to be similar. When two areas are translated into different arch types, they are considered to be dissimilar. When the areas cannot be translated into arches, they are classified as dissimilar due to different shapes.

When the arch of one melodic line corresponds to more than one arches of the other, the former is compared with the second degree polynomial regression of the latter. The second degree polynomial will give us a curve that is either convex or concave. Through the comparison of the two melodic lines, we obtain (a) the degree of similarity, (b) the degree of dissimilarity due to difference arches, and (c) the degree of dissimilarity due to difference shapes (Figure 3).

3.3 Method 3: distances of Markovian models of the attributes

As a third method, we capture the viewpoints as sequences (n-grams). We apply Markovian models on the n-grams to examine the divergence of the corpora. The melodic features of the notation are those that refer directly to the basic melodic line of the chant: pitch, interval, voiced unit. The information carried by the first two attributes is identical to that of the western staff. Voiced units are those that encapsulate the music information of the main melodic line as it is imprinted on the other two features (pitch, interval). In essence, the voiced unit attribute concerns the sign itself as it is imprinted in the score, while the pitch and the interval concern the aspects of the melody that the voiced units indirectly indicate (signified and signifier).

From the pitch and interval we also extract three others features which are redundancies of the melodic line: general syllabic pitch, general syllabic interval, and melodic

Algorithm 1 Pitch plotting algorithm.

1: Let $syllables$ be the sequence of syllables of a music piece.
2: Let $pitches$ be the sequence of pitches of a music piece.
3: Let $f^{assoc} : syllable_k \rightarrow pitches_k$ where $pitches_k$ is the sequence of pitches associated with $syllable_k$ and $pitches_{n_k}$ is the nth pitch of $pitches_k$.
4: Let $f^{pos} : syllable_{i=1}^{n} \rightarrow \mathbb{Z}^+$ be the mapping of the position of a syllable i in the sequence of the music piece to positive integers, this mapping defines the values of the x-axis.
5: $\forall n \in [\ 1,\ |pitches_k|\ ]$ where $pitches_k = f^{assoc}(syllable_k)$, we plot the points, $P = \{\ (x, y)\ :\ x = f^{pos}(syllable_{k-1}) + n/|pitches_k|,\ y = pitches_{n_k}\ \}$. Point (x_0, y_0) is reserved for the initial pitch given by a special sign known as Martyria.
6: Create an abstraction by removing the embellishments, in the context of syllable, from the melodic line, defined as $\mathbb{P}^- = \{(x, y) : (x, y) \in P, x \in \mathbb{Z}^+\}$, i.e. for every syllable keep the last pitch.
7: For each pair of points in $\mathbb{P}^-$, we identify the melodic contour (i.e., step up or down). Zero intervals inherit the melodic contour of the previous pair, hence they do not change the melodic contour.

contour of syllable. For the general syllabic pitch, instead of extracting every pitch from every sign of the syllable, we extract only the last pitch of the syllable. For the general syllabic interval, instead of extracting every interval from every sign of the syllable, we extract the sum of all intervals of the syllable. For the melodic contour of the syllable, we extract the values $(-, +, 0)$, which describe the contour of the general syllabic interval.

Using our Knowledge Representation [11], the corpora is translated into sequences of values based on the logic of viewpoints [20, 21]. For the aforementioned viewpoints, we train Markov models of different order, and we measure the distance of the models using the Jensen-Shannon distance (i.e., the square root of the Jensen-Shannon divergence) [34, 35]. To tackle the zero-probability problem we use Laplace smoothing [36].

Markov models express the probability of an n-gram appearing in the corpus. However, Markov models do not capture the position of the n-gram in the corpus and since we are restricted to low order Markov models due to overfitting, two different corpora can theoretically result in the same probability distribution. As we are using this method to find the relation of two corpora, we apply it both on the detailed dataset that reflects the music surface and on a simplified dataset that has a single value associated with each syllable. Since the corpora contain the same lyrics and in the simplified dataset every syllable has one value (one pitch, one interval, or one contour), the n-grams span the same regions for both melody and lyrics.

Furthermore, since the divergence is derived from the

Algorithm 2 Arch extraction algorithm.

1: Let $\alpha = (start, peak, end, shape)$ be an arch, where $start,\ peak,\ end \in \mathbb{P}^-$ and $shape \in \{CONVEX, CONCAVE\}$.
2: Let point x be the starting point, then $start^\alpha = x$.
3: Find x_i such that all pairs in the range $[x, x_i]$ have the same contour or zero intervals, then $peak^\alpha = x_i$.
4: Find x_j such that all pairs in the range $[x_i, x_j]$ have the same contour or zero intervals, then $end^\alpha = x_j$.
5: Set $shape^\alpha = CONCAVE$ when $start^\alpha < peak^\alpha$, otherwise $shape^\alpha = CONVEX$.
{Since zero intervals do not change the contour, the arch will include zero intervals.}

Markov tables, and since we are using it for comparison, we make sure that the Markov tables of the corpora under comparison consist of a common set of n-grams, spanning the union of the set of symbols found in the corpora under comparison. As such, the divergence reflects the distance of the probability distributions over a single set of n-grams.

We study n-grams between the orders of 2 and 4, and favour higher orders until the point where all lines show decrease due to over-fitting. As we are interested in the comparison of the corpora, higher orders with the same probability indicate areas of similarity between the corpora. However, with higher order Markov, we tend towards the scenario where an n-gram appears once in one corpus and not the other, the Markov table is dominated by noise due to smoothing, and Jensen-Shannon distance reflects the noise rather than the relation of the data.

Finally, the absolute values of the Jensen-Shannon distance are not meaningful without a reference. As we are studying the distances of corpora, we need a reference in order to quantify the magnitude of their distance. For this reason, we make use of a case study corpus consisting of 16 Heirmoi in first echos which have the property that the 8 pre-Karykis [4] and 8 Karykis [5] Heirmoi belong to the pre-Karykis' music style. Generally, Karykis changes the compositional style in first echos, but for some reason, he keeps the previous style (pre-Karykis) for only these 8 Heirmoi. This is confirmed by the similar cadential pitches and pitch profiles, the highest melodic arch similarity (similar arches 84.4%, dissimilar arches 12.9% and dissimilar shapes 2.7%), and low Jensen-shannon distance (gray line in Figures 4 & 5). For these reasons, we consider the distance of these case study corpora as a threshold for similarity.

4. RESULTS

Table 1 presents the notational textures (i.e. the number of voiced units per syllable) of the three corpora. The three corpora show a syllabic notational texture. We observe that Karykis tends even closer to compose Heirmos with absolute syllabic notational texture (i.e., near to 1).

Algorithm 3 Arch comparison algorithm.

1: Let A and A' be the sequences of arches of the two melodic lines under comparison.
2: **while** $A \neq \emptyset$ and $A' \neq \emptyset$ **do**
3: Let α_1 be the first arch in A, and α'_1 be the first arch in A'.
4: Let $L = \emptyset,\ R = \emptyset$.
5: **if** $start^{\alpha_1} < start^{\alpha'_1}$ **then**
6: $L = \{\alpha_1\}$.
7: $R = \{\alpha'_n \in A' : end^{\alpha'_n} \leq end^{\alpha_1}\}$.
8: **else if** $start^{\alpha_1} > start^{\alpha'_1}$ **then**
9: $L = \{\alpha'_1\}$.
10: $R = \{\alpha_n \in A : end^{\alpha_n} \leq end^{\alpha'_1}\}$.
11: **else**
12: $L = \{\alpha \in A : end^\alpha \leq \max_{\alpha'' \in \{\alpha_1, \alpha'_1\}} end^{\alpha''}\}$.
13:
14: $R = \{\alpha' \in A' : end^{a'} \leq \max_{\alpha'' \in \{\alpha_1, \alpha'_1\}} end^{\alpha''}\}$.
15: **end if**
16: Let $area^L = \sum_{i=0}^{n} end^{\alpha_i} - start^{\alpha_i}$ where $\alpha \in L$. Equally we define $area^R$.
17: **if** $area^L \neq area^R$ **then**
18: Expand smallest area by adding padding, i.e. zero intervals.
19: **end if**
20: Let $quad(area^L)$ and $quad(area^R)$ be the two quadratic regressions using the points of the arches and the padding included in these areas. The two areas are considered similar if the curves have the same shape, i.e., both curves being convex or concave.
21: Remove from A and A' the arches in L and R.
22: **end while**

corpora	pre-karykis	karykis	balasis
notational texture	1.22	1.13	1.23

Table 1. The notational texture of the corpora.

Figure 3 shows the results of the similarity of the melodic arches. The melodic arches of the Karykis-Balasis corpora show the greatest similarity (78.99%). In the second place we have the pre-Karykis – Karykis pair with similarity (68.18%), and in the last place the pre-Karykis – Balasis pair with similarity (62.34%). The exact opposite is true for dissimilarity and the percentage of dissimilar shapes. Our results follow the observation of Stathis [13, pp. 26], quoting "the seventeenth-century Heirmologia contain kallopismoi [literally, to make beautiful or embellishments, but not to be confused with improvisations] of the Heirmologia of Theophanes Karykes and Iohasaph the New Koukouzeles", i.e. the 17th onwards Heirmologions are not considered original compositions as they use as a basis the 16th century Heirmologions.

Figures 4 & 5 present the Jensen-Shannon distances of the corpora on the studied viewpoints. We observe that Karykis-Balasis show the smallest difference, while pre-Karykis – Karykis and pre-Karykis – Balasis show similar

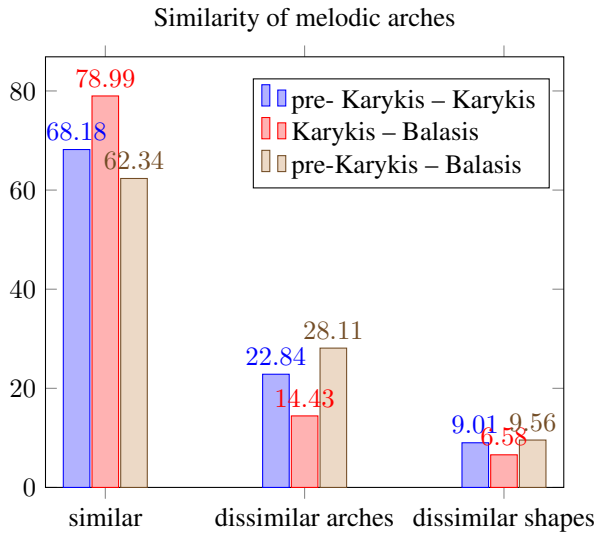

Figure 3. The bar charts of the melodic arches' similarity.

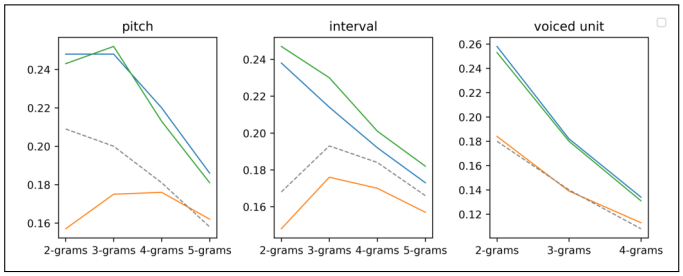

Figure 4. The Jensen-Shannon distances (abbr. JSd) of the Markov models. The reference line shows the JSd of the case study corpora (pre-Karykis and Karykis) where Karykis chooses exceptionally to keep the pre-Karykis tradition. The Blue line shows the JSd of the pre-Karykis – Karykis, the orange shows the JSd of the Karykis - Balasis, and the green line shows the JSd of the pre-Karykis – Balasis. The orders of n-grams are kept low in order to reduce the negative effect of higher order n-grams [38].

distances which are greater than of Karykis – Balasis. The close relation of Karykis – Balasis is confirmed by the near placement of the orange and gray lines of the case study corpus (section 3.3). The low rate of dissimilarity of the Karykis – Balasis Markov models is consistent with the observation of Makris [37] that the modality of Karykis – Balasis remains the same in contrast to the modality of the pre-Karykis era.

5. DISCUSSION

The notational texture (i.e. the number of voiced units per syllable) of the corpora outlines a change that occurred in the Heirmologic style. As shown in Table 1, the notational texture of Karykis presents a drop ($1.22 \rightarrow 1.13$) which leads us to a more syllabic texture. At the same time, however, Balasis shows an increase of notational texture, which reaches the same value as pre-Karykis ($1.13 \rightarrow 1.23$). If we consider that there is no important difference in the

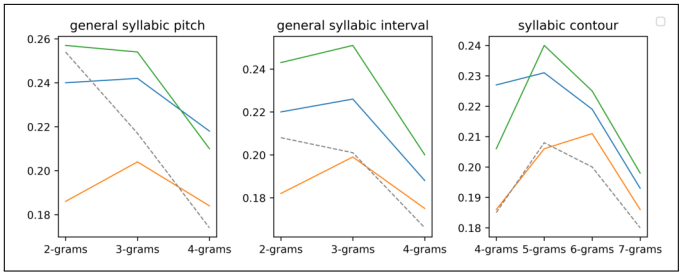

Figure 5. As of Figure 4, the Jensen-Shannon distances of redundant viewpoints.

interpretation-performance of the notation of the three corpora, then we can conclude that the values of the notation texture also correspond to values of durational texture. From these changes to the values of the notational texture, we can observe that Karykis simplifies the pre-Karykis melos and Balasis makes it sophisticated again by increasing the textures (notational and durational).

According to the bar chart of similarity of the melodic arches, the Karykis and Balasis pair present the greatest similarity than the other two. This presupposes that Karykis changes the tradition of the Heirmologion and Balasis largely follows Karykis. Also, we observe that all pairs present a melodic similarity that is more than 60%. This can be justified by the fact that the compared pieces are different compositions of the same lyrics (different melodies of the same Heirmoi). It seems that there are some constraints between the text and the melody, especially in the accented syllables. For example, we can guess that the composers want the accented syllables to be in local maxima. So, the peak areas influence the melodic contour of the melodic lines. This presupposes that Karykis changes the tradition and Balasis largely follows Karykis. Specifically, Karykis – Balasis have less distances than pre-Karykis – Karykis and pre-Karykis – Balasis ones.

These results can be viewed within the context of the *Theses* concept in Byzantine music. *Theses* are *formulae* that work as building blocks in Byzantine music pieces. Since the Markov models capture the melodies as frequencies of small patterns, we can infer that similar models of two corpora indicate that the two corpora use similar *Theses*.

6. CONCLUSIONS

This paper presented three related corpora belonging to the Heirmologic subgenre of the Byzantine music. The corpora are digitised using the Knowledge Representation of [11] which captures the MBn. Through this effort we envisage the creation of a large database of MBn scores. Through the computational analysis we observed that Karykis changes the style of the subgenre while the succeeding tradition of the subgenre (Balasis) follows the Karykis style. Even though the analysis presented addresses a specific research question, it offers us insights which will become the inspiration for further research in the domain of Computational Byzantine Musicology.

7. ACKNOWLEDGMENTS

We would like to thank Fabian Moss for his insights in the digitisation of the corpora.

ABSTRACT

The Guzheng is a kind of traditional Chinese instruments with diverse playing techniques. Instrument playing techniques (IPT) play an important role in musical performance. However, most of the existing works for IPT detection show low efficiency for variable-length audio and provide no assurance in the generalization as they rely on a single sound bank for training and testing. In this study, we propose an end-to-end Guzheng playing technique detection system using Fully Convolutional Networks that can be applied to variable-length audio. Because each Guzheng playing technique is applied to a note, a dedicated onset detector is trained to divide an audio into several notes and its predictions are fused with frame-wise IPT predictions. During fusion, we add the IPT predictions frame by frame inside each note and get the IPT with the highest probability within each note as the final output of that note. We create a new dataset named GZ_IsoTech from multiple sound banks and real-world recordings for Guzheng performance analysis. Our approach achieves 87.97% in frame-level accuracy and 80.76% in note-level F1-score, outperforming existing works by a large margin, which indicates the effectiveness of our proposed method in IPT detection.

1. INTRODUCTION

The Guzheng (古箏), which is also known as the Chinese zither, is a plucked 21-string Chinese musical instrument existing for over 2,500 years [1]. Chinese traditional music attaches great importance to the melody, so a large number of playing techniques are used to enhance the vividness of Guzheng performance. The pitch variation produced by pressing the strings with the left hand is even regarded as "the soul of Guzheng music" [2]. Instrument playing technique (IPT) detection aims to classify the types of IPTs and locate the associated IPT boundaries in an audio clip. However, there were only few researches about IPTs in the field of Music Information Retrieval (MIR). Particularly, most researches on automatic music transcription (AMT) only consider pitch estimation, while a complete transcription of a Guzheng performance should contain the notations of the playing techniques as shown by the Guzheng numbered musical notation [1] in Figure 1. In this work, we propose an IPT detection method that can further be incorporated into a full transcription system of Guzheng music.

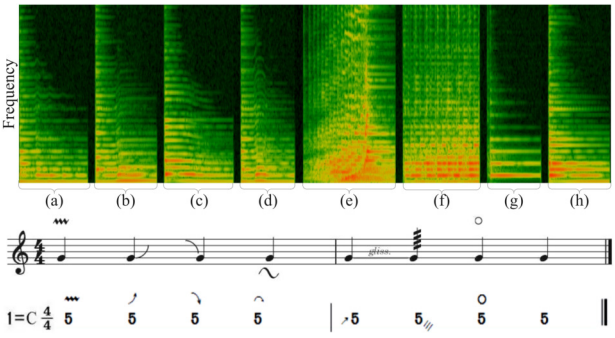

Figure 1. The spectrogram, staff notation and numbered musical notation of a Guzheng phrase that contains 8 notes with different playing techniques: vibrato (a), upward portamento (b), downward portamento (c), returning portamento (d), glissando (e), tremolo (f), harmonic (g), plucks (h)

One major difficulty for the IPT research is the lack of IPT sound databases. Most of the researches [3–6] on IPT recognition limited their experiments to samples from isolated notes in a single sound bank. However, according to [7], the performance of classifiers trained and tested with a single sound bank provides no assurance in the generalization capabilities of the classifiers. Ducher et al. [8] extended the above theory to IPT recognition research. They

[1] a musical notation system widely used in China and called *Jianpu* in Chinese

used five available IPT sound banks in their experiments but did not annotate any recorded corpora of audio.

Existing methods for IPT detection are mainly implemented through two steps [5,6,9]: locating and classifying. These methods are sensitive to the errors caused in locating. Recently, some end-to-end methods [10] have been proposed, while they are weak for variable-length audio and show low accuracy at the boundary of adjacent notes.

Note onset detection aims to localize the very beginning of each note. The beginning of a Guzheng note is easier to identify because the amplitude of that note is at its peak. In Guzheng performance, strings are usually plucked using special nails attached to fingers bottoms. When string is plucked, it has a pre-attack before the string reaches its full level vibration so the onset has a unique broadband spectrum. As shown in Figure 1, each Guzheng playing technique is applied to a note and each note in Guzheng music starts with a clear onset. So onset information is crucial to the Guzheng playing technique detection. However, to the best of our knowledge, no research has taken use of the onset information in the end-to-end IPT detection field.

The main contributions of this paper are as follows: 1) We create a new dataset, GZ_IsoTech, which consists of Guzheng playing technique clips from two Guzheng sound banks and real-world recordings recorded by a professional Guzheng performer; 2) We propose the first end-to-end method that can be applied to variable-length audio for Guzheng playing technique detection; 3) We propose a decision fusion method where an onset detector is trained to divide an audio into several notes and the predicted IPTs produced by the IPT detector are added frame by frame inside each note to get the IPT class with the highest probability within each note as the final output of that note.

2. RELATED WORK

Although the research on IPT detection is still in its early stage, we can summarize relevant researches and divide the development of this field into three periods.

The researches in the first period mainly focus on the playing technique classification of isolated notes [4, 11]. However, in reality, there are often continuous notes with varying playing techniques in an audio. We not only need to classify the IPT types but also locate the IPT boundaries.

The methods for IPT detection proposed in the second period can be divided into two steps: locating and classifying. In [5,6], signal processing methods were used to select candidates of the playing techniques in the melody contours extracted from 42 electric guitar solo tracks. Then the timbre and pitch features of the candidates were input into the classifiers such as Support Vector Machine (SVM). The candidates were manually selected based on the melody contour, so the methods are sensitive to errors in melody extraction and can hardly be generalized to other IPTs.

In [9], the candidates of guqin playing techniques were firstly located according to the IPT onset and duration annotations in 39 guqin solo recordings and then classified into six left-hand IPT types. Yet, we generally do not have onset and note duration as prior information in reality.

In [12], two binary classifiers bases on Convolutional Neural Networks (CNN) are firstly used to decide whether a fixed-length portion in a piano recording is played with the sustain pedal. Then sliding windows are used to apply the method to pieces with variable lengths. In [8], five different methods were proposed to classify 18 different IPTs in the cello solo audio concatenated by isolated cello notes with different IPTs from 5 different sound banks. Although the models proposed in [8, 12] can detect the IPTs in audio with continuous IPTs, the essence of them is to classify IPTs in a single block. These methods have redundancy in the computation because the input sound is split into overlappping frames that are fed individually to the network through a sliding window. Each convolution is thus computed several times on the overlapping parts.

We regard end-to-end IPT detection as the approach in the third period. In [10], the authors presented an end-to-end method based on Fully Convolutional Networks (FCN) to detect the IPTs in 10-second segments concatenated by isolated erhu notes. However, the method shows low accuracy at the boundary of adjacent notes and has computational redundancy when applied to variable-length audio.

Our model is built upon the FCN model presented in [10], with some improvements. We add a dedicated onset detector to take advantage of the significance of note onsets in Guzheng music. A decision fusion is implemented for the onset and IPT prediction to make a note-level prediction. In this way, we achieve a better performance for IPT predictions at the note boundaries. To apply our method to audio with variable lengths, 1D max-pooling layers which only halve the length of frequency axis are used.

3. GZ_ISOTECH DATASET

In this section, we introduce the Guzheng playing techniques considered in our work and the process of making the dataset.

3.1 Guzheng playing techniques

The traditional Guzheng playing techniques can be divided into two classes: plucking string with the right hand and bending string with the left hand [13]. In our work, we consider the following eight playing techniques which are the most frequently used in Guzheng solo compositions.

Left-hand playing techniques:

- **Vibrato (chanyin颤音):** the periodic oscillation of tones caused by the periodic pressing of a string with left hand (region (a) of Figure 1).
- **Upward Portamento (shanghuayin上滑音) (*UP* for short thereinafter):** press a string with left hand to increase the pitch of a ringing note to a desired pitch within major third (region (b) of Figure 1).
- **Downward Portamento (xiahuayin下滑音) (*DP* for short thereinafter):** decrease the pitch of a ringing note by releasing a bended string (region (c) of Figure 1). It is the opposite of Upward Portamento.

IPT	VSB		RW	
	num	seconds	num	seconds
vibrato	192	261.1	42	51.5
UP	488	752.0	48	94.4
DP	333	508.5	51	87.5
RP	272	327.0	94	94.7
glissando	316	595.3	42	95.9
tremolo	205	259.8	23	59.7
harmonic	318	305.8	61	42.0
plucks	204	204.0	135	99.7

Table 1. Quantity of data in the virtual sound banks (VSB) and real-world (RW) recordings. The Guzheng playing technique clips from VSB is used in the training set and that from RW is used in the test set.

- **Returning Portamento (huihuayin回滑音) (*RP* for short thereinafter):** pluck a string, press it with left hand, and then release it, creating an up-down slide (region (d) of Figure 1).

Right-hand playing technique:

- **Glissando (guazou刮奏, huazhi花指):** play several strings consecutively up or down with thumb or index finger rapidly (region (e) of Figure 1).
- **Tremolo (yaozhi摇指):** pluck a single string in rapid succession by "shaking" the index finger or thumb of the right hand back and forth across it as shown in the region (f) of Figure 1.
- **Harmonic (fanyin泛音):** tap a special location of a string with the left hand, and lift the left hand while playing the string with the right hand to produce a corresponding harmonic effect as shown in the region (g) of Figure 1.
- **Plucks (gou勾, da打, mo抹, tuo托...):** as shown in the region (h) of Figure 1, plucks are defined as simply plucking a string with a finger, including gou, da, mo, tuo [2], and so on.

3.2 Data collection and labelling

In order to ensure the diversity of the data, we collected audio clips of single playing techniques (we called these audio clips *short clips* thereinafter) from real-world recordings (RW) and 2 virtual Guzheng sound banks (VSB) which had different players and recording setups: Yellow River Sound and Kong Audio 3 KONTAKT. We sampled 2328 *short clips* covering almost all the tones in the range of Guzheng from the sound banks and annotated them into 8 classes one by one according to the sound bank manuals. Their durations range from about 0.6 to 11.5 seconds, in total 3213.4 seconds (see Table 1). The 496 real-world recordings of *short clips*, in total 625.3 seconds, were recorded and annotated by a professional Guzheng performer.

We use the *short clips* sampled in VSB as the training split and the set of *short clips* recorded in real world as the test split. This division well simulates the test situation in the real world as we usually do not have access to recordings of a testing Guzheng at training time. The dataset with detailed information and demos is available on the website [3] [14].

4. METHODS

As shown in Figure 2, our proposed model consists of two modules: the IPT detector and the onset detector. In the training phase, we train the onset detector and the IPT detector separately. Then, in the fusion phase, we apply decision fusion to the thresholded output of the onset detector and the raw output of the IPT detector to get the final result.

4.1 Input Representation

Since our goal is to generalize to actual solo recordings, we have generated series of audio sequences which simulate such recordings. Firstly, on both training and test, we concatenated our *short clips* in the dataset mentioned in Section3 one after another randomly until the length of the concatenated audio sequence is greater than 12.8 seconds. A check operation was executed to confirm that every generated audio sequence is unique. A 50 milliseconds crossfade was made in each boundary of adjacent *short clips* to ensure the audio sequence sound more realistic. We cut the audio sequence generated from the training set directly to 12.8 seconds long for training and use the unsplit audio sequence whose length is greater than 12.8 seconds generated from the test set for testing.

We also label the start time and duration of the corresponding playing techniques. Then we generate two kinds of labels (the onset lables and the IPT labels) by quantizing the continuous time labels into timestamps in the unit of 0.05-second-long frame.

The input representation is a log mel-spectrogram. Following [10], we use *librosa* [15] to compute log mel-spectrogram with 128 logarithmically-spaced frequency bins, an FFT window of 2048, a hop size of 2205, and a sample rate of 44.1kHz.

4.2 IPT Detector

Guzheng playing technique detection can be regarded as a part of the task of Guzheng music transcription. As most of the transcription task [16, 17], we treat the frame as a basic unit so we need to identify the playing techniques frame by frame. We can treat the task as a semantic segmentation task since there is no overlap of playing techniques in our data and frames in music are similar to pixels in images. Inspired by the success of FCN in semantic segmentation [18], which is also extended to audio processing research [10, 19], we applied FCN in our task.

[2] gou, da, mo, tuo are the names of the Guzheng playing techniques for simply plucking a string using the middle finger, ring finger, index finger, and thumb respectively.

[3] https://ccmusic-database.github.io/en/database/ccm.html#GZTech

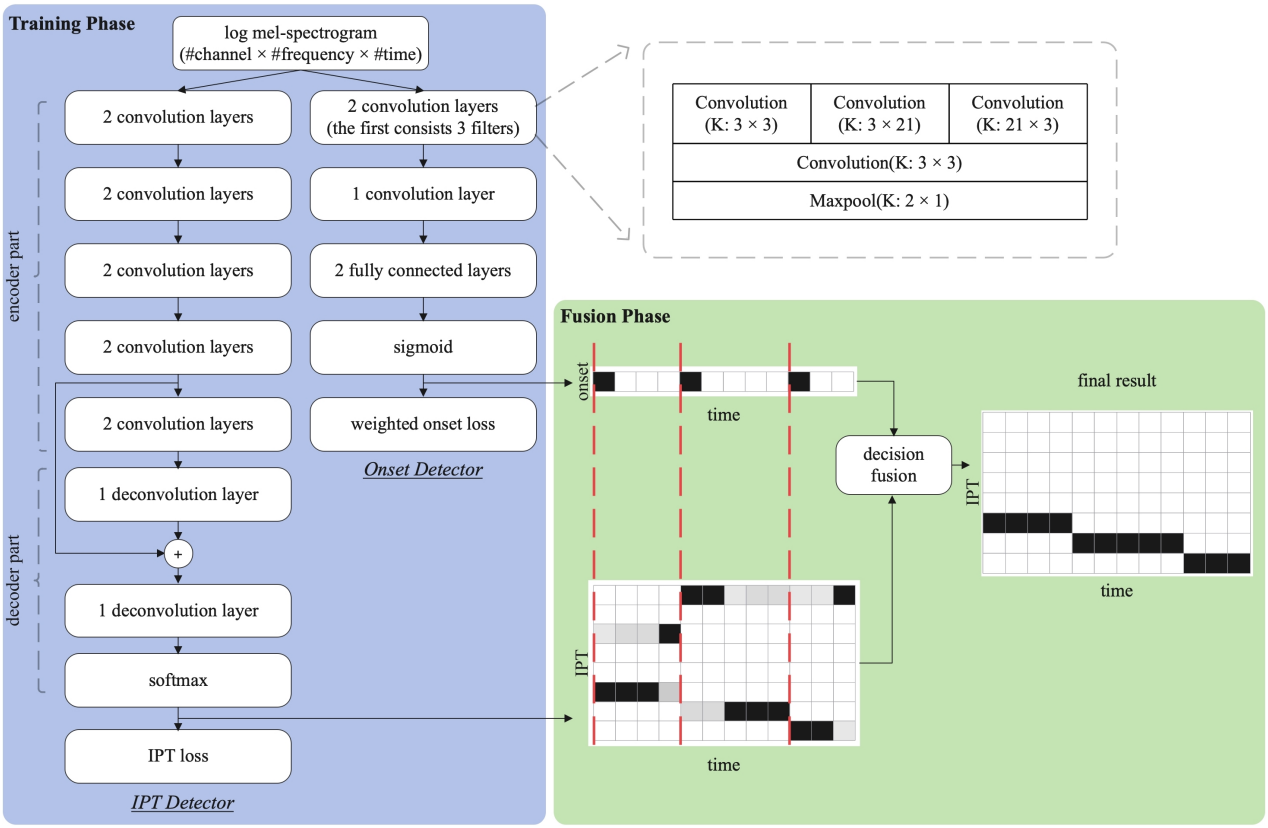

Figure 2. System architecture of our proposed model. In the training phase, the IPT detector and the onset detector were trained separately and then decision fusion was applied to their outputs in the fusion phase to get the final result. The vertical red dotted lines in the "fusion phase" stand for the starts of all onset predictions.

As shown in Figure 2, the IPT detector can be divided into the encoder and the decoder. The encoder part consists of five convolution modules. Two identical convolutional layers were stacked in each module and each of them has square (3×3)[4] filters. At each convolutional layer, zero padding was applied to make the output have the same length as the input and the output of every convolutional layer was then passed through a Rectified Linear Unit (ReLU). To apply our model to variable-length audio, a 1D max-pooling layer which only halve the length of frequency axis was implementd at the output of each convolution module followed by a dropout layer with the probability 0.25 to aid generalization. The output of the encoder part is the input of the decoder part which is made of two deconvolution layers. The decoder part is used for upsampling the feature map to the shape that we need and then make a frame-level prediction to the IPT. A skip connection of element-wise adding was used from the output of the fourth module in the encoder part to the first module output in the decoder part to help the decoder fuse the information.

4.3 Onset Detector

The onset detector is composed of two convolution modules, followed by two fully connected layers. The last layer is a fully connected sigmoid layer with 1 output for representing the probability of an onset for this frame. It has been suggested in recent research [20] that using different musically motivated filter shapes in the first convolutional layer of CNN could improve the model performance. As we discussed in Section 3, different playing techniques in Guzheng vary a lot in the temporal and spectral domain. Thus, we apply three filters of different shape (3×3, 3×21, 21×3) to the first convolutional layer and the 3×21 filter is designed to better capture the feature of long playing technique such as *portamento* or *glissando*. The following two convoliutional layers each has 3×3 filters.

We use weighted binary cross entropy (WBCE) loss as the loss function for our onset detector.

$$L_{onset} = mean(\sum_{t=0}^{T} WBCE(\beta, x_t, y_t)) \quad (1)$$

$$WBCE(\beta, x_t, y_t) = \beta y_t \log x_t + (2-\beta)(1-y_t)\log(1-x_t) \quad (2)$$

where T is the number of frames in the example, y_t is the label that is 1 when there is a ground truth onset at the frame t, x_t is the probability output by the model at frame t and β is the weight factor of the positive samples. Recent models in the onset detection research showed a lower recall than precision [16, 17] and it is largely caused by class imbalance that positive samples for onset are far less than the negative samples. So we decided to increase the weight of the positive samples to balance the performance of the model. We set β to 1.94 by coarse hyper-parameter search.

[4] 2D filters are noted: N frequency bins x M time frames.

model	Frame-level	Note-level		
	accuracy	precision	recall	F1-score
FCN+Onsets	**87.97**	**78.20**	**83.78**	**80.76**
Z.Wang's model [10]	69.44	35.18	47.45	39.53
J.-F. Ducher's model_Reproduced [8]	66.93	19.37	21.31	20.05
B.Liang's model_Reproduced [12]	53.98	41.38	44.50	42.81

Table 2. Frame-level accuracy and note-level precision, recall and F1-score on GZ_IsoTech dataset. Note-based scores calculated by the *mir_eval* library. Final metric is the mean of scores calculated per piece in the test set.

4.4 Fusion of IPT Detector and Onset Detector

In evaluation, the IPT detector and the onset detector are firstly used separately. Then we use a threshold of 0.5 to make the onset output binary. We separate the IPT output into several clips by the binary onset output. Then we selected an IPT as the final result of each clip by "voting" within it as described by Algorithm 1. We set n as the number of IPTs and t as the number of time frames. D_{onset} whose shape is [t] is the binary output of the onset detector. D_{IPT} whose shape is [n, t] is the raw output of the IPT detector, representing the probability of each IPT for each frame. D is the final one-hot result that implies the IPT at every frame. There are two intermediate variables in our algorithm. V whose shape is [n] represents the total "voting" score for each IPT in the current clip and b denotes the frame number where the current clip starts.

Algorithm 1 Decision fusion

  end for
  if $i+1 = t$ or $D_{onset}[i+1] = 1$ **then**
    $D[\text{argmax}(V)][b, \ldots, i] \leftarrow 1$
    $V[0, \ldots, n-1] \leftarrow 0$
    $b \leftarrow i+1$
  end if
end for
return D

5. EXPERIMENTS

In this section, we introduce the evaluation metrics we used, the details of the experiment and the result analyses.

5.1 Evaluation Metrics

The metrics used to evaluate a model consist of frame-level and note-level metrics. Note-level metrics include precision, recall, and F1 scores. They are calculated by the *mir_eval* library [21]. We require that both the IPT type and the onset are correct. In detail, an onset estimation is considered correct if it is within ± 0.05 seconds of the ground-truth. Frame-level accuracy is calculated by comparing the output of our model to the ground truth label frame by frame. More specifically, we calculated the ratio of the number of correct frames to the total number of frames as frame accuracy. Both note and frame scores are calculated every audio sequence and we calculated the mean of these scores as the final metric.

5.2 Results

To examine whether our proposed architecture (namely `FCN+Onsets`) can better detect IPTs in audio with continuous IPTs, we reproduced J.-F. Ducher's model [8], B.Liang's model [12] and Z.Wang's model [10] for comparison, while adapting their capacity to our data.

Because Z.Wang's model [10] cannot be tested on variable-length audio, we cut all the audio from the test set to 12.8 seconds long for the test of Z.Wang's model [10] while other models are still tested on variable-length data.

Table 2 shows the frame-level and note-level results of Guzheng playing technique detection on the GZ_IsoTech dataset. Our `FCN+Onsets` model reaches 87.97% in frame-level accuracy and 80.76% in note-level F1-score, producing the best scores in both frame-level and note-level metrics. Besides, our proposed model outperforms other models by a large margin in all metrics and results in over a 100% relative improvement in note-level F1-score compared to other models. This is mainly because our model takes better advantage of the note onset detection results which is highly interrelated to the note-level metrics. Because the test set consists of audio of real-world recordings that is different from training set in performer, instrument and recording environment, the results show that our model offers good generalization capabilities.

The visualization of the input spectrogram, the thresholded onset output, the raw IPT output, the final fusion result and the label for a recording from the test set are shown in Figure 3. Through the images in Figure 3, we can clearly see the importance of fusing IPT activations with onset predictions. The vertical red lines in the third and fourth images are the onset predictions. We can separate the audio into several notes using the onset predictions. Each note in our dataset only corresponds to one playing technique, but there may be several IPT predictions in one note as

model	Frame-level	Note-level		
	accuracy	precision	recall	F1-score
FCN+Onsets	**87.97**	78.20	**83.78**	**80.76**
CNN+Onsets	60.80	45.01	48.30	46.51
No Onset Fusion	76.48	27.74	50.55	35.47
Onset3×3	87.70	72.67	82.76	77.19
No Skip Connection	82.45	71.05	76.15	73.39
No Weighted Loss	86.26	**80.88**	79.46	80.03

Table 3. Ablation studies with frame-level accuracy and note-level precision, recall and F1-score on GZ_IsoTech dataset.

shown in the "Raw IPT Output" image. So we implement the decision fusion method to choose one IPT as the final output of a note as illustrated in Algorithm 1. The IPT results after being restricted by the onset are presented in the second-to-bottom image ("Final Fusion Result"). The "Target" image is the visualization of the truth label. As shown by Figure 3, the accuracy of the predictions in the "Final Fusion Result" image is far exceed that in the "Raw IPT Output" image.

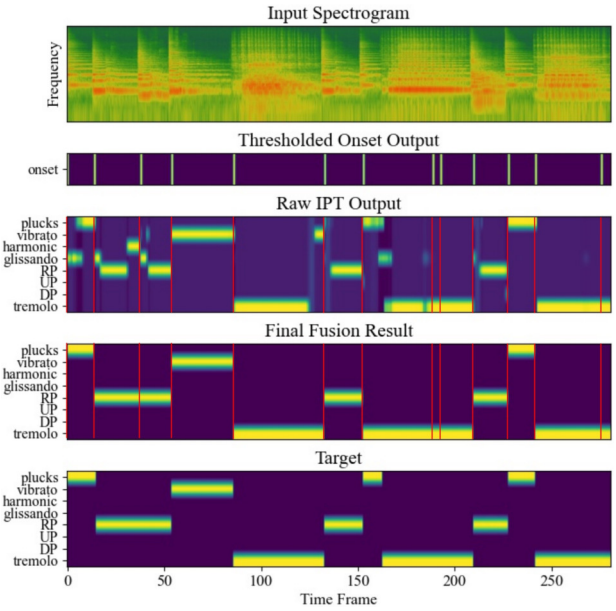

Figure 3. Inference on an audio in the test set. The log mel-spectrogram input, the thresholded onset output, the raw IPT output, the final fusion result and the target are shown from top to bottom. The vertical red lines in the third and fourth images are the onset predictions.

5.3 Ablation Studies

We conducted an ablation study where the performance of `FCN+Onsets` is compared with the following five models (namely `CNN+Onsets`, `No Onset Fusion`, `Onset3×3`, `No Skip Connection`, `No Weighted Loss`). In `CNN+Onsets`, we used the same CNN architecture for the IPT detector as presented in the onset detector instead of FCN. The result of `No Onset Fusion` is the output of the IPT detector without the decision fusion with the onset detector. In `Onset3×3`, we replaced the whole first convolutional layer of the onset detector by 3×3 filters. In `No Skip Connection`, we remove the skip connection part of the `FCN+Onsets` model. `No Weighted Loss` is the model that uses ordinary binary cross entropy (BCE) Loss in the onset detector.

The results show the importance of the onset information - `No Onset Fusion` results in a significant 11.49% decrease in the frame-level accuracy and a 45.29% decrease in the note-level F1-score. Our model can locate the IPT boundaries precisely and rectify some mispredicted frames for IPTs through fusing the IPT results with the note onset information. `CNN+Onsets` results in decreases in all metrics. It shows the FCN can better distinguish different IPTs than CNN. `No Skip Connection` shows a 5.52% decrease in frame-level accuracy and a 7.37% decrease in note-level F1-score. This proves the effectiveness of our skip-connection operation. `No Weighted Loss` has a little rise in note precision but decrease in all other metrics that shows weighted loss can better balance the precision and recall.

6. CONCLUSION

In this paper, we create a new dataset consisting of abundant Guzheng playing technique clips from multiple sound banks and real-world recordings. We propose an end-to-end Guzheng playing technique detection system using FCN that can be tested on variable-length audio. We propose a new decision fusion method where an onset detector is trained to divide an audio into several notes and the predicted IPTs are added frame by frame inside each note during fusion. The final output of each note is the IPT class with the highest probability within the note. Our method outperforms existing works by a large margin, which proves that our model is effective and offers good generalization capabilities that transfer well between different training and test sets. Moreover, by visualising the results, we find that the onset information is crucial for the Guzheng playing technique detection task.

In different genres of Guzheng music, there are slight differences in the same playing technique. In the future, we will continue to expand our dataset and add real-world Guzheng music pieces from different genres. Moreover, Guzheng is polyphonic and even one note may have more than one playing techniques. We will investigate how to detect more complicated playing techniques.

rafael.caro-repetto@kug.ac.at

ABSTRACT

Iranian *dastgāhi* music is considered as the classical repertory of contemporary Iran. In the 19th century, the melodic modes that developed during its long history were grouped in categories, each of them known as *dastgāh*. The *dastgāhi* system presents unique features, that have been object of musicological study since its inception. However, computational methods for its research are still scarce, due in good part to the lack of open, well curated corpora. The aim of the KUG *Dastgāhi* Corpus (KDC) is to contribute to the development of computational corpus driven research for this tradition. KDC is created following the FAIR principles, and in close collaboration with performers and scholars, who contribute to it with annotations and qualitative evaluations. Besides presenting the first version of KDC, in this paper we explore the possibilities that Iranian *dastgāhi* music offers to computational research. In order to test the performance of state-of-the-art technologies applied to this music tradition, we present preliminary results for several analytical tasks, and discuss their opportunities and limitations learnt in the process.

1. INTRODUCTION

The potential of computational methods for supporting musicological research tasks is increasingly being recognized and adopted by musicologists. Due to the high degree of specialization required both from the technical and musicological sides of this kind of research, collaboration between specialists from both disciplines is one of the most fruitful approaches for computational musicology. Developed at the Institute for Ethnomusicology of the Kunstuniversität Graz (KUG), the KUG *Dastgāhi* Corpus (KDC) aims to offer a growing collection of well curated and annotated data of Iranian *dastgāhi* music around which engineers, musicologists and researchers from other disciplines interested in this music tradition can collaborate. In this first section we describe the main features of the *dastgāhi* musical system and offer an overview of the state-of-the-art of its computational research. Then, we introduce and describe in detail the first version of KDC. In section 3 we discuss the potential of Iranian *dastgāhi* music for computational research. In the following sections, preliminary analyses carried out to test such potential are presented and discussed. The paper closes with our plan for expanding KDC and future work.

1.1 Iranian *dastgāhi* music

Iranian *dastgāhi* music is modal. The basic modal entities in this tradition are known as *guše*s and they are defined by a model melody built on a specific intervallic structure, a series of characteristic melodic patterns, and a modal centre known as *šāhed* [1]. Related *guše*s are grouped in specific collections, and in a specific order. These collections are known either as *dastgāh* or *āvāz*, each of them with its own specific name. A *dastgāh* is larger than an *āvāz* in terms of number of *guše*s, and an *āvāz* is considered to be a subcategory of a specific *dastgāh*. Nowadays, the canonical repertoire consists of 7 *dastgāh*s and 5 *āvāz*es (see Table 1). For simplicity, in this paper we are using *dastgāh* to refer to both of them collectively. The *guše*s in a particular *dastgāh* are organized in a fixed order, and even though the performance of a *dastgāh* does not required all its *guše*s to be performed, the order has to be maintained. The first *guše* in all *dastgāh*s is called *darāmad*, and it has a very significant meaning since it introduces the *dastgāh*. Most performances start and end with *darāmad*.

Along the history of Iranian *dastgāhi* music, great masters (*ostād*s) of this tradition defined their own canonical repertory of the 7 *dastgāh*s and 5 *āvāz*es, fixing the number of *guše*s in each of them, their particular order, their specific melodic contour and their rhythmic rendition. These canonical repertoires are known as *radif*s, always associated with their corresponding *ostād*. These fixed *radif*s are nowadays only used for learning the tradition. Contemporary musicians perform their own interpretation of the repertory, but through the rules they experientially extracted from the *radif* they learnt. As a more encompassing concept, different performance schools are recognized, each of them with idiosyncratic performance styles. The most extended ones today are Tabriz, Tehran and Isfahan.

Iranian *dastgāhi* music uses a microtonal tuning system, resulting in specific intervallic structures defined for each *guše*. Three basic interval categories are considered, namely tone, semitone and an intermediate one between the previous two, whose specific width is not fixed but flexible [1], depending on *guše* or even performer, and that is the result of altering one natural tone less than a semitone

© B. Nikzat, and R. Caro Repetto. Licensed under a Creative Commons Attribution 4.0 International License (CC BY 4.0). **Attribution:** B. Nikzat, and R. Caro Repetto, "KDC: An Open Corpus for Computational Research of *Dastgāhi* Music", in *Proc. of the 23rd Int. Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

up (*sori*) or down (*koron*). These intervallic structures form specific scales, in which particular tones receive predominant roles, such as *šāhed* and *ist*, which are fundamental for defining the modal features of a *guše*.

Specific techniques for vocal and instrumental performance, including an extensive repertory of ornamentation, is another essential aspect of this music, showing a great diversity depending on school, instrument, and personal style. The most common instrumental ornaments include: *ešāreh*, *tekiyeh*, *qalt*, *dorrāb*, *riz*, and *šalāl*. *Tahrir* is the most significant singing ornament, which requires a specific technique in which the singer switches between chest and head voice (see Fig. 5).

*Guše*s can be performed in free rhythm or using rhythmic cycles. Even though this is fixed per each *guše* in the *radif*s, it is decided by each musician in contemporary performance. When a *guše* is sung in free rhythm, the prosodic rules, known as *aruz*, of Persian classical poetry, to which most of the sung lyrics in Iranian *dastgāhi* music belong, informs the rhythmic rendition of the singing. This results in a characteristic rhythmic style that is also adopted when a *guše* is perfomed only instrumentally [2, 3]. *Aruz* not only informs musical rhythm through the sequence of long and short syllables, but also through the qualitative features of the vowels (*hejā*) [4, 5]. For metred performance, musicians can draw on rhythmic cycles known as *adwār-e iqāi*, the most common ones being *kerešme*, *čāhār-pāreh*, *zanguleh* and *gereyli* [4]. Each *dowr-e iqāi* is defined by a number of pulses, known as *naqareh*, and a structure of accents.

A typical ensemble of Iranian *dastgāhi* music is formed by *santur* (hammered zither), *tār* (long-neck lute), *setār* (long-neck lute), *ney* (bamboo flute), *kamanče* (spike fiddle), *tonbak* (goblet drum) and a singer. The music, however, is also commonly performed by a solo singer or instrumentalist.

Dastgāhi music is an oral tradition and conventionally the students learn it by memorizing a specific *radif* taught in private lessons by an *ostād*. The learning process is based on observation and imitation. In the contemporary context some teachers use transcriptions in staff notation as teaching material. However the notation functions just as memory aid, since many details cannot be represented in the staff notation system.

1.2 Computational analysis of Iranian *dastgāhi* music

Considering the magnitude of Iranian *dastgāhi* music, in terms of history, wide performance realm, complex theorization and extensive musicological research, this music tradition has received comparatively little attention from computational approaches. Pioneering work has been carried out by the researcher and *santur* performer Peyman Heydarian. Since his master thesis [6], Heydarian is working on the computational analysis of this instrument, especially its acoustic features [7–9], as well as on *dastgāhi* music performed in this instrument, with a special focus on *dastgāh* classification [10–12]. In fact, this second task, automatic *dastgāh* identification and classification, has been the most common one by other researchers who approached this tradition from computational methods [13–16].

Computationally aided musicological research on *dastgāhi* music is still very rare. Shafiei used score to audio alignment for the analysis of *tahrir* [17], while Sanati analysed intervals from *ney* recordings [18]. There has also been some work on *dastgāhi* music generation using deep neural networks [19].

We argue that one of the reasons that explains that the computational analysis of *dastgāhi* music is not yet been fully established in an unified trend, instead of occasional isolated works, is the lack of a comprehensive, publicly accessible datasets upon which continuous research can be built. All the publications referenced in the previous paragraphs gathered their own research datasets, but none of them offer any indication about possibilities for accessing them. Only Heydarian has been able to sustain a decades long research on this tradition based on his own dataset [20], but it is not public, and it only includes recordings of *santur*. Hence, the goal of KDC precisely is to contribute to the establishment of a coherent line of computational research on Iranian *dastgāhi* music by providing an open, well curated corpus of high quality recordings, upon which this research can be built.

2. DESCRIPTION OF KDC

KDC is conceived as an ever growing corpus, so in this paper we present its first version. Although far from its ideal size in terms of coverage, it already offers a coherent and comprehensive representation of the *dastgāhi system*. Currently, KCD contains 213 solo recordings by four professional musicians, 65 of which consist of complete *guše* performances and hence form the core of the corpus.

In order to analyse the corpus, we draw on the five criteria defined by Serra [21]:

Purpose: As described in section 1, KDC is created for the analysis of Iranian *dastgāhi* music using corpus driven computational methods. Due to the lack of a notational system originally devised for this music tradition, and the difficulties of staff notation for capturing key elements of this music, especially regarding tuning, intonation and ornamentation, KDC primarily aims at gathering audio recordings. However, the inclusion of other data types, such as scores, lyrics, videos, images, etc., that might contribute to the general purpose of the corpus, is not excluded. A key point in the creation of KDC is the close collaboration with musicians. They do not only contribute with recordings and annotations, but also with their knowledge, evaluation, and research ideas. Musicians are thus considered as active collaborators of KDC.

Coverage: According with KDC's purpose, we focus on voice and melodic instruments. In this first version of the corpus, being one of our goals to test state-of-the-art technologies for the analysis of this music tradition, we have focused on solo performances, and consciously excluded ensemble performances, that would present a greater challenge for computational analysis. In order to

		Performance		*Šāhed*	*Ist*	Pitch Set	*Radif*

ney	R. Zalpour, M. Khodadadi	37	45:54
setār	M. Shaari	35	47:57
Total		96	131:41

Table 2. Number of performance and *radif* recordings in KDC according to instrument.

build a first dataset that provides a coherent and comprehensive representation of the *dastgāh* system, this first version of KDC contains the first *guše* of all 7 *dastgāh*s and 5 *āvāz*es, known as *darāmad*, which holds great significance (see section 1.1). Four professional musicians (see Table 2) have contributed to KDC with original recordings of complete performances [1] of these 12 *darāmad*s. Hence, the corpus currently contains five full renditions of the 12 *darāmad*s, namely, two vocal ones, one female and one male (with the exception of the *darāmad* of *dastgāh rāst-panjgāh*, whose female vocal rendition could not be recorded), two by *ney*, and one by *setār*. According to their own decision, the musicians occasionally recorded more than one version of a particular *darāmad*, and all of them are included in the corpus. This results in 65 performance recordings, which is the core of KDC (see Table 1).

Completeness: KDC includes a csv file with metadata and annotations for all recordings, including the corresponding *dastgāh*, *guše*, artist, instrument, recording type, and duration. Considering the methodological purpose of the corpus, the musicians who collaborate with KDC were asked to record the *šāhed* of the performed *darāmad* as a single, stable pitch. The 59 resulting recordings are included in KDC, and they were used to compute the frequency of the *šāhed*, [2] which is added as an annotation in the metadata file. The musicians who collaborate with KDC show a great interest in the project and actively propose contributions to it, according to their understanding of which data could benefit the purpose of KDC. As a consequence, some musicians recorded the *ist* of the performed *darāmad* in a separate file as a single, stable pitch, resulting in 38 recordings, the corresponding pitch set, resulting in 20 recordings, and one or more related performances according to *radif* (see Table 1). Since pattern analysis is a key task for the study of Iranian *dastgāh*s, two of the collaborator musicians manually annotated the characteristic patterns that identify the performed *guše* using the software Praat [23]. Each of them annotated two full renditions of the 12 *darāmad*s, so that only the *setār* recordings are still not annotated in terms for patterns.

Quality: all the recordings in KDC are provided in the lossless compression format flac. The recordings by M. Shaari and F. Sahebghalam were recorded in a professional recording studio at KUG, those by M. Khodadadi were recorded by the first author using a Zoom H4 recorder, and those by R. Zalpour by himself using his cell phone. The musicians, all having previous recording experience, evaluated the quality of their own recordings both in terms of sound and performance quality and agreed to include them in KDC as good representatives of their art. To validate the pitch frequencies of *šāhed*, mp3 files were generated, and R. Zalpour assessed their correctness.

Reusability: All the collaborator musicians contributed their recordings to KDC for them to be published under the Creative Commons Attribution-NonCommercial-NoDerivatives 4.0 International License (CC BY-NC-ND 4.0). [3] In order to ensure the reusability of KDC, we follow the FAIR principles. [4] To ensure that all recordings are findable and reusable, they are made available through the KUG's Phaidra repository. [5] Regarding accessibility, the

[1] Given its improvisational nature, there is no standard rendition of a particular *guše*. By complete performance we mean a rendition that completely conveys the performed *guše*.

[2] The pitch of the *šāhed* was computed with the pYin: Notes plugin [22] of Sonic Visualiser

[4] https://www.go-fair.org/fair-principles/

[5] The following Phaidra collection is created for KDC: https://phaidra.kug.ac.at/view/o:127195

metadata of all recordings are also stored in MusicBrainz [6] in its original Farsi and with English aliases, and linked to their corresponding Phaidra objects. A specific protocol for interoperable structuring of Iranian *dastgāhi* music is still being developed, and is expected to be evolving along with the expansion of the corpus.

3. RESEARCH POTENTIAL OF KDC

The hypothesis that motivated the KDC project is the conviction that musicological study of Iranian *dastgāhi* music can deeply benefit from computational methods. Conversely, we argue that the characteristics of this music raise interesting research tasks for music information retrieval. In this section we point out some of the most relevant of these tasks. Since KDC was created with the purpose of researching the modal aspect of this music, tasks related to this domain are described in more detail.

3.1 Melody and mode

The study of melody in Iranian *dastgāhi* music is one of the most essential tasks, especially for the purpose of KDC, therefore pitch track extraction is essential. According to our preliminary analyses, state-of-the-art algorithms perform satisfactorily for monophonic recordings as those by voice or *ney*. However, further research is still needed to obtain equally satisfactory results for instruments with high resonance as the *setār* (see section 4). A relevant research task based on these pitch tracks is the corpus driven analysis of vibrato and *tahrir* (see Fig. 5). Their automatic identification and measurement would contribute to their deeper understanding, but also to better define school styles, or idiomatic performance for specific instruments.

Tasks conducing to the characterization of *guše*s are also of key importance. A particularly relevant one is automatic pattern analysis. A main challenge for this task from the computational point of view is evaluation. In order to contribute to that, KDC includes manual annotations by expert musicians. Analyses of each *guše*'s tonal hierarchy are also essential, especially those contributing to the understanding of concepts like *šahed* or *ist* (see section 1.1).

Given the classification system of *guše*s, *dastgāh*s and *āvāz*es, this music tradition is well suited for automatic recognition and classification tasks, which in fact are the ones most commonly explored to date (see section 1.2).

Finally, even though Iranian *dastgāhi* music is not easily represented on staff notation, a tradition of transcriptions using this notation system exists. This music then can be also taken as a challenging case for automatic transcription, for which existing scores (currently only in print) can be used for evaluation.

3.2 Other musical aspects

Iranian *dastgāhi* music offers interesting tasks for rhythm research. In metred performance, automatic *dowr-e iqāi* detection becomes a significant challenge, given the heterophonic nature of ensemble performance and the timbral and stylistic characteristic of solo performance. Expressive microtiming deviations from isochrony is a meaningful analysis for characterising performance style. Unmetred performance of *dastgāhi* music offers a great opportunity for multimodal analysis combining audio and lyrics analysis (this would require incorporating text data to KDC). Natural Language Processing methods can be applied to model the prosodic features of *aruz*, that can later be mapped to music performance.

Timbre is a very diverse and expressive feature of Iranian *dastgāhi* music performance. Combined with nuances in dynamics, singers use vowel shades to introduce variability in sustained notes. Equally, *ney* performers use a wide range of timbres from bright, clean ones to raspy, breathy ones. Automatic analysis of the timbral categories can inform about stylistic preferences and if a relationship exists with specific *guše*s. The use of dynamics is another important element in Iranian *dastgāhi* music expressivity, and its computational analysis can shed light about its systematic or stylistic use.

4. PRELIMINARY ANALYSES

In order to test the potential of KDC as described in the previous section, we carried out a series of preliminary analyses. The current size of KDC does not allow to obtain general conclusions about Iranian *dastgāhi* music. Our aim is to explore the possibilities for computational methods, and therefore to suggest further lines of research for future stages of KDC.

Since our main interest is the melodic dimension of *dastgāhi* music, our analysis started with pitch track extraction. To that aim, we applied the CREPE algorithm [24] to all monophonic recordings of KDC, that is, those by voice and *ney*. After visual and aural examination, we concluded that state-of-the-art algorithms, both for monophonic and polyphonic signals, [7] do not produce results usable for further analysis on the recordings of *setār*, an instrument with high, and sought after, resonance and common use of chords. Consequently, the recordings by *setār* were excluded for these analyses. In order to ensure reproducibility, the data, metadata and annotations used for these analyses are shared as a dataset. [8] The code and resulting plots are also shared in a public repository. [9]

4.1 *Šāhed*

In order to study *šāhed*, we compute pitch histograms from the previously extracted pitch tracks using the algorithm developed in [27]. The histograms are computed in cents aligned to the *šāhed* that KDC has annotated for each individual recording. We also compute pitch histograms for the aggregated pitch tracks of all recordings of the same

[6] The following MusicBrainz collection is created for KDC: https://musicbrainz.org/collection/6ee214c7-f116-4691-b46d-36033c8b17b0

[7] Pitch extraction was attempted on the *setār* recordings using the algorithms CREPE [24], pYin [22] and Melodia [25], the last two in their Sonic Visualiser [26] plug-in version.

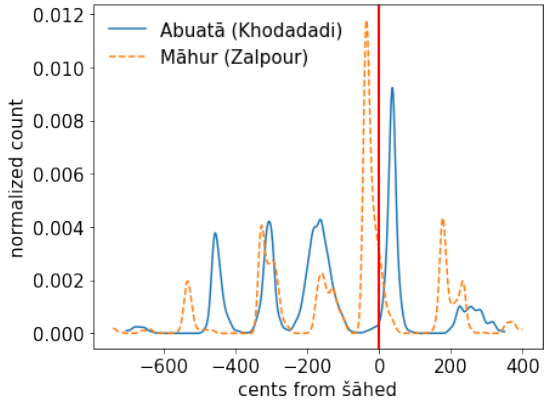

Figure 2. Pitch histograms of two *ney* recordings. The vertical line indicates the *šāhed*

dastgāh. Besides, histograms folded to one octave are also computed for individual recordings and for *dastgāh*s.

One of the most discussed issues in Iranian classical music is the concept of *šāhed*. Different definitions for this concept can be found in the existing literature. According to Farhat, "[i]n most of the Persian modes one tone assumes a conspicuously prominent role. It may or may not be the finalis" [1]. Nooshin argues that *šāhed* is "[t]he most prominent pitch, functioning as the tonal center of the mode" [28], while Talai defines it as "[t]he most frequently repeated pitch" [29]. We argue that corpus driven analyses can help to examine which of the definitions for *šāhed*, namely, "prominent" tone, "tonal center" or "most frequently repeated" tone better represents our results.

Fig. 1 shows the folded pitch histograms of three different performances of the same *guše*, *darāmad abuatā*. It can be seen how the *šāhed* is the most frequent tone in M. Khodadadi's performance, but that is not the case in the two ones by R. Zalpour, both vocal and *ney*. This preliminary result, together with other examples not mentioned here, suggests a more nuanced understanding of *šāhed*, that would escape a unique, universally applicable definition.

Mus. (inst.)	Mean	SD	Lowest	Highest
Saheb. (voice)	4.19	10.28	-10.11	28.10
Zalp. (voice)	6.92	7.26	-5.02	16.46
Zalp. (*ney*)	-3.19	16.87	-35.43	23.99
Khod. (*ney*)	13.95	13.70	-7.69	37.07

Table 3. Mean and SD of the differences in cents between the *šāhed*'s pitch in their isolated recordings and in performance per musician and instrument. The difference between the lowest and highest performance of the *šāhed* compared with the isolated recording is also given in cents.

4.2 Intonation

One interesting issue is the musicians' abstract notion of the *šāhed*'s pitch and its actual intonation in performance. Since all the collaborator musicians recorded the *šāhed* of their performances as an extra, isolated file according to their aforementioned abstract notion, we can compare its pitch in both contexts. Fig. 2 shows how M. Khodadadi performs the *šāhed* 37.07 cents higher than the isolated version he recorded himself, whilst R. Zalpour performs it 35.43 cents lower. We computed the difference between isolated *šāhed* and its performed version (obtained from the value of the closest peak in the histogram) for all recordings (excluding *setār*), and calculated the mean and SD for each musician and instrument, as it can be seen in Table 3. The results show a great variability in the divergence between conceptualized and performed *šāhed*, frequently reaching easily audible deviations.

These observations points to an interesting line of future research regarding the perception of intervallic structures by musicians. The specific width of the intervals of a particular *guše*, an essential element for the conceptualization of Iranian *dastgāhi* music, is part of the implicit knowledge of each individual musician, enacted mainly during performance. Their intellectual formulation, as the examples here analysed suggest, might no correspond with this implicit knowledge.

4.3 Pitch alteration

In some *gušes* specific degrees can be rendered by two neighbouring pitches. For example, in the case of *darāmad afšāri*, the degree above the *šāhed* can be performed at 119 cents above it, which is considered the main tone for this degree, or at 204 cents over the *šāhed*, which is considered an altered version of the same degree, as it can be seen in Fig. 3 (cent values computed according to [1]). These altered pitches are known as *not-e moteġayer* [1,30]. The use of this pitch alteration can be observed in pitch histograms as flat peaks, as it can be seen in Fig. 4 around 200 cents. These results point to another interesting line of research, for the computational detection of *not-e moteġayer* that can contribute to the better characterization of *gušes*.

4.4 Vibrato and *tahrir*

In order to analyse vibrato, we ran the Vibrato algorithm available in the Essentia library [31] on all recordings, and

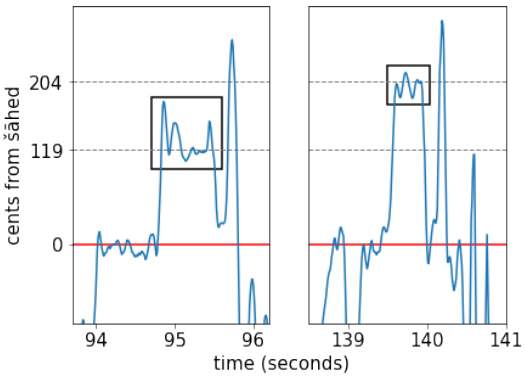

Figure 3. Two excerpts of the the pitch track of the of the vocal recording of *darāmad afšāri* by F. Sahebghalam. The horizontal red line indicates the *šāhed*, the gray line at 119 cents indicates the main pitch, whose corresponding *not-e moteġayer* is indicated by the gray line at 204 cents. The boxes mark the performance of these two notes.

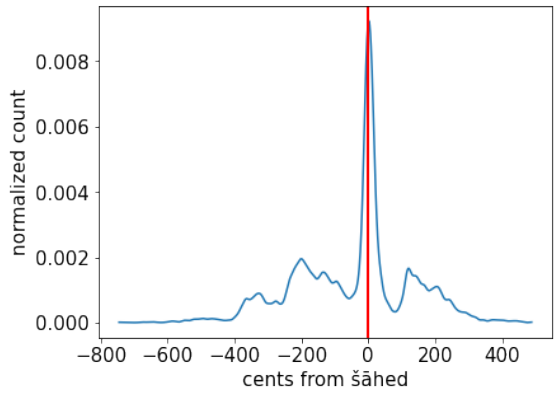

Figure 4. Pitch histogram of the vocal recording of *darāmad afšāri* by F. Sahebghalam. The vertical line indicates the *šāhed*

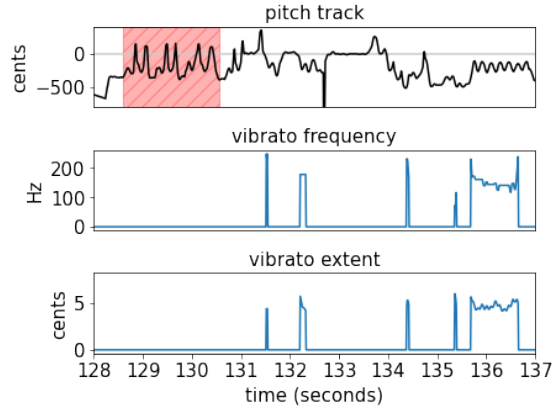

Figure 5. Excerpt of the recording of *darāmad abuatā* by F. Sahebghalam. Upper plot shows pitch track (horizontal line indicates *šāhed*), middle plot detected vibrato frequency, and lower plot detected vibrato extent. Highlighted section shows *tahrir*.

the results were plotted against the pitch track (see Fig. 5 for an example). These results, stored as csv files, together with the plots for all recordings are available in the code repository. Through visual evaluation of the results we argue that further research is required in order to improve automatic detection of vibrato for this tradition.

Dastgāhi music is an idiomatic tradition. Vocal and instrumental performances are characterized by specific techniques and sound qualities, being vibrato a relevant one. Its extent, frequency and occurrence are idiomatically specified by instrument, school or personal style. Automatic vibrato detection and measurement can contribute to characterizing idiomatic styles. Another important vocal technique is *tahrir*, which consists in wide cyclic pitch alteration of a particular tone in terms of pitch and timber. The pitch fluctuation is not realized as glissandi but jumps, and this might explain why it is not detected by the used algorithm, as shown in Fig. 5. Analysing the difference between these two techniques would help to understand the idiomatic practices in Iranian *dastgāhi* music.

5. CONCLUSIONS AND FUTURE WORK

With KDC we set a very ambitious goal: to create an open, well curated, ever growing corpus of Iranian *dastgāhi* music data, metadata and expert annotations which can contribute to the development of a coherent line of computational research for this music tradition. This is a task that requires collaborative efforts from musicologists, musicians and computer engineers. KDC is still in its infancy, but its first version presented in this paper is complete enough to test state-of-the-art methodologies, obtain preliminary results, and consequently propose new directions for future research.

The expansion of KDC is and is going to be a constant future task. As any other aspect of our lives in the past two years, the COVID-19 pandemic has hindered the development of KDC with the suspension of international travels (economic sanctions against Iran prevent working with musicians living in the country from outside). Besides the addition of recordings that cover new *gušes*, instruments and schools, increasing the number of expert annotations is one of our short term goals. In a first stage, we aim at having the 5 renditions of the whole set of 12 *daramād*s annotated at least by three different musicians, so that we can start studying this phenomenon from the perception of the performers.

Regarding computational analysis, a short term goal is to seek collaborations to perform automatic pattern analysis. This is a fundamental element for the characterization of *gušes*, and most of our collaborator musicians have highlighted the importance of this task and their interest in it. The annotations currently existing in KDC are aimed to this goal. Other tasks that are of our interest, and for which collaboration with computer engineers is also necessary, is the improvement of pitch track extraction for instruments with great resonance as *setār*. Finally, collaboration will also be sought for the development of methods for automatic *tahrir* detection and analysis.

6. ACKNOWLEDGEMENTS

The authors would like to express their sincerest gratitude and acknowledgement to their collaborator musicians Masoud Shaari, Farahnaz Sahebghalam, Reza Zalpour and Mohammad Khodadadi, not only for contributing their recordings and ideas to KDC, but also for their enthusiastic support to the project. We would also like to thank Dr. Negar Bouban and Reza Zalpour for their very valuable manual annotations of melodic patterns. Finally, we thank Kunstuniversität Graz for the financial support that makes KDC possible.

INACCURATE PREDICTION OR GENRE EVOLUTION? RETHINKING GENRE CLASSIFICATION

Ke Nie
University of California, San Diego
knie@ucsd.edu

ABSTRACT

The existing MIR research on genre classification primarily focuses on how to classify a song into the "correct" genre while downplaying the fact that genres mutate over time and in response to social change in terms of their musical properties. Songs claiming the same genre can sound very different if they are released years apart, and genres may revive musical traditions from the past. In this paper, I show that the performance of genre classifiers fluctuates as genres evolve. Unsatisfactory performance of the classifiers may not indicate algorithmic flaws but rather the change of genre characteristics. I demonstrate this by studying the case of Chinese Hip-Hop music. Specifically, I collected and analyzed 69,427 songs from four genres (Hip-Hop, Pop, Rock, and Folk) released on a Chinese music platform between 2009 and 2019. Using classifiers trained from the songs in different year cohorts to predict the genre of all the songs, I show how genre classifiers can be used to detect the stylistic shift in Hip-Hop that happened during this period. The paper thus offers a novel, sociological perspective on contending with the much-challenged idea of improving genre classification accuracy for its own sake. However, instead of questioning the effort, I argue that MIR research on genre classification can be helpful for studying genre as a social construct and cultural phenomenon if the pursuit of prediction performance and the cultural meaning of inaccurate prediction are carefully balanced.

1. INTRODUCTION

Past MIR research on genre classification has primarily strived to find ways for algorithms to correctly detect music genres. Numerous studies have experimented with various data sources, algorithmic approaches, and evaluation metrics to improve algorithmic attempts to grasp the characteristics of music genres [1-7]. Most of the existing studies rely on fixed datasets and metrics to evaluate the performance of classifiers for the convenience of comparison.

One major concern in this area, however, is that genre is an ambiguous concept [8]. After all, what distinguishes one genre from another is *subjective*, since it is "based upon subjective responses with little inter-participant consensus" [3]. This is because the boundaries according to which genres are distinguished are not entirely rooted in the musical or sonic elements; rather, they are based on people's understanding of the difference between genres, which depends on their cognitive perception and cultural knowledge [3,9]. In fact, research has found that human evaluators may also be ambivalent about the classification of genres, which problematizes the very idea of genre and challenges the purpose of classification tasks [10, 11].

Adding to this line of questioning, this paper underscores the social dimension of genres that further complicates the concept by exploring critical implications for the design and implementation of genre classifiers. I argue that genres are social constructs that constantly change over time and in response to social, economic, and political pressure [12-15]; therefore, if genres evolve, the performance of genre classifiers trained on songs from precedented cohorts will fluctuate in predicting future cohorts. Given this feature, I argue that the "inaccurate" prediction of genre classifiers can be used to detect and map the evolution of genres. I demonstrate this point by presenting a case study of Chinese Hip-Hop music. Using songs from different year cohorts as the training set, I show that the performance of the classifiers mutates over time as the genre evolves. The findings demonstrate that prediction accuracy may not be the most valuable feature of algorithmic classifiers and that inaccurate predictions may suggest genre evolution.

This paper is organized as follows. In Section 2, I review the current MIR research on genre classification tasks and identify the common concern shared in this research area regarding the ambiguity of the genre concept. I propose taking a deeper look at the social dimension of genres, a generally understudied subject in the MIR field, as a way to advance our understanding of the evaluation of genre classifiers. In Section 3, I present the case of Hip-Hop music in China, a genre that has enjoyed a dramatic turn of events in the past decade. Drawing from different pieces of evidence, in Section 4 I show how the evolution of genre could complicate the performance of genre classifiers and how classifiers can be used to help understand the development of a genre. I then conclude the paper by discussing the impacts of genre evolution on the design and performance of genre classifiers.

2. RELATED WORK

The existing MIR literature on genre classification is primarily aimed at exploring, devising, and experimenting with algorithmic designs that could be used to understand and predict music genres automatically. These studies can be roughly categorized into three main themes.

First and foremost, researchers have attempted to identify different kinds of *data sources* that are useful for earmarking the characteristics of music genres, such as music and sonic features extracted from the digital signals of the songs [1], as well as information on the performers, musicians, communities, and other social-cultural features associated with the genre [2]. Second, contingent upon the data sources mentioned above, researchers have been trying to improve on the *algorithmic approaches* to achieve better performance in genre classification tasks by experimenting with various types of acoustic representations (MFCCs, spectrograms, etc.) and machine learning architectures (SVM, CNN, etc.) [4,5,6,7,8,16]. The primary goal here is to improve the accuracy of the classification algorithms, which are usually tested on an existing dataset.

Studies aligned with the above two themes have explored pathbreaking methods through which genre classification tasks are performed at higher accuracy. Nevertheless, some scholars have also reflected on the *evaluation metrics* of genre classifiers, arguing that "accuracy is not enough," as genre classification is essentially a task of musical recognition rather than classification accuracy [17,18]. Furthermore, researchers highlight the ambiguity of the concept of "genre" itself, pointing out that the notion is essentially "subjective" [3]; therefore, human evaluation needs to be included in the process [19]. While there is suspicion about the validity of genre classification tasks due to the ambiguity of the genre concept, most scholars still acknowledge the relevance of the research while looking for instruments to mitigate the problem of subjectivity [11]. Previous studies from this third, reflective approach have shared incisive thoughts on how to refine algorithmic frameworks for better classification performance.

Following past reflections on this issue, I want to further point out that genre is a social construct that depends on mutual agreement among evaluators or the community as a whole. This view is close to that of the social scientists and business scholars of the music industry, who have long argued that genres are classificatory apparatuses used by producers, consumers, and intermediaries to make sense of a distinct type of music [12-14]. This sociological view of genre claims that while music content may matter in the identification of genre, genres are, above all, divided by communities. This helps explain cases where different genres sound similar to each other or where the same genre may sound very different in different regions. For example, sociologist William Roy pointed out that "hillbilly music" and "race records" in the 1920s America were two genres that were associated with the same type of music, although the former was used as a market label for African American audience while the latter was for the "rural whites" due to segregations at the time [20]. They are, nevertheless, considered two disparate "genres" as they are tied to different communities.

A more important component of the sociological view of genre that is usually underplayed in the MIR research is that genres can evolve. In other words, the way in which genre classification systems upon which producers, consumers, and intermediaries agree to distinguish different types of music can change across time and localities [12,13]. Additionally, genre categories may also evolve in response to external shocks to the industry or the social environment in general. One example is the case of censorship, in which censored genres have to change their content in response to political pressure [15]. Similarly, advancements in technology or sound devices also help to define or shift music genres, such as the use of the Roland TR-808 as the defining sound of early-1980s Hip-Hop music. The idea here is that genres are constantly shaped and reshaped by social, economic, and political forces; therefore, they cannot be seen as fixed, immutable entities.

The mutability of genre adds a further question to the design of genre classification algorithms in terms of their data sources, algorithmic architecture, and evaluation metrics. This paper attempts to address the issue of evaluation specifically. If genres evolve over time, one should then expect that the classification accuracy of a genre classifier will drop when it is used to predict the songs that are released a long time apart from the songs that were used to train the classifier. Specifically, we may expect that a classifier that was trained on a set of songs released in the 1980s will have a harder time predicting the correct genre of songs from the 2010s than songs from the 1990s. In this case, the accuracy metric is not useful for understanding the performance of the classifier. Rather, the evaluation metrics may have a richer meaning than simply as a criterion for making the genre distinction: they may be used to understand how genre evolves or how genres influence each other. For example, inaccurate predictions may not necessarily indicate algorithmic flaws; they may imply that the actual genre is moving toward the predicted genre in terms of its sound. The trickiest part of making such a claim, however, is how to distinguish genre evolution from the drawbacks of the algorithmic design when prediction accuracy is low. This will be discussed further in the analysis and discussion sections below.

3. DATA & METHOD

To demonstrate how genre evolution may confound the performance of genre classifiers, I study the case of Chinese Hip-Hop music from the past decade. Hip-Hop has long been a relatively low-profile genre in China since it was introduced to the country in the 1990s [21]. In recent years, however, Chinese Hip-Hop experienced a series of dramatic external shocks, which elevated the genre's prominence extraordinarily. In summer 2017, the first season of *The Rap of China* started to stream on iQiyi, one of the most popular streaming platforms in China. The reality-show-style music competition attracted an unexpectedly expansive audience, securing 2.7 billion views in the

course of three months and becoming the most successful online program ever in the history of the sector. The contestants featured in this program, as well as their music, soon became the iconic representatives of an unprecedented fad. Most significantly, many of the high-profile contestants, including the co-winners of the competition, GAI and PG One, were known for their involvement in Trap music, a style that originated in the Southern United States and is characterized by its distinct use of synthesized drums (above all, Roland 808 drums). Moreover, it is remarkably different from the jazzy, pop-oriented Hip-Hop style prevalent in the genre before. In January 2018, Hip-Hop's rise was met with state censorship aimed at blocking Hip-Hop musicians from mainstream media, as the state was concerned about past Hip-Hop figures' problematic practices of including subversive and delinquent content in their songs. Although many musicians had to remove some of their songs from the internet under political pressure, Hip-Hop songs, in general, were still allowed to circulate online via music streaming platforms, and the censorship loosened up six months later without any official announcement [15].

The story of Chinese Hip-Hop music thus provides an interesting case for investigating the issue of genre evolution, as the genre became remarkably popular and potentially turned in a new stylistic direction due to the success of *The Rap of China*. To understand the impact of this stylistic change on machine learning classifiers, I collected songs from one of the most popular music streaming platforms in China. I collected the songs' audio files, as well as their metadata, including their genre and tags. The platform's setup requires each song to have only one identified genre, while the song can have multiple tags that are considered its "subgenres." Because of copyright issues, only a portion of the available songs could be downloaded at the time of the data collection in September 2019. Eventually, I collected 69,427 songs released between 2009 and September 2019 from four genres (Hip-Hop, Pop, Rock, and Folk), constituting the dataset on which I conducted my analysis. The other three genres are also well established in China in that they have distinct fanbases, although the Chinese Hip-Hop community was more connected to the Rock community particularly in the early 2000s for sharing resources and venues [22].

The structure of the dataset is given in Figure 1 below. As shown in the graphic, the number of total song releases consistently increases over the years, with the exception of the year 2019, when the data collection was suspended. The data and the code for the following analysis are publicly available,[1] although the metadata of the songs is left out due to copyright issues.

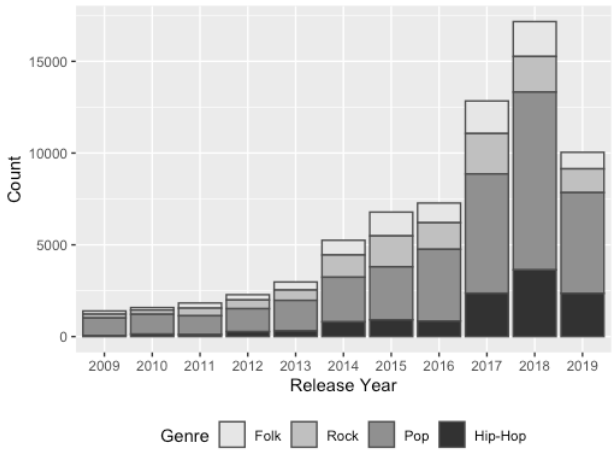

Figure 1. The structure of the dataset. The height of the bar represents the number of releases.

I used librosa [23] to extract sonic features from the audio files to prepare for training the classifiers. As my goal was not to improve classification accuracy, I followed Tzanetakis & Cook's [1] classic approach for computational efficiency. Specifically, I sliced a 1-minute long excerpt of audio signals from each song starting at 30 seconds into the song, which supposedly captures a substantive part of the song, and extracted 11 timbral texture features from this slice, including the chroma features (chroma_stft), root-mean-square of the spectrogram (rms), spectral centroid (spectral_centroid), spectral bandwidth (spectral_bandwidth), spectral roll-off (spectral_rolloff), zero-crossing rate (zero_crossing_rate), and the first five Mel-frequency cepstral coefficients (MFCC). I normalized the value of the features using a 0-1 scale and took the means of the features for each song, resulting in an 11-dimensional feature vector.

I used the songs released in 2009 and 2018, respectively, to train the genre classifiers. They represent the first and the last full year in the dataset, a fact that can be conveniently used to track changes over the year. I also used the widely studied GTZAN dataset [1] — its filtered version [24] due to the errors in the original collection [25] — as a supplementary check of the classifiers' performance trained on a dataset from a different time and region. For each of these three cohorts, I trained four classifiers: a Gaussian Naïve Bayes classifier (hereafter, GNB), a K-Nearest Neighbor classifier (hereafter, KNN), a Random Forest classifier (hereafter, RF), and a classifier trained by Extreme Gradient Boosting, a more recently prevailing tree-based algorithm. They were used in parallel to triangulate the results. For the 2009 cohort, I picked the top 50 most streamed songs of each genre, for a total of 200 songs, to compile the training set, whereas for the 2018 cohort, I picked the top 1900 songs of each genre, totaling 7600 songs. My reason for choosing these two numbers is that they are the closest number that can be divided by ten to the total number of releases of a genre with the least releases in that year (54 Hip-Hop songs in 2009; 1902 Folk

[1] The data can be found at https://github.com/norzvic.

songs in 2018), making it convenient for a 4:1 split for training and testing the classifiers. For the GTZAN dataset, I only used the data for three genres — Pop, Rock, and Hip-Hop — to train the classifiers, as there is no "Folk" in the GTZAN dataset. I extracted the data on the 11 features, normalized them, and used all 300 songs from the three genres in the dataset to train four classifiers similarly. The performance of the classifiers is shown in Table 1. I then used all four sets of classifiers to predict the genre of all the songs in the dataset, the results of which are reported in the next section.

		2009	2018	GTZAN
GNB	Acc	0.575	0.472	0.750
	AUC	0.832	0.755	0.867
KNN	Acc	0.625	0.584	0.800
	AUC	0.646	0.578	0.608
RF	Acc	0.800	0.580	0.833
	AUC	0.908	0.786	0.927
XGB	Acc	0.700	0.629	0.732
	AUC	0.905	0.864	0.916

Table 1. The performance of the classifiers across cohorts. Acc refers to the accuracy of predicting the test set, whereas AUC refers to the corresponding area under the ROC line for multi-classes.

4. FINDINGS

4.1 Overall Accuracy and Recall

As the focus of this study is Hip-Hop, I will primarily heed two metrics: Hip-Hop accuracy and Hip-Hop recall. Here, Hip-Hop accuracy refers to the rate at which the classifier correctly identifies Hip-Hop versus non-Hip-Hop, whereas Hip-Hop recall refers to the rate at which the classifier correctly identifies Hip-Hop among true Hip-Hop songs. The reason to incorporate recall is that the metric can be useful to detect potential genre evolution: the lower the recall is, the more probable that a Hip-Hop song is classified to other genres, which could mean that the genre is straying away from the sound captured by the training set.

The overall performance of the classifiers is shown in Figure 2. The "Average" column on the right of the graphic takes the average value of the corresponding metrics of the left three classifiers, showing an average trend of the metrics. The graphic demonstrates that the performance of most classifiers follows a fuzzy U-shape trend, with higher values at the start and the end than in the middle years of the dataset. The U-shape trend is statistically tested by a series of polynomial regressions of the metric on year and its quadratic term. In particular, the U-shape is demonstrable in the performance of the averaged classifier. All three recalls from the averaged classifier (bottom right of Figure 2) fit a polynomial regression on year and its quadratic term, where their coefficients are all statistically significant ($p < 0.05$). On the other hand, only the averaged classifier trained from the 2018 cohort songs yields significant results in the regression of accuracy on year and its quadratic term, while the other two averaged classifiers did not.

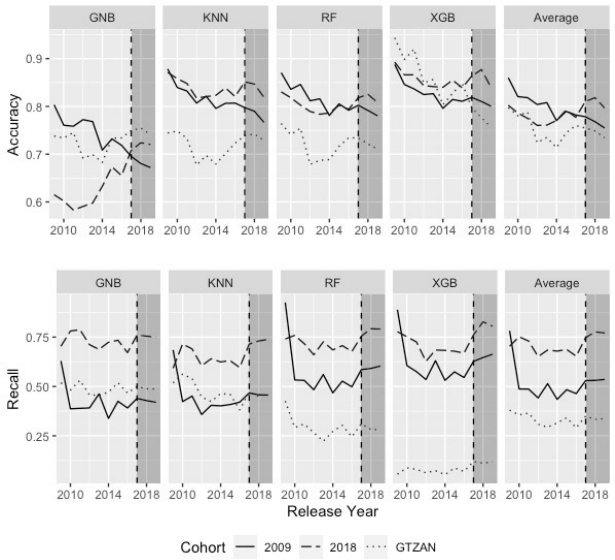

Figure 2. Hip-Hop accuracy and recall across cohorts and classifiers. The darker section on the right of each grid indicates the years since the first season of *The Rap of China* in 2017.

The results from the recalls, which imply how the true Hip-Hop songs of each year are similar to those of the benchmark cohort, indicate that Hip-Hop deviated from its late 2000s conventions in the middle of the 2010s but bounced back later, in particular after 2017, when the first season of *The Rap of China* aired. The downward trend of the prediction accuracy of the 2009 cohort classifiers may suggest more nuanced changes in the genre: given that the recall of the 2009 cohort is also U-shaped, it implicates that the 2009 cohort classifiers are able to detect the bouncing back of the genre conventions but confused other genres with Hip-Hop when the bounce took place in the late 2010s. This may be primarily because of the relatively small size of the 2009 cohort classifiers' training set, but it also suggests the possibility of other genres' cross-over to Hip-Hip, which I will discuss in 4.3.

4.2 Metrics and Subgenre Salience

Genres are comprised of "subgenres," which are subsets of their parent genre but can be distinctly different from each other in terms of their sound [1,26]. The idea of distinct subgenres under the same genre category thus suggests that genre evolution may be understood as changes in the most salient subgenres, i.e., subgenres that take up the highest proportion of the genre. It is intuitive, then, to speculate that the classifier's performance is better when it predicts a set of songs whose most salient subgenres are more similar to those of the training set.

Testing this speculation requires, above all, identifying the most salient subgenres of the training set, or the subgenre to which most songs of that genre are affiliated. I thereby designed an original approach to measuring subgenre salience, and I used the approach for measuring the

		GNB			KNN			RF			XGB			Average

Note: Standard errors are in parentheses. Among the subtitles, Subg refers to subgenre, Acc refers to accuracy, and Rec refers to recall. Abbreviations in the Subg column: OS for Old-School Hip-Hop; I for Instrumental Hip-Hop; Con for Conscious Hip-Hop; A for Alternative Hip-Hop; CR for Cloud Rap; U for Underground Hip-Hop; Pop for Pop Rap; HH for Hip-Hop; T for Trap; CU for Chinese Underground Hip-Hop.
*p < .05; **p <.01; ***p<.001

Table 2. Performance of genre classifiers on songs released 2010-2019.

salience of Hip-Hop subgenres as follows. First, I extracted the subgenres from all the Hip-Hop songs in the dataset and counted their appearances each year. In many cases where a song has multiple subgenres, one more appearance was added for each of them. To account for the fact that prediction performance on each subgenre can significantly impact the prediction performance on the genre as a whole, I used the 2009 cohort classifiers and the 2018 cohort classifiers, respectively, to predict the genre of the Hip-Hop songs released in the year of the same cohort. After that, I calculated the prediction accuracy of each subgenre (which is also identical to recall, as only true Hip-Hop songs are examined here) by computing the proportion of correct predictions among all the songs with the subgenre in question. In this case, the prediction accuracy of each subgenre also indicates how the classifiers were trained to favor certain subgenres over others. I multiplied the prediction accuracy of each subgenre by their number of appearances. The product is the measurement of subgenre salience, which nicely captures the size of the impact that a subgenre can make on the pooled metrics of the genre. I identified the top 1 subgenre and top 5 subgenres with the highest salience score, which are presented in the note in Table 2. Then, I calculated their proportion in the total number of releases each year, respectively. Finally, I employed linear regression of Hip-Hop accuracy and recall on the proportion of the most salient subgenre(s) each year to understand the association between them. The objective of the linear regression is to see if the classifier performs better when the salient subgenres, which are favored by the classifiers by design, are more dominant among all subgenres of a year. The GTZAN cohort was not included in the analysis in this part, as it does not have a corresponding year in the dataset.

The coefficient estimates of the proportions of salient subgenres according to the regression models are presented in Table 2. The overall pattern generally substantiates a positive relationship between performance metrics and the size of the salient subgenres' proportions. In other words, the classifiers perform worse in years where there are fewer salient subgenres among the total releases of the year in question. Specifically, the average classifier trained on 2009 songs performs better when there are more songs in that year that are Old School Hip-Hop, Instrumental Hip-Hop, Conscious Hip-Hop, Alternative Hip-Hop, or Cloud Rap, whereas the average classifier trained on 2018 songs performs better when there are more Pop Rap, Trap, Old School Hip-Hop, or Chinese Underground Hip-Hop present in that year. The results imply that it is possible to detect genre evolution from the performance of the classifiers, which is demonstrable in the metrics when the genre deviates from the salient subgenres of the classifier.

4.3 Metrics and Genre-Crossing

As implied in Figure 2, the evolution of a genre may involve other genres. This could either mean "assimilation," where the genre in question is absorbing musical elements from other genres, or "dispersion," where the musical elements of the genre in question penetrate other genres. In either case, it is reasonable to speculate that the interaction between genres will likely do harm to the performance of the classifiers that are trained on songs where genre-crossing is not prominent. To investigate this issue, I first identified the number of releases in non-Hip-Hop genres (i.e., Folk, Rock, and Pop) with at least one subgenre that is explicitly associated with Hip-Hop. I did so by searching all the songs whose subgenres incorporate strings such as "Hip-Hop," "Hip Hop," "Rap," "Trap," and their Chinese equivalent. Table 3 presents the number of Hip-Hop-crossing non-Hip-Hop songs and their percentage among the total releases over the years studied. The table has some important implications for understanding classifiers' performance, as illustrated in Figure 2. First, there are no Hip-Hop-crossing non-Hip- Hop songs from 2009-2011. This

	Hip-Hop-crossing Non-Hip-Hop	Total Non-Hip-Hop	(%)
2009	0	1344	0
2010	0	1446	0
2011	0	1717	0
2012	22	1991	1.1

Note: Standard errors are in parentheses. *p < .05; **p <.01; ***p<.001

Table 4. Two-sample T-tests of key metrics between Hip-Hop-crossing non-Hip-Hop songs and those that do not cross the Hip-Hop boundary. Among the subtitles,

means that the 2009 cohort classifiers were not well-trained to correctly detect Hip-Hop-crossing non-Hip-Hop songs, which occur more frequently in the subsequent years. This possibly explains why 2009 cohort classifiers have a downward trend in their accuracy, as they are underperformed when identifying crossover songs. Second, the fact that there are more Hip-Hop-crossing non-Hip-Hop songs in terms of their percentage in the total non-Hip-Hop releases in the middle years than in the early and the late 2010s coincides, inversely, with the U-shaped trend of the metrics in Figure 2. This makes sense, as the prominence of genre-crossing is supposed to curb classification performance.

To further understand the relationship between genre-crossing and the performance of the classifiers, I also analyzed the difference in performance between genre-crossing non-Hip-Hop songs and those that did not cross the boundary of Hip-Hop. To do so, I conducted two-sample t-tests on two metrics between the two groups. The first metric was prediction accuracy, indicating the rate at which the non-Hip-Hop genre of the song was correctly identified. The second metric was the False Negative rate, indicating the rate at which the non-Hip-Hop song was incorrectly identified as Hip-Hop. Table 4 shows the results of the test, which unanimously demonstrate how genre-crossing discounts classification performance. Specifically, the consistent and statistically significant negative values under the columns of the difference in prediction accuracy suggest that the classifiers' ability to predict non-Hip-Hop songs that do not cross the boundary of Hip-Hop is always better than their ability to predict those that do so. Similarly, all the positive values under the False Negative columns provide strong evidence that classifiers are better at identifying non-Hip-Hop songs when they do not claim Hip-Hop as one of their subgenres. In short, the performance of genre classifiers may be an indicator of genre evolution, as bad performance points to genre-crossing.

5. DISCUSSION

Genres will evolve, and this will affect the performance of genre classifiers regardless of the data sources or algorithmic approaches they use. By analyzing the case of Chinese Hip-Hop, I demonstrate that the performance of genre classifiers is significantly impacted by genre evolution, particularly when the training set has less songs of the salient subgenres and when genres start to cross boundaries.

The goal of the present study is to highlight genre as a mutable cultural construct and to examine what this means for MIR research on genre classification. This study has at least three implications. First, similar to what has been argued in some of the previous MIR studies of genre, I contend that musical genre is a cultural construct and that the musical elements associated with a genre can change over time. My findings also suggest that the prevalence of a particular music style in a genre may be revived after a period of relative silence, which echoes what music industry scholars call a "revival" of music styles [13].

Second, because genres change and evolve, one possible application of genre classifiers is to understand the patterns of such change. I show it is possible to use genre classifiers, if trained on a particularly designed dataset, to detect the way genres evolve. It is difficult, though, to separate genre evolution from flaws in algorithmic design; therefore, it is important to supplement the analysis with a more detailed investigation of the soundscape of the songs across subgenres and songs that cross genres.

Third, the findings suggest that using accuracy or accuracy-related metrics to train genre classifiers might not be the only best application in practice. Regardless of their algorithmic framework, genre classifiers are almost always better at predicting the genre of songs released within a similar timeframe as those in the training set. As a result, if genre classifiers are meant to help classify newly released songs, it might be futile to aim at improving prediction accuracy, as the genre might evolve. This implies that we need to find an optimal balance between raising the prediction accuracy of the algorithms and understanding the developing trend of genres, which might require data exploration or even qualitative data beyond the design and optimization of machine learning algorithms.

There are obvious limitations in the data analysis; however, I argue that they will not severely affect the findings. Since a significant number of songs were inaccessible, especially in very distant years, it may twist the conclusion that Hip-Hop has been "revived" from its convention 10 years ago. However, it remains true that, if a genre classifier is trained on the songs of a particular composition of subgenres, the classifier might better predict the genre of a song when it shares commonalities with that subgenre's composition. In that case, classifiers can still be used to understand the evolution of genres, although they would be better "detectors" if more data were available.

6. ACKNOWLEDGEMENT

The author would like to thank Jin Ha Lee, Oriol Nieto, and the anonymous reviewers for their insightful comments and suggestions. The author would also like to acknowledge Leo Y. Yang for his assistance with data collection.

ABSTRACT

Carnatic Music is a South Indian art and devotional musical practice in which melodic patterns (motifs and phrases), known as *sañcāras*, play a crucial structural and expressive role. We demonstrate how the combination of transposition invariant features learnt by a Complex Autoencoder (CAE) and predominant pitch tracks extracted using a Frequency-Temporal Attention Network (FTA-Net) can be used to annotate and group regions of variable-length, repeated, melodic patterns in audio recordings of multiple Carnatic Music performances. These models are trained on novel, expert-curated datasets of hundreds of Carnatic audio recordings and the extraction process tailored to account for the unique characteristics of *sañcāras* in Carnatic Music. Experimental results show that the proposed method is able to identify 54% of all *sañcāras* annotated by a professional Carnatic vocalist. Code to reproduce and interact with these results is available online. [1]

1. INTRODUCTION

Musical styles around the world are often structured in relatively idiosyncratic ways, which can require bespoke tools for MIR tasks and computational music analysis [1]. This is the case in Carnatic Music, a South Indian art and devotional music tradition, in which several characteristic features of the style necessitate tailored MIR approaches.

Relative to other musical styles, Carnatic Music is heavily ornamented. This ornamentation is not superficial decoration but rather is integral to musical meaning [2]. The ornaments, known as *gamakas*, can greatly alter the sound of the notated *svaras* (notes); for example, some *gamakas* do not rest at all on the theoretical pitch of the notated *svara*, and instead involve oscillations between pitches either side of it [3, 4]. This oscillatory movement is particularly characteristic of the style, and can often subsume individual *svaras* [4]. The surface effect on the melodic line is that it typically has fewer stable pitch regions than many other styles. Such qualities makes it impossible for researchers who are not themselves Carnatic musicians to reliably identify *svaras* from audio recordings, although recent work has attempted to automate this task by creating descriptive transcriptions that assign *svara* names to key points in the melodic flow [5–7].

Another important feature of the style is the structural and expressive significance of motifs and phrases known as *sañcāras*, which can be defined as coherent segments of melodic movement that follow the grammar of the *rāga* (melodic framework) [2, 8]. Some musicians use the term in a narrower sense to refer to phrases that are particularly characteristic of the *rāga*, but here we use the term in its broader sense, referring to any melodic segment that is coherent from a Carnatic performer's perspective. These melodic patterns are the means through which the character of the *rāga* is expressed and form the basis of various improvisatory and compositional formats in the style [2,9]. There exists no definitive lists of all possible *sañcāras* in each *rāga*, rather the body of existing compositions and the living oral tradition of *rāga* performance act as repositories for that knowledge.

In this work we take advantage of two deep learning models, CAE [10] and FTA-Net [11], and the Dunya Carnatic corpus [12] for an improved, variable-length, and tradition-informed melodic pattern discovery in Carnatic Music. We first introduce the collections of data we build on top of, and we present our process relating each decision with the tradition-specific characteristics introduced in Section 1.1. We also include an empirical evaluation against expert annotations, brief musicological discussion of results and make available all code, features, models, results and an interactive application to explore them.

1.1 Characteristics of Carnatic Music

Many of the decisions taken in developing the methodology presented here are informed by certain characteristics of Carnatic Music and *sañcāras*, which to varying extents may be shared with other musical traditions around the world. We list some of those most relevant to this task, assigning each a unique code which will be referenced later.

CHAR1. *Sañcāras* conform in some ways to concepts of phrase more widely held; for example in Western Art Music, phrases are understood as influenced by gestalt

Pearson, X. Serra, "In Search of Sañcāras: Tradition-informed Repeated Melodic Pattern Recognition in Carnatic Music", in *Proc. of the 23rd Int. Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

principles wherein segments are separated by features such as silence and long periods of stasis [13]. Also, as in other musical styles, longer phrases/*sañcāras* can be understood as comprising shorter but still meaningful segments [14].

CHAR2. The ideal boundary between these shorter segments within a longer phrase is not always clear-cut, as there might be no point of rest or silence between them. Based on discussions with the expert annotator during this project, it is clear that often a longer phrase may be plausibly segmented in two or three different ways. However, there are rules of *rāga* grammar, and understandings of typical *sañcāras* that restrict the number of plausible segmentation points. This is similar to the segmentation of Western Art Music, where in any given section, several plausible segmentations may be made, but where the options are not unlimited [15].

CHAR3. A given *sañcāra* when repeated in a performance may be immediately preceded or followed by different melodic material. This feature is relatively common in many musical styles.

CHAR4. When a *sañcāra* is repeated, it is often elaborated on, which involves the insertion of additional *svaras* and *gamakas*. So the same basic or underlying *sañcāra*/phrase may appear many times in a composition with different elaborations. The commonly occurs in the style because the main compositional format, the *kriti*, has a theme and variation structure.

CHAR5. There can be tempo variations between instances of the same *sañcāra*. This can range from minor fluctuations due to extemporisation, to playing a *sañcāra* at double or half the speed it was originally performed, which is a particular feature of some musical formats such as the *varṇam*.

CHAR6. Single performances within a concert can typically range from between approximately 6 to 60 minutes in length. In the longer examples, the presentation is made up of different musical formats, often involving a composition (e.g., a *kriti*) as well as a number of more extemporised formats (*ālāpana*, *niraval*, *kalpana svaram*), based on *sañcāras* and the *rāga* grammar. This freedom for performers to combine different musical formats to create a larger whole is a typical feature of the style.

CHAR7. A final characteristic feature of the style is its instrumentation. The most widely found contemporary ensemble consists of a vocalist accompanied by violin, *mridangam* (double ended drum) and *tambura* (plucked lute, which creates the drone). Other ensembles led by instrumentalists can also be found.

1.2 Related Work

The automatic retrieval of melodic patterns is a prominent problem in MIR given its applications for music analysis [16], segmentation [17] and music theory [18]. Despite efforts to settle consensus in melodic pattern discovery [19, 20], said task may be built on top of diverse representations of audio signals, such as mel-frequency cepstral coefficients (MFCC) [21], chroma [22], or predominant pitch time-series [23]. In a Carnatic Music context, most existing work relies on processes that consider pairwise distance metrics, such as dynamic time-warping (DTW), between sub-sequences of pitch transcriptions of the predominant sang melody [23–29]. However, this can often be computationally expensive and does not necessarily account for some of the idiosyncrasies of the tradition. To reduce the complexity, several works notate the patterns for an optimized similarity computation [30].

In a Carnatic context, gathering musically-relevant pattern annotations for entire recordings is expensive and time-consuming, and requires the involvement of experts. The most common approach is to ask experts to judge the relevance of the retrieved patterns and evaluate via standard classification metrics [9, 23].

2. DATA

For this research we use the Dunya Carnatic corpus [12], which includes $\approx$ 500 hours or music, divided into 2,380 audio recordings and organized in 235 concerts. Up to 259 artists and 227 unique *rāga*s are present in the corpus. The Saraga dataset is extracted from such corpus and is one of the largest and more complete, open-access datasets for research on the Carnatic and Hindustani music traditions [31]. For a total of 168 Carnatic recordings in Saraga, close-microphone tracks are available. Since the vocalist is the soloist and lead performer in these recordings, for this research we create a sub-dataset comprised of such tracks (168 in total) and denote it Saraga Carnatic Vocal (SCV). All tracks have a sampling rate of 44.1kHz.

We also rely on the Saraga-Carnatic-Melody-Synth (SCMS) dataset [29], a large dataset of vocal melody ground-truth for Carnatic Music compiled using a Carnatic-specific Analysis/Synthesis method, which is currently the largest open source collection of such data and has been shown to positively impact the melodic analysis for Carnatic Music [29].

3. METHOD

Our goal is to extract and group regions of repeated melodic patterns from audio recordings of Carnatic Music performances, Figure 1 provides an overview of this process. Many design decisions are informed by the characteristics introduced in Section 1.1, where relevant, we reference these characteristics using their corresponding **CHARx** code.

3.1 Features

Two feature sets are extracted from each recording in SCV: (1) An automated transcription of the predominant sung pitch in Hz (Section 3.1.1), from which we derive a mask corresponding to silent/stable regions (Section 3.1.1), and (2) Transformation-invariant melodic features extracted using a Complex Autoencoder (CAE) from audio in CQT representation (Section 3.1.2), which we use for self-similarity computation.

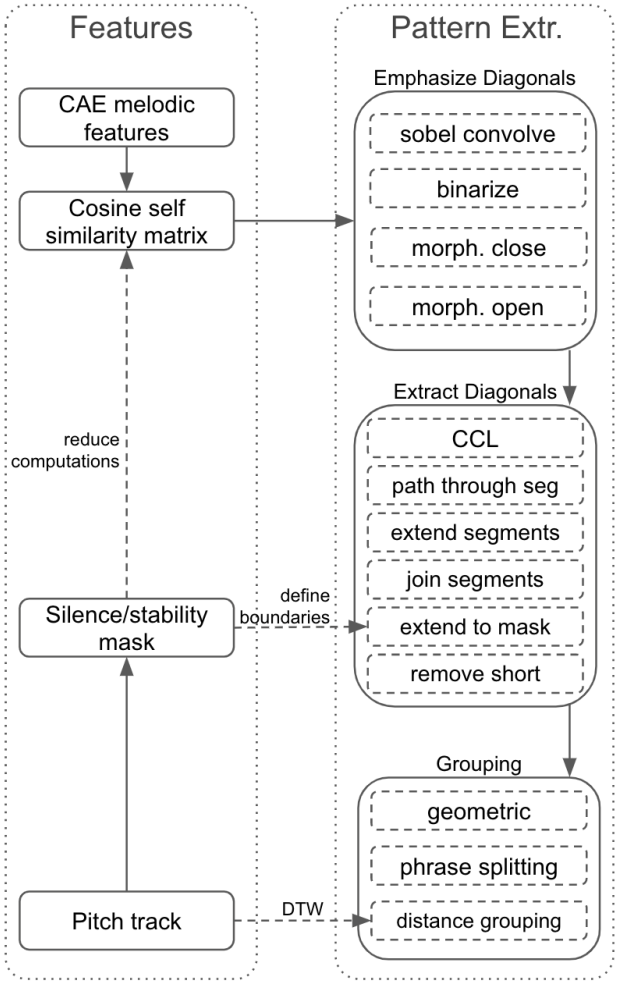

Figure 1. Pipeline overview - two feature sets are extracted from audio (pitch track and CAE features) and used to inform the extraction process.

3.1.1 Pitch Track and Mask

Recent work on vocal pitch extraction for Carnatic Music shows that state-of-the-art heuristic and data-driven methods for such tasks struggle to discriminate between singing voice and violin, and are not able to fully capture the vocal ornamentations in this tradition [29] **[CHAR7]**. To overcome this problem, a frequency-temporal attention network denoted FTA-Net [11] is re-trained using the SCMS dataset, further illustrating the positive impact this has for downstream tasks such as melodic pattern recognition. In this work we take advantage of this procedure to extract cleaner and more versatile pitch tracks from the audio in the Saraga dataset. We prioritize the close-microphone singing voice track for the extraction if available, however, there is no significant performance drop when running the Carnatic-tuned FTA-Net on top of mixed recordings. To account for incorrectly annotated silence that occur within ornaments due, for example, to glottal closure or other rapid vocal movements, we interpolate the pitch tracks to fill gaps shorter than or equal to 250ms [32].

As noted in [29] and [27], sañcāras are unlikely to contain long regions of sustained silence or pitch stability. We identify these regions in our pitch tracks and use this information to inform our search [**CHAR1**].

Silence is annotated as the regions of the pitch track that correspond to 0 Hz, in theory these are all regions where there is no sung voice (remembering that all silences of 250ms or less have been interpolated).

Stability is computed using the method outlined in [27, 29] - for a hop size of 0.2s, a window is passed across the entirety of the pitch track, those windows in which the maximum/minimum frequency is within $\pm$8Hz of it's mean are considered stable. Regions of the pitch track that contain consecutive stable windows whose total length sum to more than 1s are annotated as corresponding to a held note. The remaining windows, stable or not, are left unannotated. The final silence/stability mask, M_{ss}, annotates regions that correspond to silence or a held note with 1, and 0 otherwise.

3.1.2 Melodic Features and Self-similarity

We extract melodic features using a Complex Autoencoder (CAE). Mapping a signal, x, onto complex basis functions learnt by the CAE results in a transformation-invariant "magnitude space", $\mathbf{r}_x$, and a transformation-variant "phase space", ϕ_x. Exploiting the invariance-property of $\mathbf{r}_x$ has proven to achieve state-of-the-art results in repeated section discovery for audio [10].

We train a CAE on the vocal tracks in SCV, represented by their constant-Q transformed spectrogram with a hop size of 1984. The range comprises 120 frequency bins (24 per octave), starting from a minimal frequency of 80 Hz (selected as the minimum frequency expected in Carnatic vocal performance [33]). The spectrogram is split into n-grams of 32 frames. Before training, samples from the training data are randomly transposed by [-24 .. 24] frequency bins or time shifts of [-12 .. 12].

Each audio recording in SCV is mapped onto the complex basis functions learnt by the CAE and the transformation invariant "magnitude space", $\mathbf{r}_x$, used as melodic features relevant to the task of repeated pattern discovery.

As in [10], we compute a self-similarity matrix, $\mathbf{X}$, of $\mathbf{r}_x$, using the reciprocal of the cosine distance (plus some negligible epsilon to avoid division by zero). With some Carnatic performances lasting upwards of one hour, this computation rapidly becomes expensive. We use the masks learnt in Section 3.1.1, M_{ss}, to reduce the computation to include only those areas corresponding to regions we are interested in, reducing the number of pairwise comparisons by around 67%. Typically, $\mathbf{X}$ is between around 10,000 and 50,000 elements squared **[CHAR1, CHAR6]**.

Diagonals in $\mathbf{X}$ of high value correspond to two regions of continued similarity (repeated pattern). It is these diagonals we want identify and extract.

3.2 Repeated Pattern Extraction

Strong diagonal segments in $\mathbf{X}$ correspond to two occurrences of a repeated pattern. We define and extract them using a series of image processing techniques.

3.2.1 *Emphasizing diagonals*

To accentuate the diagonal segments, $\mathbf{X}$ is first convolved with a Sobel Filter to emphasize edges and then binarized about some experimentally set threshold, T_B. Since the emphasized edges correspond to the borders of a diagonal segment and not the segment itself, the binary matrix is morphologically closed to fill gaps and morphologically opened to smooth and remove noisy artifacts. Figure 2 illustrates this process.

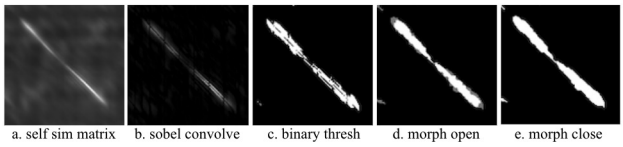

Figure 2. Emphasizing diagonals with convolution and morphological transformations: (a) Self-similarity matrix, (b) convolve with sobel filter, (c) binarize, (d) morphological opening, (e) morphological closing.

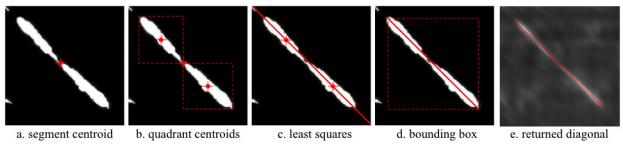

Figure 3. Defining diagonals from non-zero regions. Each segment is a thick region of non-zero values in $\mathbf{X}$, we extract a single line through this region corresponding to the underlying diagonal segment: (a) Identify segment centroid, (b) identify quadrant centroids, (c) least squares line, (d) identify bounding box, (e) return diagonal within bounding box.

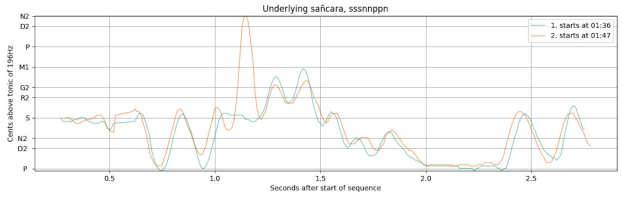

Figure 4. Two instances of the underlying sañcāra, sssnnppn, corresponding to the diagonal segment in Figures 2 and 3

3.2.2 *Extracting Diagonals*

Since instances of the same sañcāra can be performed at differing tempos, segments in $\mathbf{X}$ are not necessarily parallel to the $x = y$ diagonal, as such the method used to extract them in [10, 34] is not appropriate. We instead use a two-pass binary connected-components labelling algorithm (CCL) with a structuring element that considers elements that touch diagonally [35] to identify and group connecting non-zero elements, this can be conceptualized as a *flood fill* algorithm applied to all non-zero regions of $\mathbf{X}$. Each non-zero group corresponds to multiple x, y coordinates, we want to define a single path through this group to nominate as a candidate for the underlying true diagonal segment. First we compute the centroid of these coordinates and split the bounding box into an upper left quadrant and lower right quadrant centered on it. A line is learnt using least squares regression on the points connecting the two quadrant centroids and the underlying diagonal segment defined along that line between the bounding box of the group as a whole (Figure 3) **[CHAR5]**.

Segments are extended along their trajectory for a maximum of up to 50% of their length either side if the similarity in $\mathbf{X}$ for these regions is below some reduced threshold, T_{ext} where $T_{ext} < T_B$ (Figure 5) **[CHAR3]**.

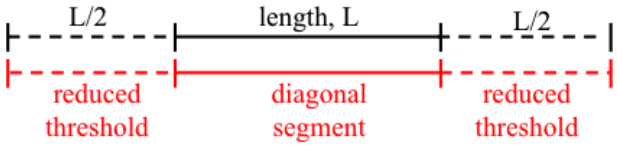

Figure 5. Reducing threshold for significant similarity in regions bordering returned segments. The two regions bordering the trajectory of a returned segment are subject to a lower threshold for similarity to account for variations in preceding and succeeding svaras in sañcāras.

Neighboring segments are joined if they are within 0.5s of each other and their gradients differ by $\leq$0.07rad **[CHAR4]**.

Segments that traverse regions identified in M_{ss} are broken along the center points of these silent/stable regions. Segments that are within 50% of their length to a silent or stable region (annotated in M_{ss}) are extended to the centroid of that silent/stable region **[CHAR1]**.

3.3 Grouping

Relationships between identified patterns are implicit in the geometry of $\mathbf{X}$ - each segment corresponds to two separate instances of the same pattern, those segments that intersect in x correspond to the same region in the recording (that represented on the x-axis) and those in y, vice versa. This information is used to iteratively group all patterns.

3.3.1 *Phrase Splitting*

We can further exploit segment positions in $\mathbf{X}$ to learn boundaries between shorter segments and longer phrases. If two segments intersect on one axis but are of different lengths, new segments are created corresponding to the intersecting portion of the segments **[CHAR2]**. Figure 6 illustrates an example of such. Segment A (corresponding to two patterns, $[x_1 : x_2]$ and $[y_1 : y_2]$) intersects with Segment B (corresponding to two patterns, $[x_1 : x_3]$ and $[y_3 : y_5]$). Consequently, two new segments are created from Segment B, $[y_3 : y_4]$ and $[y_4 : y_5]$ where $[y_3 : y_4]$ is another occurrence of $[x_1 : x_2]$. All patterns corresponding to Segment A, Segment B and the two new sub-segments are included in the final results.

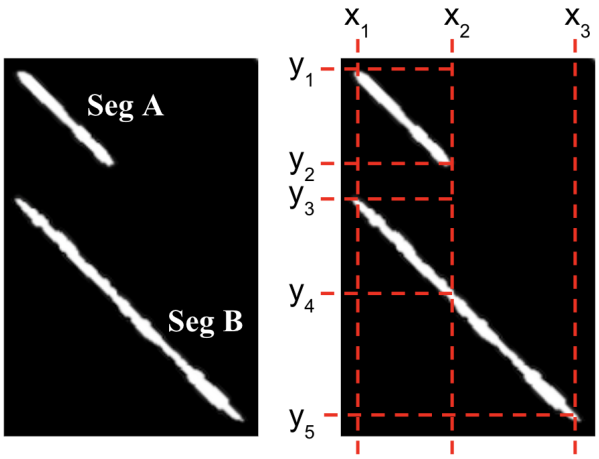

Figure 6. Learning sub-phrase relationships using geometry in $\mathbf{X}$ - Segment B is split into two since a subsequence of Segment B exists in isolation elsewhere (Segment A), both the entire Segment B and it's two subsequences are returned.

Performance	N_r	N_a	Recall	Precision	F1
KJ	174	168	0.73	0.76	0.74
SJ	214	106	0.53	0.54	0.52
VNK	90	144	0.33	0.42	0.37
Overall	478	418	0.54	0.60	0.57

Table 1. Melodic pattern discovery results for the three performances in Table 2. N_r and N_a are the number of returned and number of annotated patterns respectively

3.3.2 Distance Grouping

Further grouping is attempted by comparing each pairwise combination of groups. In each comparison, the dynamic time-warping distance is computed between 10 sets of two randomly selected patterns (one from each group) using the pitch tracks. If the average DTW distance between two groups is below some threshold, T_{dtw}, the groups are considered to represent the same pattern and merged to form one **[CHAR4]**.

4. EXPERIMENTAL SETUP

We apply our approach to three Carnatic performances (Table 2) and compare the results against expert annotations.

4.1 Annotations

Ground-truth annotations of all *sañcāras* in the audio recordings were created by a professional Carnatic vocalist who has 21 years of performance experience in South India. Annotations were created in Carnatic notation, known as *sargam* [36], using the software ELAN [37]. As there is no definitive list of *sañcāras* in a given *rāga*, the segmentations are based on the annotator's experience as a professional performer and student of a highly esteemed musical lineage. These annotations are therefore subjective to some degree, but have the benefit of being based on expert performer knowledge rather than on an externally imposed metric that may be irrelevant to musical concepts held by culture bearers.

In *kritis*, one of the most popular compositional formats, initial phrases are repeated with variations, known as *saṅgatis*. This means that there will be initial *sañcāras* that are subsequently varied. These musical connections are captured by grouping the related musical material together with an 'underlying *sañcāra*' annotation, which refers to the first occurrence and typically simplest version of the *sañcāra*. To reflect the hierarchical nature of plausible musical segmentations, longer full phrase-level annotations that can comprise several shorter *sañcāras* are also created **[CHAR1]**. The evaluation reported here is made on the 'underlying *sañcāra*' and 'underlying full phrase' levels.

4.2 Method and metrics

The various parameters at every step are optimized on one performance, Koti Janmani, representing 35% of the total number of minutes performed across the three performance. Those parameters related to the diagonal segment extraction are selected so as to maximize recall in identifying 'underlying *sañcāra*s' and 'underlying full phrases' that occur more than once in the ground-truth annotations. To consider whether a returned pattern, *R*, is a match with an annotation, *A*, we consider the overlap between them. Since the ideal boundary between shorter segments within a longer phrase is not always clear cut **[CHAR2]**, the expectation of 100% overlap is unrealistic **[CHAR1]**. As in [29], we consider *A* and *R* to be a match if the intersection between them is more than two-thirds the length of *A and* more than two-thirds the length of *R*, inspection of results find this limit to be sufficient in identifying and exploring regions of melodic interest.

5. RESULTS

Table 1 presents the results for the three performances. Our process is able to find 226 of the 418 annotations across the three recordings, corresponding to a total recall of 0.54, precision of 0.60 and F_1 of 0.57. The reader is encouraged to browse and listen to the results using the online visualisation tool provided in our Github repository.

6. DISCUSSION

Although far from 100 percent of annotated patterns were found, we significantly exceed what would have been achieved if we had used out-of-the-box methods without any consideration for the specifities of the Carnatic traditon. For example, when applying the pattern extraction process presented in [10] using our CAE model trained on the SCV, we are able to identify only 8% of annotated patterns at a precision of 7%. It is unsurprising that our performance exceeds this figure since our process is built, in part, on the same underlying model, replacing the pattern extraction steps with more tradition-informed ones.

The results achieved could contribute to a useful tool for musicologists needing to find many instances of the

Table 2. Three Carnatic performances used for evaluation.

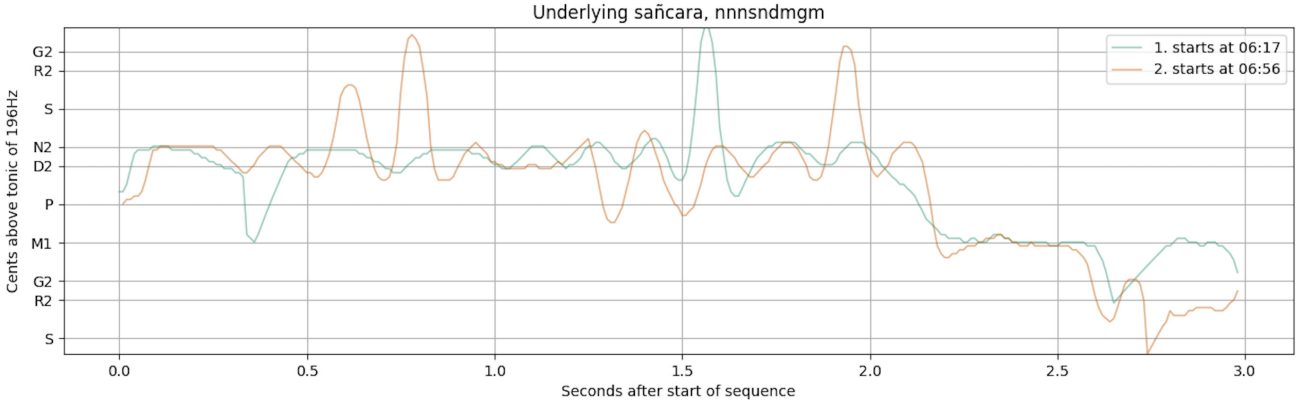

Figure 7. The pattern "nnnsndmgm" in Koti Janmani. The underlying *sañcāra* (blue line) is performed "nnnsndmgm", then later as a distinct variation "nnssndpdnndmmgrgm" (orange line).

same *sañcāra* across a long or many performances, a process that would otherwise involve extremely time consuming labour. While yet to be evaluated formally, the nature of the groupings returned appear promising from a musicological perspective. Figure 4 displays the pitch tracks for the two patterns corresponding to the diagonal segment in Figures 2 and 3. Each pattern would be considered instances of the same underlying sañcāra, "sssnnppn", but in fact are realized slightly differently ("snsgrsnnpn" at 01:36 and "snsmgrsnnpn" at 01:47). The steps outlined in Figures 2 and 3 illustrate how this subtle variation in performance is captured by considering the structural features that are particular to this musical style. However, there comes a point where the variation performed on the underlying or initial *sañcāra* is too great to be found by the process, and indeed it would also not be considered the same *sañcāra* by musicians, but rather a variation or new *saṅgati*. For example, in Koti Janmani, the initial *sañcāra* "nnnsndmgm" is later performed as a distinct variation "nnssndpdnndmmgrgm", and these two are successfully separated by the matching process into two motif groups (11 and 12) (Figure. 7).

While in the *kritis*, Koti Janmani and Sharanu Janakana, the majority of patterns annotated are found, fewer were found in the *varṇam*, Vanajaksha Ninne Kori. This might be explained by the differing structural features of the two compositional styles and of these particular compositions. This *varṇam* has a long 28 beat metrical cycle that lasts approximately 22 seconds. Furthermore, the melodic line has a more discursive and wandering character than the two *kritis* in this analysis. *Kritis* are based on a theme and variation (*saṅgati*) structure, while *varṇams* typically have fewer repetitions of any given phrase. As a result of these qualities, it might be harder for our process to find the borders of segments that match with those of the annotator. As discussed, there is often more than one plausible option for segmentation within longer units. It is possible that even expert annotators would find a larger number of plausible segmentation options in this *varṇam*, something that we could test for in future work by asking two or more annotators to annotate all plausible options, rather than only those that seem optimal **[CHAR2]**.

To demonstrate how our results could be useful to musicologists and fans of the style, we provide a high-level tool to explore and listen to them. We also include the results for 6 more performances across 6 ragas not mentioned here for a total of 9 performances across 8 distinct ragas. We do not have expert annotations for these extra performances and hence cannot empirically evaluate the results. One important factor in how valuable such a tool is, is the extent to which retrieved *sañcāras* are effectively sorted into groups of high melodic similarity that matches musicians' concepts of musical similarity in the style. It is obvious when exploring the results, that even for a listener with little musical background, there is a strong degree of similarity between patterns returned in the same group, both for those patterns that correspond to annotations and otherwise.

7. CONCLUSION

By considering and incorporating the characteristic features of a musical tradition into the development process, we obtain musicologically relevant results for the task of repeated melodic pattern recognition in Carnatic Music. In an effort to provide value for researchers, musicologists and fans of the Carnatic Music tradition, we provide all code, data and a high-level visualisation tool to explore the results.

8. ACKNOWLEDGEMENTS

Thanks to the Carnatic vocalist, Brindha Manickavasakan for her considered annotations of the audio recordings.

ABSTRACT

Chinese national pentatonic modes, with five tones of Gong, Shang, Jue, Zhi and Yu as the core, play an essential role in traditional Chinese music culture. After the early twentieth century, with the development of new Chinese music, the ancient Chinese theory of scales gradually developed into a new pentatonic modes theory under the influence of western music. In this paper, we briefly introduce our self-built CNPM (Chinese National Pentatonic Modes) Dataset, then design residual convolutional neural network models to identify which TongGong system the mode belongs, the pitch of tonic, the mode pattern and the mode type from audio signals, in combination with musical domain knowledge. We use both single-task and multi-task models with three strategies for identification, and compare them with a simple template-based baseline method. In experiments, we use seven accuracy metrics to evaluate the models. The results on identifying both the tonic pitch and the pattern of mode correctly achieve an average accuracy of 69.65%. As an initial research on automatic Chinese national pentatonic modes recognition, this work will contribute to the development of multicultural music information retrieval, computational ethnomusicology and five-tone music therapy.

1. INTRODUCTION

The modern Chinese national pentatonic modes theory based on the five tones of Gong, Shang, Jue, Zhi and Yu was created by Chinese musicians who combined music theories such as absolute pitch, twelve-tone equal temperament and major/minor modes used in western music with Chinese music theory after the early twentieth century.

Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

Figure 1. Examples of mode scales. Chinese national pentatonic modes include pentatonic mode, hexatonic mode and heptatonic mode which are based on the five tones. Only pentatonic mode scales are shown here. The C Gong mode and the D Gong mode share the same mode pattern but with different pitch of tonic. The C Gong mode and the four modes in the second and third rows all belong to the C TongGong system.

From the 1920s to the 1960s, Chinese musicians such as Guangqi Wang [1], Zhengya Wang [2] and Yinghai Li [3] gradually proposed the theory of Chinese national pentatonic modes based on the ancient Chinese scales and related concepts, with reference to western scales and modes. The theory was later written by Chongguang Li into the basic music theory textbook [4], and became the version commonly used in Chinese music teaching. The musical data selected and the analyses conducted in this paper are based on the modern Chinese national pentatonic modes theory. It can be applied to most of the traditional music pieces, especially those works of Chinese national orchestral instruments adapted from traditional tunes. Further explanation and clarification of the theory and ancient Chinese music are listed here [1] .

Gong, Shang, Jue, Zhi and Yu can be called step names in the modern theory. They have a fixed interval relationship which can be described as Gong-Shang major second, Shang-Jue major second, Jue-Zhi minor third, Zhi-Yu major second and Yu-Gong minor third. In addition, Qingjue indicates the tone a minor second above Jue. Biangong and

[1] https://github.com/Hellwz/CNPM-ISMIR2022/blob/main/notes.md

Type	Step names
Pentatonic	Gong / C - Shang / D - Jue / E - Zhi / G - Yu / A
Hexatonic (Qingjue)	Gong / C - Shang / D - Jue / E - Qingjue / F - Zhi / G - Yu / A
Hexatonic (Biangong)	Gong / C - Shang / D - Jue / E - Zhi / G - Yu / A - Biangong / B
Heptatonic Yayue	Gong / C - Shang / D - Jue / E - Bianzhi / $^{\sharp}$F - Zhi / G - Yu / A - Biangong / B
Heptatonic Qingyue	Gong / C - Shang / D - Jue / E - Qingjue / F - Zhi / G - Yu / A - Biangong / B
Heptatonic Yanyue	Gong / C - Shang / D - Jue / E - Qingjue / F - Zhi / G - Yu / A - Run / ^{b}B

Table 1. Six mode types in Chinese national pentatonic modes. The pitch after each step name is just one of the possible matches, listed for better understanding.

Bianzhi indicate the tones a minor second below Gong and Zhi, respectively. And Run [2] is the tone a major second below Gong. The original Gong, Shang, Jue, Zhi and Yu tones are called Zheng-tones (i.e. main tones), and others are considered as Bian-tones (i.e. changed tones). Figure 1 shows several pentatonic scales for better understanding.

A complete mode name in Chinese national pentatonic modes can be divided into three parts: the pitch of tonic, the mode pattern, and the mode type. The pitch of tonic is indicated by pitch names such as C, D and E. The mode pattern has five categories according to the step name of tonic. Gong mode use Gong tone as tonic, Shang mode use Shang tone as tonic, and by analogy, there are five mode patterns of the Gong, Shang, Jue, Zhi and Yu. The mode type has six categories which are called Pentatonic, Hexatonic (Qingjue), Hexatonic (Biangong), Heptatonic Yayue, Heptatonic Qingyue and Heptatonic Yanyue mode. The step names these six mode types contain are shown in Table 1. Any Zheng-tone (i.e. Gong, Shang, Jue, Zhi and Yu) in it can be used as the tonic to form a mode. Therefore, combining the pitch of tonic, we get a total of 12x5x6=360 kinds of modes theoretically.

There is also a unique concept in Chinese national pentatonic modes theory called the TongGong system. If the Gong's pitch of two modes are the same, they are said to belong to the same TongGong system. For instance, the C Gong mode, D Shang mode, E Jue mode, G Zhi mode and A Yu mode all belong to the C TongGong system. The TongGong system to which the mode belongs, the tonic pitch and the pattern of the mode are related. Identifying any two of them can infer the third one. This is also a main idea of the approach in this paper.

Automatic key/mode recognition is an important research direction in MIR, but little research has been done on automatic Chinese national pentatonic modes recognition for audio. The main reasons include the lack of annotated data, the variety of national modes, and the difficulty of accurately identifying the pitch of Chinese instruments, etc. These reasons make recognition more difficult.

In this paper we develop deep learning models based on residual convolutional neural network for automatic recognition of Chinese national pentatonic modes. By entering the spectrogram of the audio, the models will output the full name of the national mode it belongs to. The correct recognition of the mode pattern and the pitch of tonic is the main focus of this paper. The benefits of using neural networks are that they can automatically extract features from spectrograms and have better generalizability to different musical genres and instruments. We use both single-task and multi-task models with three strategies, as described in section 3, for identification, and compared them with a simple template matching approach, as shown in section 4. Data augmentation is also adopted for better results.

The significance of Chinese national pentatonic modes automatic recognition includes: 1) Strengthening computer's understanding of music that can assist humans in musicological and ethnomusicological analysis; 2) Used to carry out the research of five-tone music therapy. Music in Chinese national pentatonic modes can regulate the body, assist in treatment and has a positive effect on some mental diseases [5, 6]; 3) Enhancing and further understanding the algorithmic mechanism of automatic mode recognition itself; 4) Assisting in the preservation of traditional music culture; 5) Auxiliary to other MIR studies.

2. RELATED WORK

The related work on automatic mode recognition and the application of convolutional neural networks in Chinese music information retrieval are introduced in this section.

2.1 Automatic Key/Mode Recognition

Automatic Key/Mode Recognition is one of the core tasks of MIR. The early studies on western major and minor key recognition were traditionally handled by template matching and Hidden Markov Models (HMMs). [7] proposed 24 major/minor key templates and algorithms for automatic key detection. [8] improved these templates and focused more on harmonic minor in minor key templates. [9] calculated Harmonic Pitch Class Profile (HPCP) for key matching of audio. [10] obtained templates from real instruments. [11] utilized probabilistic models (HMMs), combined with templates, to assist in key recognition. [12] extracted Pitch Class Profile (PCP) sequences and then used a single HMM directly.

[2] Run is also referred to as Qingyu (a minor second above Yu) by some scholars.

Classification basis	Names	Amount	Labels
TongGong System	C; ♯C (♭D); D; ♯D (♭E); E; F; ♯F (♭G); G; ♯G (♭A); A; ♯A (♭B); B	12	0-11
Pitch of Tonic	C; ♯C (♭D); D; ♯D (♭E); E; F; ♯F (♭G); G; ♯G (♭A); A; ♯A (♭B); B	12	0-11
Mode Pattern	Gong; Shang; Jue; Zhi; Yu	5	0-4
Mode Type	Pentatonic; Hexatonic (Qingjue); Hexatonic (Biangong); Heptatonic Yayue; Heptatonic Qingyue; Heptatonic Yanyue	6	0-5

Table 2. Definition of the mode category

With the development of deep neural networks, Convolutional Neural Network (CNN) has also been applied to the study of automatic key recognition. [13] proposed an end-to-end framework based on CNN for global key detection and can be adapted to different music styles. [14] improved the above model by removing the dense layer and keeping only the convolutional and pooling layers to obtain a genre-independent model and enhance generalization ability. [15] recognized local key for classical music, comparing the HMM and CNN methods and the effect of segmenting the dataset by song or version. [16] compared the influence of different directional convolutional architectures on the results along VGG-style networks. [17] designed a complex CNN architecture based on InceptionV3 to recognize 24 major/minor keys and evaluated a broad range of data augmentation methods.

In the literature, we found three works related to the recognition of Chinese national pentatonic modes, with two from symbolic format and only one from audio signals. None of them used neural networks. [18] used a manually designed decision tree for Chinese pentatonic mode recognition, and [19] used a template-matching based algorithm for automatic recognition of Chinese pentatonic mode and heptatonic mode. These two studies aim at MIDI files that are more conducive to recognizing musical meta-information such as pitch rather than audio signals. [20] designed uniform and ordinal templates for mode recognition of guqin music, using template matching to identify Gong, Shang and Zhi pentatonic modes from audio. We compare this method with our baseline in subsection 4.2.

2.2 Convolutional Neural Networks in CMIR

There have been several studies related to Chinese national music in the field of MIR in recent years, and some relevant datasets have emerged [21–24]. CNN models such as VGG [25], GoogLeNet [26] and ResNet [27] have made great progress on image recognition tasks. Inspired by this, CNN has also been applied in the CMIR (Chinese Music Information Retrieval) field. [28] utilized Convolutional Recurrent Neural Network (CRNN) for activity detection of Chinese national polyphony instruments and achieved a temporal resolution of seconds. [29] extracted Mel Frequency Cepstral Coefficients (MFCC) features of the audio and used VGGish network to classify 78 Chinese musical instrument timbres. [30] adopted Fully Convolutional Networks (FCN) to achieve the best results in the playing technique detection task of Chinese Erhu and Bamboo Flute instruments.

3. METHODS

The methods we propose and use are described below, including template matching and neural network models.

3.1 Definition

According to the definition in this paper, there are 360 kinds of Chinese national modes theoretically. We show their category definitions based on different classification basis and the numbering method of data annotation in Table 2. For simplicity, in the following we refer TongGong system to which the mode belongs as "system", pitch of the tonic as "tonic", mode pattern as "pattern", and mode type as "type". The primary task when classifying is to identify pattern and tonic, with system as auxiliary item, followed by type classification as a secondary task.

Based on the tonic t and the system s, we can infer the mode pattern. When t equals s, it is Gong mode. When t is 2 semitones higher than s, it is Shang mode. 4 semitones higher is Jue mode, 7 semitones higher is Zhi mode and 9 semitones higher is Yu mode.

3.2 Baseline

In order to compare the knowledge-based method with the data-driven method (i.e. neural network method), we use a template matching method designed for Chinese national pentatonic modes as the baseline.

The chroma features of the entire audio are obtained using the librosa package [31] and summed to get a twelve-dimensional chroma vector which reflects the energy of each pitch among the whole audio without octave information. Firstly, classify the TongGong system to which the audio belongs. The template of C TongGong system is [1, 0, 1, 0, 1, 0, 0, 1, 0, 1, 0, 0] and others can be obtained by shifting the template in a loop. The Pearson correlation coefficient between chroma vector and each template is calculated respectively. The larger the correlation coefficient is, the higher the matching degree is. The template with the maximum value is the recognition result. Then for the tonic pitch, since most of the music we analyze returns to the tonic at the end, we use a simple way to identify the tonic: directly sum the chroma features of the last 500 frames according to the pitches, and regard the pitch name

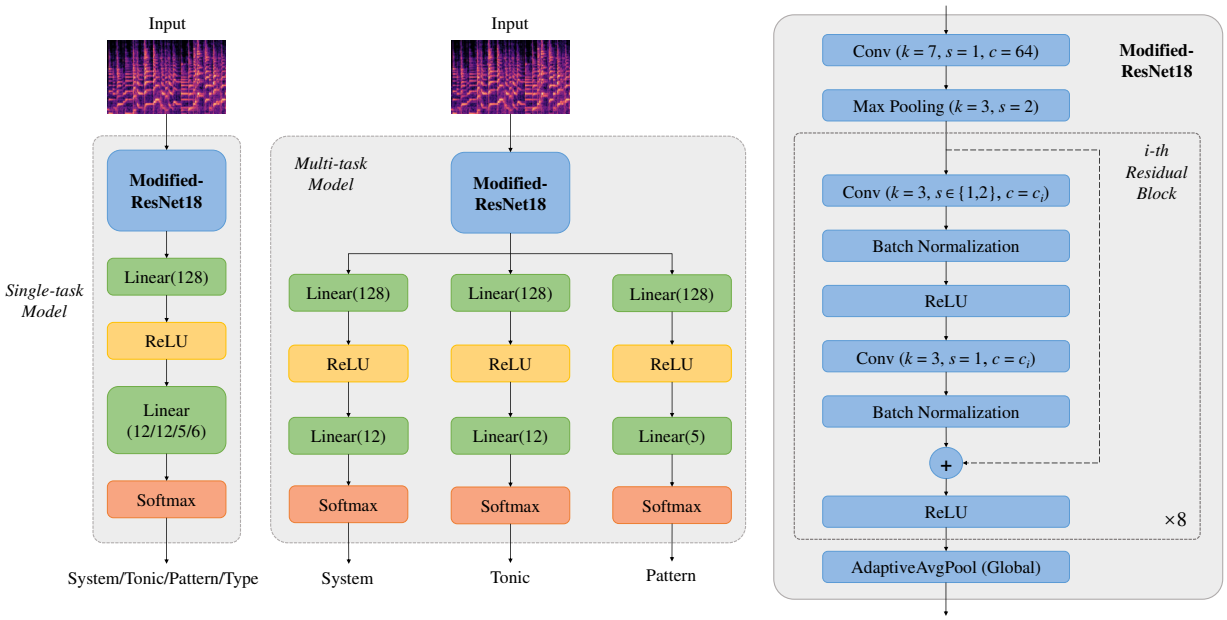

Figure 2. Model architectures. The shape of input is [Batch_size, Channel=1, F=168, T]. There are 4 single-task models for predicting TongGong system, tonic pitch, mode pattern and type respectively. Specifically, the single-task model for tonic prediction has no linear layer of 128 neurons and the following ReLU layer. In modified-ResNet18, k means the kernel size is $k \times k$, s indicates the stride and c stands for the number of channels. For 3rd, 5th and 7th residual block, the first s of conv layer equals 2, and others are 1. $c_i \in$ [64, 64, 128, 128, 256, 256, 512, 512]. A 1×1 convolutional layer is also used on the dashed line in the residual block if the number of channels does not match.

corresponding to the maximum value as the tonic pitch. As for the mode type recognition, the templates consisting of 0s and 1s are obtained according to the scale corresponding to each mode, and the results are acquired using a calculation method similar to that of the TongGong system identification. At last, the pattern of the mode can be obtained through the TongGong system and the tonic pitch.

3.3 CNN Models

Our CNN models use a modified ResNet18 [27] structure as the backbone. ResNet models have reached SOTA on multiple classification tasks in history and have simple structures which make them easy to tune and train. Their residual blocks are also widely used in various neural networks. For the input of our models, we use Constant-Q Transform (CQT) spectrogram, which is more appropriate for music audio than other spectrograms and contains more information than chroma features. Referring to the configuration of [14] and [17], we set the spectrogram frequency range from C1 to C8 with 168 frequency bins totally, and then downsample to 5 frames per second in the time axis. Because of the specific structure of our models, we can use any length of spectrogram as input.

The architectures of our models are shown in Figure 2. Compared to the original ResNet, our main changes include: 1) Modify the three channels of the input to a single channel for audio task; 2) Remove the downsampling from the first convolutional layer to accommodate a smaller size input; 3) Add the fully-connected layer in the output section to facilitate establishing different mapping relationships for different subtasks, and fit our tasks of less categories, compared to image classification task.

Due to the diverse types of modes but small amount of data, it is not reasonable to directly classify 60 or 360 categories. Therefore we use the following three strategies for recognition: 1) Directly use two single-task models to predict the tonic and pattern respectively; 2) Use two single-task models to predict the system and tonic respectively, and then indirectly calculate the pattern from these two results; 3) Use one multi-task model to recognize system, tonic and pattern, where pattern can be derived both directly and indirectly. When training the multi-task model, the losses of three outputs are summed for back propagation. As for type recognition, due to its unbalanced data distribution, difficulty of identification and little relationship with the other three, we directly use a single model to predict without adding it to multi-task model.

For the training input, we divide the spectrogram without overlap into 20s snippets, which is the same length as [17], to perform mini-batch training. Especially, the last snippet must be taken out regardless of whether it overlaps with the previous one, because it is critical for the tonic recognition. All snippets in the training set will be involved in the training, except that only the last snippet of each recording will be used when training the tonic model due to the characteristic of music. The tonic labels of non-final snippets will be masked when training the multi-task model for the same purpose, with other labels unchanged.

In the inference process, it is possible to either input the whole spectrogram directly or divide it into snippets,

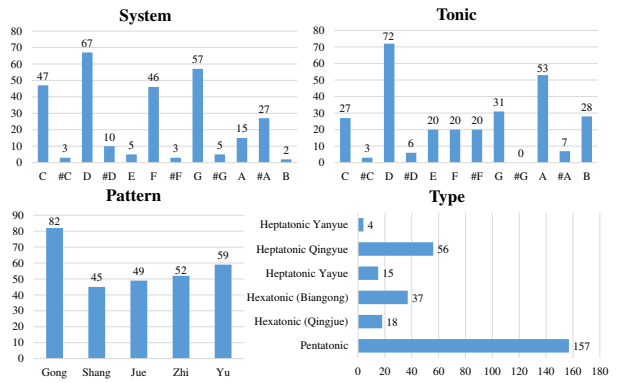

Figure 3. Data distribution of the CNPM Dataset

and then combine the results of each snippet to obtain the final result. In preliminary experiments we discover that for system, pattern and type tasks, using the whole spectrogram as input gives better results. In contrast, the tonic recognition only requires the last snippet of each song.

4. EXPERIMENTS

In the following we present the dataset we use and the experimental results we obtain using different methods.

4.1 Dataset

We use and expand our self-built CNPM (Chinese National Pentatonic Modes) Dataset. After expanding, the dataset contains 287 music recordings, including instrumental and vocal music, with instruments mainly being traditional Chinese instruments such as Guzheng, Guqin, Pipa, etc. The complete mode information is also included as labels, annotated by faculty and students in related disciplines. The average audio duration is 179.5s and the distribution of data is shown in Figure 3. Most of the audio comes from the Internet, with some Shang and Jue mode pieces being created and recorded by our musicians. In collecting and labeling the data, we select music pieces with clearer modes, more stable pitches, and mostly performed by contemporary musicians to avoid controversy in judging the modes. For music with modulation, we divide and label them accordingly. The dataset can be found here [3] .

The distribution of mode pattern in the database is relatively balanced, but system and tonic are not. To address the problem of fewer samples in some categories, we perform data augmentation by pitch shifting. To be specific, our processing of audio includes ascending a semitone, ascending a whole tone, descending a semitone and descending a whole tone with labels changing accordingly. Note that this augmentation only changes system and tonic, not pattern or type. And it is only applied to the training data.

4.2 Results

To ensure the effectiveness of the baseline approach, we first compare it with the 12-D ordinal template matching method proposed in [20] which also uses the chroma feature of audio. Different from our indirect prediction of five mode patterns from system and tonic, the ordinal templates directly predict three mode patterns of Gong, Shang and Zhi. The recognition accuracy is shown in Table 3, and our baseline method achieves better results.

Accuracy (%)	Ordinal	Baseline
Gong	62.20	**71.95**
Shang	55.56	**64.44**
Jue	-	**63.27**
Zhi	46.15	**67.31**
Yu	-	**62.71**

Table 3. Accuracy results of mode pattern recognition using template matching methods.

Metric	Object
ACC1	System
ACC2	Tonic
$ACC3_D$	Pattern (Directly)
$ACC3_I$	Pattern (Indirectly)
ACC4	Tonic and Pattern
ACC5	Type
ACC6	Tonic, Pattern and Type

Table 4. Accuracy metrics. Indirectly here means we get the mode pattern via system and tonic recognition results. Higher ACC4 is our primary task. And ACC6 means all correct.

For the neural network training, we use the Adam optimizer, cross-entropy loss function and a learning rate of 0.001. The batch size of each model is set to 32. For recognition results, we develop seven accuracy metrics to evaluate, as shown in Table 4.

In preliminary experiments, we adopt and modify the main structure of the InceptionKeyNet [17] network which is designed for major/minor keys recognition to perform our modes recognition. The usage method is similar to the modified-ResNet single-task models. We conduct experiments on the same random test set and find the two models have similar performance. But because the original InceptionKeyNet is implemented by TensorFlow and our models are implemented by PyTorch, it is hard to achieve a completely fair comparison and claim which structure is better. Since our models based on ResNet have a simpler structure and can converge in fewer epochs, making them easier to implement and train, the following experiments are performed using modified-ResNet18-based models.

The main experiments are conducted on the template-based baseline approach, the ResNet-based single-task models, as well as the ResNet-based multi-task model, and the results are shown in Table 5. To fully evaluate the models, we use a 5-fold cross-validation to obtain more con-

vincing accuracy results and compare them with the baseline method acting on the whole dataset. When dividing the data, we divide it by music tracks, keep the mode pattern ratio constant and ensure that only the corresponding training data are involved in back propagation in each fold of training.

As seen in the results, CNN-based methods outperform template matching method, and indirect mode pattern prediction is much better than direct prediction. The correct system and tonic predictions can introduce the correct pattern, but the correct pattern prediction can also be brought out by the wrong but relatively correct system and tonic. Therefore we need ACC4 to make sure all three (i.e. system, tonic and pattern) are correct. Since $ACC3_I$ is higher, we use the pattern results of indirect prediction to calculate ACC4 and ACC6. The accuracy of the system, tonic and pattern being predicted correctly at the same time achieved by our ResNet-based models is a satisfactory result. Due to the very uneven data distribution of mode type, the model responsible for type prediction is hard to train. So ACC5 and ACC6 are listed for reference only, and are not the primary tasks of this paper. In the comparison of single-task model and multi-task model, we find that the multi-task model has better ability to identify the tonic and directly recognize the mode pattern, which indicates the effectiveness of the multi-task learning strategy. Then for $ACC3_I$ and ACC4, the single-task and multi-task models perform similarly. The multi-task model performs more consistently over different folds with less parameters compared to using multiple single-task models.

Due to the relatively good performance of the multi-task model, we combined the indirect mode pattern recognition results of each fold to obtain a normalized confusion matrix and visualized it, as shown in Figure 4. Note that if the result of a certain indirect prediction is invalid, we use the direct prediction instead. From the confusion matrix, we can see that the CNN model has a high recognition ability for Gong, Jue and Yu modes, but the recognition of Shang and Zhi modes needs to be improved. This difference should be more related to the quality, distribution and representativeness of the data than the model itself. Besides, a larger value of k in k-fold cross-validation may lead to better results.

5. CONCLUSION & FUTURE WORK

In this paper, we explore the automatic mode recognition for Chinese national music composed after the early twentieth century with the characteristics of Chinese national pentatonic modes. For music from diverse ethnic and cultural backgrounds, the musical concepts and logic will be different, as well as the use of different tuning systems, rhythmic patterns, instruments and expressions. Traditional Chinese music played by traditional Chinese instruments is rich in the use of tuning systems, including compound tuning systems. This requires researchers to design more appropriate algorithms and models based on the characteristics of the music in order to get better results. Meanwhile, this can also facilitate the development of mainstream MIR algorithms.

We combine the musical domain knowledge when designing the methodology used in this paper. When identifying the mode pattern, we do so indirectly by considering its relationship to the TongGong system and the tonic pitch. As for the pitch of tonic, only the ending fragment of the music is considered according to the musical characteristic. We also use multi-task learning for recognition based on the correlation between system, tonic and pattern.

The accuracy of mode type is relatively low due to the difficulty of recognition and uneven data. In the future, more detailed annotation with segmentation can be carried out for audio to improve the accuracy. It is also possible to use other methods to identify each instrument and its pitches first before recognizing, but this remains a challenge for traditional Chinese instruments.

For the issue of small data size, more data augmentation methods can be used, such as time scaling, random masking, adding noise, etc. Transfer learning can also be utilized to train the backbone neural network on a large dataset first to have the ability of capturing tonality and pitch features, and then on a small dataset to accomplish a specific task.

ABSTRACT

New datasets of non-Western traditional music contribute to the development of knowledge in MIR and allow computational techniques to inform ethnomusicology. We present an annotated dataset of traditional vocal polyphony from two regions of the Republic of Georgia with disparate musical characteristics. The audio for each song consists of four polyphonic recordings of one performance from different microphones. We present a process and workflow that we use to annotate the dataset, which takes advantage of the salience of individual voices in each recording. The process results in an f_0 estimate for each vocal part.

1. INTRODUCTION

To evaluate algorithms in Music Information Retrieval (MIR) it is essential to have a variety of extensive datasets of annotated music [1]. Annotated datasets of vocal *a cappella* music have been scarce until recently, particularly of non-Western music. The work of [2] provides a list of datasets of vocal polyphony that includes two datasets of songs from the Republic of Georgia: the Erkomaishvili dataset of [3] and the collection recorded in the work of [4].

Multi-f_0 estimation is a sub-problem of Automated Music Transcription (AMT) consisting of identifying the fundamental frequency f_0 of each part in a polyphonic recording. Datasets of polyphony that are annotated with the fundamental frequency of each part are useful as ground truth for multi-f_0 algorithms. Multi-f_0 estimation is a challenging problem for *a cappella* vocal music because of the variety of sounds produced by the human voice and the similarity in timbre of different voices [5].

In this work we present an annotated dataset of 38 three-part songs from the Republic of Georgia, including 29 from the region of Guria and nine from the region of Samegrelo. The total duration of the collection is 89 minutes. Gurian songs are a particular challenge for multi-f_0 estimation. The three parts are independent melodic lines that often cross and contain rapid movement. The top part often consists of *krimanchuli*, Georgian yodeling, with as many as six changes of octave per second. These features make our dataset a useful contribution as part of a training set for multi-f_0 algorithms. We have created a web-based visualization of the dataset that is potentially useful as an aid to singers learning their parts on Georgian songs, which was the purpose of the original recordings.

We also present a new process and workflow for multi-f_0 estimation where several recordings exist of a single performance. Our dataset is an unusual challenge for annotation in that it does not include isolated tracks for each vocal part. Instead there are four recordings of one performance made from different microphones. One recording presents a balanced mix of voices. In each of the other three recordings one of the voices is more salient than the other two, but all three voices are easily audible and create a polyphonic mixture. Our process and workflow consist of isolating the salient voice, applying several algorithms for monophonic f_0 estimation, and using a graphical interface to select the correct estimate. In addition to f_0 estimates we present the median absolute deviation of the estimates, a measure of confidence in the estimates.

Other interactive methods have appeared for extracting melody from audio. The work of [6] introduced the Tony software for monophonic audio. It presents to the user several pitch estimates generated by an early stage of the pYin algorithm, from which the user can select ranges of time and frequency. It is designed for ease of use and has many features such as octave correction [7]. The system of [8] designed for the Erkomaishvili dataset presents to the user a spectrogram with one melody highlighted as a result of dynamic programming performed on a set of salient frequencies at each time step, followed by automatic corrections that take into account musical knowledge such as voice ranges. The user is able to delete and replace lines in the spectrogram. There is a web interface for the Erkomaishvili dataset which plays the audio of each song accompanied by a scrolling score with lyrics. The work of [2] created the Dagstuhl dataset by recording each singer with a larynx microphone, a headset microphone, and a dynamic microphone. The researchers applied both the pYin and CREPE algorithms to each recording and derived confidences for each algorithm on each microphone using a subset of recordings manually annotated by a sound engineer who used Tony.

Our method differs from these methods in that it is designed for polyphonic recordings that contain one salient voice, it makes use of several f_0 estimates, and it presents

Kutlay, "*Teach Yourself Georgian Folk Songs* Dataset: An Annotated Corpus Of Traditional Vocal Polyphony", in *Proc. of the 23rd Int. Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

a measure of confidence in the estimates. We have created a web interface for the dataset which plays the audio of each song accompanied by a scrolling visualization of the pitches. Unlike that of [2] our visualization shows the f_0 estimates of the three vocal parts, and the median absolute deviation of the each estimate is displayed in the manner of a confidence interval.

1.1 Georgian music datasets

The Republic of Georgia, bounded on the north by the Caucasus Mountains and on the west by the Black Sea, contains within its borders several starkly varying traditions of three-part *a cappella* vocal music [9]. Georgian singing is an aural tradition that uses a scale of its own [10]. The intervals that make up the Georgian scale are an area of research in ethnomusicology, as well as the extent to which singers in the tradition adjust to one another and deviate from a fixed scale to produce desired harmonies [11, 12]. Annotated datasets of Georgian music have been useful in advancing this research [9, 13].

The Erkomaishvili dataset contains Georgian sacred songs performed by a single performer on all three parts, with overdubbing. The most recent version of the dataset due to [3] includes f_0 annotations due to [8], onset annotations, and musical notation due to [14]. The dataset due to [4] includes Georgian folk songs from various regions recorded using individual larynx and headset microphones and a microphone for the ensemble. The authors observe that larynx microphones isolate the three parts well, and they illustrate this point by showing estimates of f_0 derived for one song in the collection.

The present dataset, like these other datasets, consists of recordings of performances by expert Georgian singers of interest to ethnomusicologists. However, unlike the dataset due to [3], our dataset consists of studio recordings of live ensembles, and unlike the dataset due to [4], our dataset was recorded without the benefit larynx microphones and therefore presents a greater challenge for pitch estimation.

Our dataset contains the recordings in the collections *Let Us Study Georgian Folk Songs (Gurian Songs)* and *Teach Yourself Georgian Folk Songs - Megrelian Songs*, both published in 2004 by the International Centre for Georgian Folk Song. The performers are highly trained musicians and experts in the music of their regions. [1] The performers were recorded together as an ensemble in close proximity in a single room in a studio [15]. There was one microphone for each part and one microphone for the room. This system of recordings was intended as an aid for singers learning their parts on Georgian songs, a setting in which it is beneficial to hear all three parts, but one above the other two. All songs are in three parts except during short intervals of overlap between antiphonal ensembles or solo and trio. The ensemble for each song is one high tenor (*pirveli* in Georgian), one middle tenor (*meore*) and one bass (*bani*), with a few exceptions. The song "Khasanbegura" has two antiphonal ensembles, one a trio and the other consisting of one high tenor and a choir of middle tenors and basses. The three songs "Maq'ruli", "Orira", and "Shvidk'atsa" also have two ensembles, one a trio and the other consisting of two tenors and a bass choir. Two songs, "Indi-Mindi" and "P'at'ara Saq'varelo", have a fourth part, a brief solo bass, that we have ignored for purposes of f_0 estimation. All but the two songs "Sabodisho" and "Mi Re Sotsodali" are *a cappella*. The accompaniment in these songs is a *chonguri*, a picked Georgian lute.

1.2 f_0 Estimation

Research on monophonic f_0 estimation has developed over several decades. The work of [16] introduced the use of the "cepstrum" in f_0 estimation, which exploits the fact that harmonics are regularly spaced in the frequency domain. Building on the work of [17], which exploited the same fact using the technique of spectral compression, the work of [18] introduced the technique of subharmonic summation to model the ability of the human ear to detect a weak fundamental pitch and used numerical methods to reduce the susceptibility of the estimate to noise [19]. The work of [20] introduced an algorithm for f_0 estimation and voiced-unvoiced classification which used the autocorrelation function of the signal to generate candidate pitches and dynamic programming to generate a sequence of pitches with few large jumps in frequency and few isolated voiced or unvoiced points. The well-known Praat software uses this algorithm [21]. The work of [22] introduced the well-known Yin algorithm, which used the sum of squared differences between the signal and lagged signals instead of the autocorrelation function. The work of [23] introduced the use of the fast-lifting wavelet transform for f_0 estimation. The work of [24] introduced the use of a neural network for f_0 estimation with the CREPE algorithm.

We use these six algorithms – Noll [16], Hermes [18], Boersma [20], Yin, Maddox [23], and CREPE – as a "panel of experts" to estimate f_0 in these recordings. [2] One may anticipate that algorithms based on autocorrelation or deep learning are strictly better than those based on Fourier or wavelet analysis. However, we find that for the high-quality non-monophonic recordings of this dataset, each algorithm produces correct estimates that tend to persist through the duration of a musical note or longer, and the algorithms err under different conditions. The errors we observe are mainly pitches in the wrong octave and pitches on the wrong part, including pitch estimates at times when the current part is silent or is a fricative consonant. Despite the presence of such errors, on harmonic content (judged subjectively as vowels sung by a healthy voice) at least one of the algorithms typically estimates f_0 correctly.

The paper is arranged as follows. In Section 2 we give details about the data and describe the process and workflow. [3] In Section 3 we present visualizations that com-

[1] The performers on the Gurian songs include Guri Sikharulidze, Tristan Sikharulidze, Otar Berdzenishvili, Anzor Erkomaishvili, Gedevan Mzhavanadze, Kote Papava, and Levan Goliadze. The performers on the Megrelian songs include members of the Odoia Choir directed by Polikarpe Khubulava.

[2] pYin did not improve over Yin in initial testing.

[3] The code resides in a public Github respository [25] The raw data and annotations are available to researchers upon request.

pare the performance of the six estimation algorithms on the dataset and that support the use of median absolute deviation as a measure of confidence in the estimates. We also introduce two types visualization that shed some light on musical content of the collection. Finally we present an illustration of the web interface of the dataset. [4]

2. PROCESS AND WORKFLOW

2.1 Estimates and alignment

The first step in our process is to apply six algorithms for monophonic f_0 estimation to each recording. The outputs of these algorithms are shifted in time, typically by a few hundredths of a second. We align the six estimates in time by fixing the estimates of one arbitrarily-chosen algorithm (Boersma) and shifting each of the others by multiples of $0.01s$. We choose the shift that minimizes $d(\delta t)$, the time-lagged ℓ_2-distance between the two time series at lag δt. We limit our search to the range $[-0.1, 0.1]$ because the vibrato of the human voice is $5-7Hz$, which is the Nyquist frequency of a sample rate of $10 - 14Hz$ [27].

Figure 1 shows a plot of $d(\delta t)$ for one song in the collection. In most cases δt_0 is very close to 0.

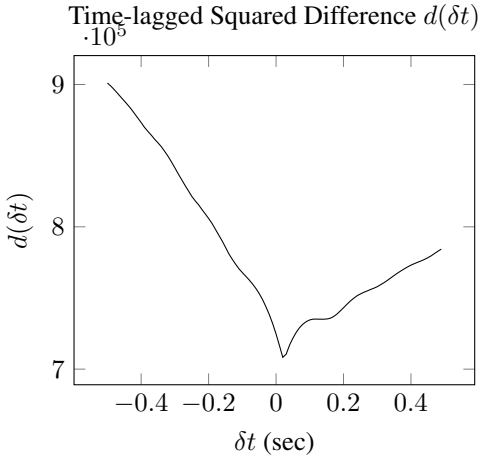

Figure 1. The squared difference between Boersma at time t and another f_0 estimator at time $t + \delta t$ for the middle part of *Ak'a Si Rekisho* from the Megrelian collection.

2.2 Note estimation

The next step in our process is a heuristic method for identifying notes in the target estimate. We chose a method that is simple to code and produces note values that serve well as a visual aid for the analyst, as opposed to a state-of-the-art method such as [28]. For purposes of post-processing non-note sections longer than $0.2s$ are considered unvoiced and the rest are considered voiced consonants.

The idea behind the heuristic is that a note transition is typically a monotone change in pitches between a local peak and a local trough in the singer's vibrato. The heuristic traverses the time series forward and identifies a note transitions as a change of 7% from the most recent local peak or trough. The pitch value of the note estimate is the average of the target estimate pitches over the duration of the note. The heuristic sets a minimum note length of $0.07s$. The heuristic also identifies as *transitions* monotone sequences of pitches between notes and increasing sequences of pitches before notes. Anything else is a non-note. We tuned the parameters during development. The 7% note transition threshold typically errs on the side of false negative note transitions.

[4] The web interface for the dataset makes available the f_0 estimates of the three vocal parts of each song [26].

2.3 Voiced-unvoiced detection

In parallel to the two steps just described, a heuristic "voiced/unvoiced" method removes non-salient voice parts that are present when the salient voice part is silent. This heuristic is a simple threshold based on the histogram of amplitude and the technique of weighted zero crossings. The recording is divided into overlapping frames of length $0.015s$ spaced $0.01s$ apart. For each frame the root mean squared of amplitude is divided by the zero crossing rate. A histogram of the ratio is created and smoothed using a Hanning window. The smoothed histogram typically has a local maximum near 0 that is due to sections of silence in the recording. There are typically one or two other local maxima near 0 that correspond to silence in the salient part. The "voiced" threshold is characterized by a high local maximum preceded by a low local minimum.

We tuned the parameters to result typically in some false positive sections of the recording that require manual correction but only isolated false negatives that can be corrected automatically. Figure 2 shows the smoothed histogram for one part of one song.

In Georgian music there is often a *decrescendo* in each voice at the end of a phrase. The threshold produced by the algorithm tends to correctly classify the ends of phrases but also tends to generate false *voiced* classifications during the subsequent silence. To combat this problem we added an automatic post-processing step which reclassifies short *voiced* sections within *unvoiced* sections.

We hand-tuned each of the heuristics mentioned above on a sample of varied musical sections, with the goal of minimizing the use of the interactive tool.

2.4 Interactive tool

The analyst uses a graphical interface to construct a target f_0 estimate for each part by stitching together the best estimates for different sections of the part. In sections of a part where no estimate is correct the analyst can specify a pitch range. The interface presents a window containing plots of the time series of f_0 estimates for one part of one song. The analyst can switch between parts and can turn the visibility of each time series on and off. The time series include the f_0 estimates of the six algorithms before and after application of the voiced-unvoiced algorithm. The window also includes the *target estimate*, which is initially equal to the CREPE time series, and note estimates for the target estimate. Selection tools and buttons enable the main functionalities of the tool, which are as follows:

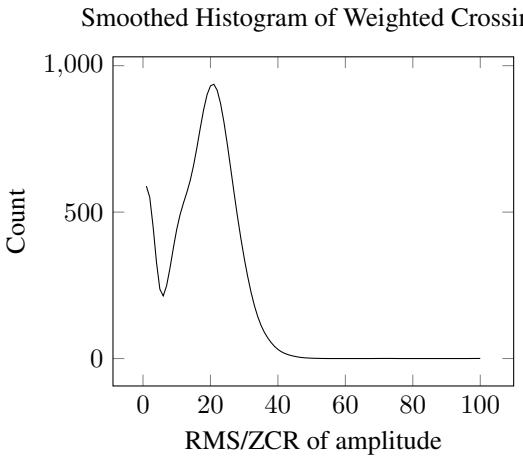

Figure 2. Smoothed histogram of weighted crossing for the top part of *Ak'a Si Rekisho* from the Megrelian collection

- to delete a section of the target estimate, i.e., set $f_0 = 0$ at selected times
- to set a section of the target estimate equal to the estimate of a selected algorithm
- to override a section of the target estimate with a pitch range

After using the tool on one part of a song, the analyst post-processes and saves the target estimate.

Figure 3 shows a screenshot of the tool in operation.

Figure 3. The interactive tool in operation at $84s$ in the middle part of *Adila-Alipasha* from the Gurian collection.

The last step of the process is to rerun the f_0 algorithms Noll, Hermes, Boersma, and Yin, constrained to be within a fixed percentage of the target estimate or within the pitch range. For CREPE and Maddox we use implementations that do not allow pitch constraints as input. If an algorithm is unable to find an estimate within the pitch range, its estimate is dropped.

2.5 Automatic Post-processing

The post-processing algorithm makes the following changes to the analyst's final choice of target estimate:

1. Revert isolated $(0.01 - 0.02s)$ unvoiced pitches to the estimates that were made before the application of the voiced-unvoiced algorithm.
2. Set unvoiced non-note sections (those shorter than $0.2s$) of the target estimate to 0.
3. Set voiced non-note sections of the target estimate to -10 to indicate *undecided*.

2.6 Manual Post-processing

The process described above generally results in a median absolute deviation of the estimates that is less than 1% of the median of estimates. (See Figure 6.) There are exceptions, sections of harmonic content where the estimates disagree. In some cases, typically sustained, well-tuned chords, it is clearly audible that two or more estimates are incorrect and skew the result. In these cases we have manually set a narrow pitch range in the interest of accuracy in the annotations.

3. RESULTS

In this section we discuss qualitatively the effectiveness of our method of combining multiple f_0 estimates. We provide descriptive statistics about the f_0 estimates that we include in the dataset of Gurian and Megrelian songs. First, we assess the estimates produced by each of the six algorithms on this dataset by comparing the initial estimate of each algorithm with the final estimate. Second, we assess the variability of the estimates as a measure of confidence in the final estimate. Third, we provide visualizations of the pitches and intervals of one song, *Gepshvat Ghvini*. Finally, we describe the web interface for the dataset and illustrate it with an example.

3.1 Discussion of the method

In most situations our process of combining multiple f_0 estimates "works" in the sense of producing near agreement among estimates where the fundamental frequency is unambiguous to the human ear. There is one noticeable failure mode. On non-monophonic input Hermes and Yin may fail to produce an estimate within given upper and lower frequency limits, and Boersma may label the sample *unvoiced*. In particular, Hermes, Yin, and Boersma tended to produce no estimate or incorrect estimates on prolonged, well-tuned chords. This is not a noticeable problem for Noll. We do not have a theoretical explanation, but we have found cases where the normalized difference function of Yin either does not have a minimum on the given interval or the location of minimum is unstable. On a small fraction of samples our process produced only two estimates or widely varying estimates.

3.2 Assessing each f_0 estimate

In this subsection we measure the accuracy of each monophonic f_0-estimation algorithm relative to the final f_0 estimate, separately on each collection. We consider the f_0 estimate of each algorithm, after applying alignment and the voiced-unvoiced algorithm, limited to samples that the note estimation algorithm labels as notes. Figures 4 and 5 show one smoothed histogram for each algorithm; it is a histogram of the ratio of the algorithm's f_0 estimate to the final f_0 estimate. By this measure Boersma is the most accurate when it is in the right octave (near 1.0), but Crepe and Noll are in the right octave more often.

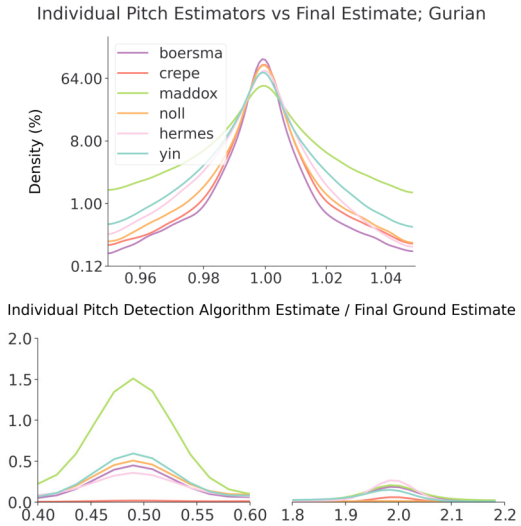

Figure 4. Smoothed histogram of ratio of f_0 estimates, algorithm/final, Gurian collection. Percentage of samples shown: boersma: 85.7%, crepe: 94.7%, maddox: 56.9%, noll: 85.9%, hermes: 86.0%, yin: 81.7%.

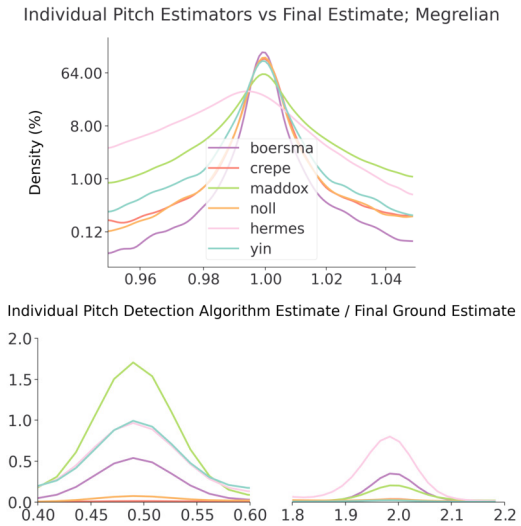

Figure 5. Smoothed histogram of ratio of f_0 estimates, algorithm/final, Megrelian collection. Percentage of samples shown: boersma: 84.3%, crepe: 96.3%, maddox: 63.1%, noll: 91.8%, hermes: 63.0%, yin: 79.4%.

3.3 Variability of the f_0 estimates

At each time step the final f_0 estimate is the median of the estimates of several algorithms. In this subsection we measure the variability of the estimates around the median. This measurement lends credibility to our method by showing that when there is a note (according to the note estimation algorithm) the variability is small (the estimates agree) and when there is not a note the variability is large (the estimates disagree). For our measure of variability we choose the median absolute deviation (MAD) around the median. This measure is robust to outliers, which means that when there is agreement among at least three estimates the MAD will be small. This choice corresponds to our intuition that during a vowel there will be general agreement among estimates and during a consonant there will be general disagreement. Figure 6 shows two graphs of smoothed histograms of MAD (in Hz), one for *note* samples and one for *non-note* samples. The graphs show 97.7% of Gurian note samples and 96.1% percent of Megrelian note samples. They show 70.9% percent of non-note Gurian samples and 74.7% of non-note Megrelian samples.

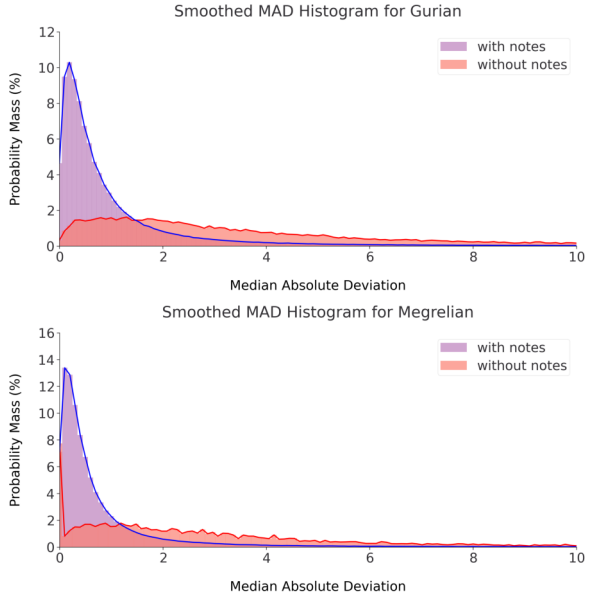

Figure 6. Smoothed histograms of MAD of each estimate, in Hz, *note* vs. *non-note* samples. Top: Gurian collection. Bottom: Megrelian collection.

3.4 Musical Observations

In this subsection we provide visualizations of the pitches and intervals in one Megrelian song, *Gepshvat Ghvini*. The purpose of these visualizations is to illustrate the potential for visualizations of digital data to enable and inform research in ethmomusicology.

We return to the question mentioned in the introduction of what intervals make up the Georgian scale, and to what extent singers deviate from the scale to produce desired harmonies. Figure 7 shows a histogram of the pitches of the three voices for *Gepshvat Ghvini*. The variation in

the peaks of the histograms for the three voices between 210Hz and 220Hz possibly indicates deviation from a fixed scale. Further investigation is needed.

Figure 8 shows a two-dimensional histogram of the chords of *Gepshvat Ghvini*. The x-axis is the ratio of pitches between the middle and bass parts. The y-axis is the ratio of pitches between the top and middle parts. The histogram is shown as a heatmap. The dark patch roughly at coordinates $(1.22, 1.22)$ shows that triads with a perfect fifth are common, and that these triads cluster around those with a "neutral" third between the minor and major third.

To exclude pitches in transition between notes we have limited the data in both figures to pitches at least three time steps away from the first and last pitch of each note, as designated by the note estimation algorithm. In the two-dimensional histogram we have limited the data to samples where we have estimates for all three parts.

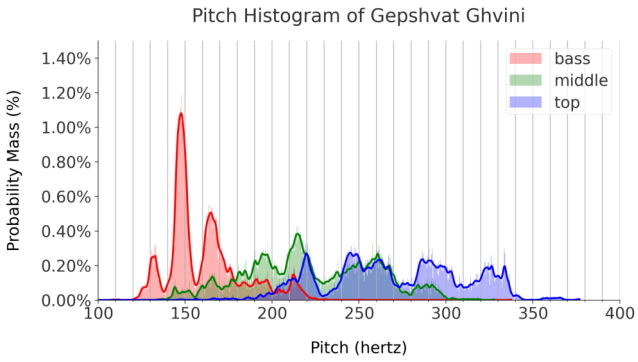

Figure 7. Histogram of pitches in *Gepshvat Ghvini*.

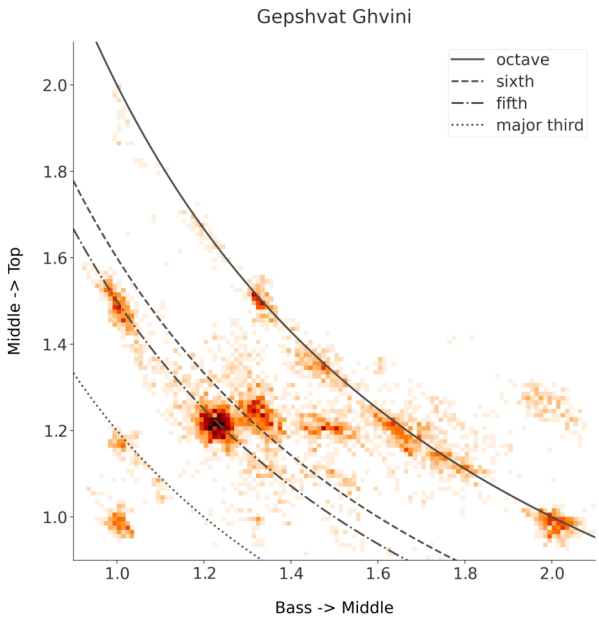

Figure 8. Histogram of chords in *Gepshvat Ghvini*. The x-axis is the ratio of middle to bass pitch. The y-axis is the ratio of top to middle pitch.

3.5 Web interface

In this subsection we describe the web interface for our dataset and illustrate the interface with an example. The web interface serves as a visual tool for the analyst to assess the accuracy of the results, as well as for ethnomusicologists to analyze of songs and for singers to learn the songs. The interface shows a scrolling graph of pitches that is synchronized to an audio player. Figure 9 shows a snapshot of the interface for the Megrelian song *Gepshvat Ghvini*. The graph optionally displays any of the median estimates of the three parts and the median absolute deviations (MAD) of the estimates.

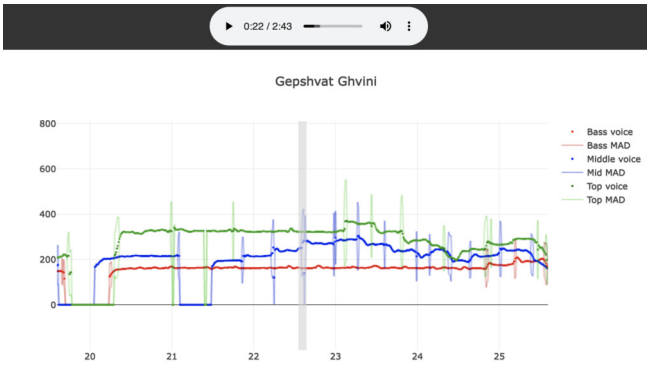

Figure 9. Web interface: *Gepshvat Ghvini*. The shaded line shows the current time. Each solid line shows the median frequency estimate for one part; the faint line of the same color shows the median absolute deviation.

4. CONCLUSION

We have presented a process and workflow for multi-f_0 annotation of a dataset of songs from the Republic of Georgia in which each song is represented by four recordings from different microphones. The annotations in our dataset represent the average of f_0 from different algorithms and are accompanied by the median absolute deviation of the estimates, which we have shown is a reasonable measure of confidence in the estimate. We hope our dataset and web interface are of interest to ethnomusicologists as audiovisual aids for analysis.

We plan to apply our process to collections of recordings from two other regions of Georgia which have been produced recently [29, 30]. We plan to use the resulting labeled datasets to develop algorithms for multi-f_0 estimation using the recordings of the mixed voices from the room microphones in our collections. We plan to develop the web interface further as a learning aid for singers by adding new features, including lyrics as subtitles.

5. ACKNOWLEDGEMENTS

The authors would like to thank the International Centre for Georgian Folk Song and the International Research Center for Traditional Polyphony, for permission to share the audio data with researchers.

ADAPTING METER TRACKING MODELS TO LATIN AMERICAN MUSIC

ABSTRACT

Beat and downbeat tracking models have improved significantly in recent years with the introduction of deep learning methods. However, despite these improvements, several challenges remain. Particularly, the adaptation of available models to underrepresented music traditions in MIR is usually synonymous with collecting and annotating large amounts of data, which is impractical and time-consuming. Transfer learning, data augmentation, and fine-tuning techniques have been used quite successfully in related tasks and are known to alleviate this bottleneck. Furthermore, when studying these music traditions, models are not required to generalize to multiple mainstream music genres but to perform well in more constrained, homogeneous conditions. In this work, we investigate simple yet effective strategies to adapt beat and downbeat tracking models to two different Latin American music traditions and analyze the feasibility of these adaptations in real-world applications concerning the data and computational requirements. Contrary to common belief, our findings show it is possible to achieve good performance by spending just a few minutes annotating a portion of the data and training a model in a standard CPU machine, with the precise amount of resources needed depending on the task and the complexity of the dataset.

1. INTRODUCTION

Meter tracking means following the pulsating temporal structure of music from audio signals, which implies identifying at least beats and downbeats [1]. It is a long-standing area of research in music information retrieval (MIR) with applications ranging from automatic DJ mixing [2] to musicological studies [3]. Meter tracking has gone through a big transformation in the last decade due to the introduction of deep learning (DL) techniques [4–7], which brought an improvement in performance as well as a change in the design paradigm of related methods [8]. Nowadays, beat and downbeat tracking models rely mostly on supervised DL [8], and thus become data-driven and requiring large amounts of annotated data to generalize to different songs, genres or datasets.

This dependence on annotated data poses many challenges to the widespread use and adoption of such models, especially for culturally specific music traditions [9–11], which often lack annotated data as producing annotations requires culturally-aware expertise. For this reason, off-the-shelf general-purpose models typically underperform in these music genres since they are underrepresented in the datasets used for training. Nevertheless, previous work on some Latin American music traditions shows that if annotations are available, training statistical models can produce good performance results [12].

Recent works have started to look at beat tracking from a different perspective. Instead of developing "universal" models capable of performing equally well across various music genres (requiring large quantities of labeled data), recent efforts have shifted towards adapting preexisting models to succeed on a subset of interest [13], which can be as restricted as a single musical piece [14, 15]. This paradigm aligns well with real-world applications, where it is reasonable for a user to spend a short time producing a few seconds of annotations to get a good performance.

We apply this idea to the refinement of a meter tracking model so that it works well in a particular music genre. We argue that if the genre presents enough homogeneity in terms of its instrumentation and metric structure, as is the case with many Latin American music traditions, it is possible to adapt meter tracking models to perform notably well with just a few annotated data points. We explore this adaptability in terms of data, performance and computational cost. While focusing on two Latin American music genres, *samba* and *candombe*, we study the adaptation of a deep learning state-of-the-art model [16] and compare it with a simpler statistical model [17]. Our contributions are: 1) We perform a detailed analysis on how much annotated data and computation time in CPU are needed to achieve close to "full-dataset" performance in *samba* and in *candombe*, including models trained from scratch and fine-tuned, and compare them to off-the-shelf models trained with Western music; 2) We propose initial experiments to understand the homogeneity conditions under which this adaptation will be successful; 3) We open-source our experiments and provide pre-trained models.

1.1 Other adaptive methods

Existing adaptive methods typically feature some form of transfer learning or fine-tuning, use deep learning models, and are concerned with either beat tracking [13–15] or onset detection [18]. Fiocchi et al. [13] adapt a beat tracking model via transfer learning from Western music to a dataset of Greek music. The authors explore both recurrent neural networks (RNNs) and long-short term memory networks (LSTMs), plus a dynamic Bayesian network (DBN) for inference. The model is fine-tuned using a big training set, though with limited success which the authors attribute to the challenges of the dataset. Even though this is an interesting approach for exploring the idea of adapting to a particular music genre, RNNs and LSTMs are known to be computationally expensive, so in the context of real-world model adaptation they are a concerning choice.

On the other hand, Pinto et al. [14] and Yamamoto [15] explore temporal convolutional networks (TCNs), and focus on the adaptation of models to a particular piece of interest of the user. These authors showed that is possible to adapt TCN models using very small quantities of data (in the order of seconds) to work well, in particular with musically challenging pieces. Furthermore, the TCN is a light-weighted model, computationally more efficient.

Finally, Fonseca et al. [18] apply similar ideas to the adaptation of an onset detection model (also featuring TCNs) to a Latin American music tradition: *maracatu de baque solto*. The authors fine-tune the last layers of the TCN with just a few seconds of manual annotations, and show the advantage of instrument-specific models for the automatic annotation of onsets for musicological studies.

1.2 Latin American Music Traditions

Candombe drumming is a musical tradition from Uruguay that constitutes an essential part of its popular culture and African heritage. Its rhythm is structured in 4/4 meter, and it is played while marching in the streets using three types of drums of different sizes and pitches: *chico*, *repique*, and *piano*. Each of these drums has a distinctive rhythmic pattern and musical role. An additional time–line pattern, called *clave* or *madera*, is shared by the three drums. The *chico* drum is the timekeeper; it repeats a one-beat pattern that establishes the pulse throughout the performance. The *repique* drum is the improviser; it alternates *clave* patterns and characteristically syncopated phrases. The *piano* drum delineates the timeline with distinctive one-cycle patterns and occasionally interposes ornamented *repique*-like figurations. The rhythm shares many traits with other musical traditions of the Afro-Atlantic world. Notably, some of its rhythmic patterns have strong phenomenological accents displaced with respect to the metric structure and divide the rhythmic cycle irregularly with few strokes on the beat.

In parallel, *samba* is a Brazilian musical genre deeply rooted in Brazilian culture, and also has African origins. The word "*samba*" actually describes a family of different subgenres, the most famous arguably being *samba de enredo*, *partido alto*, *bossa nova*, and *pagode*. Similarly to *candombe*, *samba* can be played while parading, which is most common during the festivities of *Carnaval*. It can also be performed in more informal settings, in *rodas* and bars, or even as a chamber-music-like style. Its rhythm is commonly perceived in 2/4 meter, and is conveyed by several types of percussion instruments —– *tamborim*, *pandeiro*, *surdo*, *cuíca*, *agogô*, among others. Each instrument has a handful of distinct patterns [19], and more than one instrument may act as the timekeeper. Because of this combination of timbres and pitches, the texture of a performance can become very complex. *Samba* has unmistakable characteristics as the strong accent on the second beat and the development of contrametric structures.

2. METHOD

Following our intuition about the high homogeneity of *candombe* and *samba* as discussed in Section 1.2, our objective is to understand if it is possible to train meter tracking models with small quantities of data from these music traditions, and if so, how much is needed. To that end, we train the models with increasing amounts of annotated data, ranging from less than a minute up to nearly 40 min, and compare the performance and computational cost of each configuration against the others. We contrast three different training strategies: 1) training the model from scratch with either *candombe* or *samba* snippets; 2) fine-tuning a model trained with 38 h of data from diverse datasets of Western music to work on either *candombe* or *samba*; and 3) same as the previous two, but training the models with data augmentation to artificially increase the "small data" input. We use a state-of-the-art temporal convolutional network model [16] for our experiments, as it presents a good compromise between performance and computational cost. We contrast this model against off-the-shelf models trained in Western music. To understand the adaptability and computational cost of deep learning based methods, we compare the TCN against another simple yet effective baseline, a Bayesian model (BayesBeat) [17]. In the following, we explain our methodology in detail.

2.1 Datasets

We have selected datasets of two different Afro-rooted Latin American music traditions for our experiments. First, the *Candombe* dataset [12, 20], which consists of 35 recordings of *candombe* drumming, for a total of nearly 2.5 h. Each track contains an ensemble recording of three to five drummers using different configurations of drums. Tempo varies greatly and often increases along the performance. To represent the *samba* genre, we use the "acoustic mixtures" data from the BRID dataset [21]. These correspond to 93 short tracks (about 30 s each) of musicians playing together rhythm patterns found in *samba* and two of its subgenres (*samba de enredo* and *partido alto*). Ten different instrument classes are represented, and two to four musicians take part in each track. The dataset contains a variety of tempi; however, tempo remains fairly constant within each track. In order to consistently train our models with about the same amount of data from both *candombe*

and *samba*, and also to allow the comparison between the results obtained for both sets, *candombe* tracks were segmented into non-overlapping 30 s excerpts. In each experiment repetition, we use a sample of 93 *candombe* excerpts.

We also used six datasets to train the baseline TCN model: Ballroom [17, 22], Beatles [23], GTZAN [24, 25], and RWC (Classical, Popular, Jazz) [26, 27]. These are commonly used in meter tracking tasks and together correspond to over 38 h of audio data. The Ballroom and GTZAN datasets comprise many diverse music genres (e.g., waltz, tango, rumba, rock, pop, country, etc.). We used the loaders from *mirdata v0.3.6* [28], except for a custom loader used with Ballroom.

2.2 Working with small size datasets

For our experiments, in all cases, we first separate train and test data (80% and 20% of 93 excerpts respectively) to ensure a fair assessment of the models. Then, we divide the training data into six subsets, spanning {4, 9, 18, 37, 55, 74} 30-second tracks. We want to determine how differently the models adapt to small quantities of data, so we followed a similar approach to that of [14] to define the amount of data to be used for training. We select short 10 s temporal regions at the beginning of the audio excerpts, along with the corresponding beat and downbeat annotations, and discard the remaining audio portion. Then we split each of these regions into two adjacent 5 s parts, the first to be used for training and the second reserved for validation in the TCN model; alternatively, we use the entire 10 s for training the Bayesian model with off-the-shelf parameters. Considering that each snippet only lasts 10 s, these data subsets add up to approximately 40 s, 1.5, 3, 6, 9, and 12 min of annotations, respectively. The rationale behind this strategy is that given a set of recordings of such Latin American music traditions in real-world applications, it would be reasonable to ask a user to annotate just a few seconds to a few minutes of data; of course, the less data needed, the better.

Given that we are using very few data points to train the models, performance is strongly affected by data sampling. To mitigate this, we repeat all of our experiments 10 times with different seeds for the random data split generation, which means that models are trained 10 times with each of the different subset sizes. Note that selecting the best strategies for data sampling is out of the scope of this work, and left to be addressed in the future. Test data are left uncut, i.e., we use the full 30 s, to keep compatibility with common model evaluation practices in meter tracking.

2.3 TCN Model

We use in our experiments the TCN multi-task model presented in [16], in particular the open-source implementation of [8]. In this work, we focus on meter tracking, and ignore the tempo estimation head of the network. First, the TCN estimates the beat and downbeat likelihood. Then, we use two different implementations of a DBN (*DBNBeatTracker* and *DBNDownBeatTracker* from *madmom v0.17.dev0* [29]) to infer the final positions of beats and downbeats respectively. Inferring them separately rather than jointly led to better results.

2.4 Training strategies

2.4.1 Training from scratch (TCN-FS)

For datasets with high similarity in terms of instrumentation, rhythmic patterns, and tempo, we expect that we can train a model from scratch with a few training points that would work well for most of the data.

Following the explanation in Section 2.2, we train one model per data subset, and repeat this 10 times with randomly initialized weights and seeds. We also consider the case in which all annotations are available and include the analysis of model performance when training with the entire 30-second excerpts. In this situation, we split the 74 train excerpts into train and validation (75%/25%). For every strategy, we use a learning rate of 0.005, and reduce it by a factor of 0.2 if validation loss did not improve after 10 epochs. We train for a maximum of 100 epochs, early stopping at 20 epochs.

2.4.2 Fine-tuning (TCN-FT)

We also approach the problem of meter tracking in a culture-specific setting from a "transfer learning" perspective. Following [13, 14, 18], we adapt a meter tracking model that was previously trained for a different musical context. The intuition here is that if the model is first trained on a large dataset, even if it was built around Western music, it can serve as a good starting point for a model that is to be tuned for a specific out-of-training music tradition. This is a realistic approach since most of the available annotated data and trained models are Western-based. For this purpose, we trained a baseline TCN model on the Ballroom, Beatles, GTZAN, and RWC datasets. Due to the nature of its training data, this baseline model has to cope with many different meters, genres and acoustic conditions, which makes it a good starting point. We fine-tuned it by using the same training procedure described previously with the initial learning rate reduced to 0.001, a fifth of the value used in the FS approach, as in [14].

2.4.3 Data augmentation (TCN-FTA, TCN-FSA)

Data augmentation techniques are useful for artificially increasing the number of training data points, which can be of great benefit in cases of low or insufficient data such as ours. In order to evaluate the impact of data augmentation in our models, we adopted a simple strategy inspired by [14, 16] in the experiments conducted with the TCN model: computing the input STFTs with different frame rates, i.e., varying hop sizes, so as to even out the distribution of tempi in the train set. Instead of randomly sampling from a normal distribution around the annotated tempo, we selected a set of frames rates $\pm 2.5\%$ and $\pm 5\%$ around its value. This allowed us to increase our sample size five-fold while maintaining the same amount of annotation effort. Models obtained with the data augmentation procedure are labeled TCN-FSA and TCN-FTA, for the training strategies described in Sections 2.4.1 and 2.4.2.

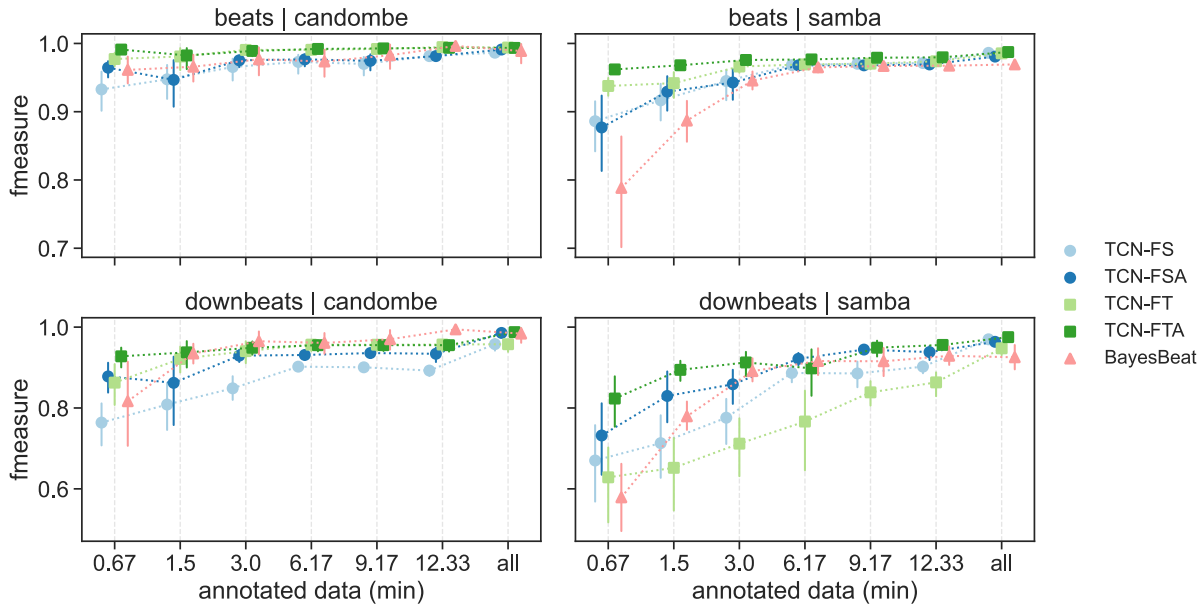

Figure 1: Performance of different model and training configurations. Label "all" indicates fully-annotated dataset.

2.5 Baselines

We include two types of baselines. Firstly, the BayesBeat statistical model [17] is used as reference to the adaptability and computational cost of the TCN. It has fewer parameters, thus training is faster. The second type of baselines are three off-the-shelf models—a Signal Processing technique, and two neural networks trained on Western music—; they illustrate the need for tailor-made solutions/adaptations in our context. Details presented below.

BayesBeat. This is based on the *dynamic bar pointer model* [30], and it simultaneously estimates beats, downbeats, tempo, meter, and rhythmic patterns, by expressing them as hidden variables in a hidden Markov model (HMM). An observation feature based on the spectral flux is computed from the audio signal and an observation model uses Gaussian mixture models (GMM) that are fitted during training to the feature values of each bin in a one–bar grid, so that rhythmic patterns are learned. Several patterns can be modeled, though one pattern is assumed to remain constant throughout the audio signal.

BayesBeat has a few hyperparameters that the user should choose depending on the music. Those are the number of rhythmic patterns, the type of feature to use (e.g., using only low, or low and high frequencies), and the feature grouping (e.g., how to compute the rhythmic pattern clusters), the tempo range, and whole note subdivisions. In [17], it is reported that using two separate frequency bands ($\gtrless$ 250 Hz) helps finding the correct metrical level and is beneficial for beat and downbeat tracking. But, considering more frequency bands did not improve the results [17]. According to [31], using one rhythmic pattern per rhythm class is usually enough to achieve a good performance and provides the best results in most cases. Following this, we use one rhythmic pattern and two frequency bands.

Off-the-shelf baselines. We use the joint beat and downbeat tracking model of Böck et al. [4] as per its implementation in *madmom v0.17.dev0* [29]. It consists of an LSTM-based model trained in ten datasets spanning Western genres, and Carnatic, Cretan and Turkish music excerpts. We also include the beat tracker from Ellis [32], which estimates a global tempo and then uses dynamic programming to find the best set of beats that reflect such tempo. As a final baseline, we include the TCN of Section 2.3 trained with the Western datasets from Section 2.1 (TCN-BL).

2.6 Evaluation metrics

We use as our main metric F-measure [33], along with the continuity-based metrics [34, 35] CMLt ("correct metrical level") which corresponds to the ratio between correct and annotated beats, and AMLt ("allowed metrical level") which accepts phase errors of half a beat period or octave errors in estimation. For the computational cost of the models, we simply report the time they take to train by using in-build timing functions in the code.

3. EXPERIMENTS AND RESULTS

3.1 Performance of models

Figure 1 shows the F-measure results for the TCN models trained for *candombe* and for *samba* with different amounts of data using each of the training strategies, as well as BayesBeat, computed as the bootstrapped results of ten experiments (95% confidence) with different random seeds for each combination of model and data amount.

A first striking observation is that for both beats and downbeats, the performance curve for most models has a small positive slope, which means it is indeed possible to nearly achieve best model performance (which would require training with full dataset) by just training with few samples. This is particularly true for the estimation of beat, for which models rapidly reach F-measure scores above 80% with less than a minute of data in both *candombe* and *samba* for almost all configurations. This is an interesting

Model	*Candombe*						*Samba*					
	Beat			Downbeat			Beat			Downbeat		
	CMLt	AMLt	F	CMLt	AMLt	F	CMLt	AMLt	F	CMLt	AMLt	F

Ellis [32]	34.8	38.1	38.0	-	-	-	82.3	87.6	87.1	-	-	-
Böck [4]	11.7	14.4	11.5	26.7	40.3	0.5	46.9	76.0	66.4	5.2	66.6	2.0

Table 1: Mean F-measure (F) and continuity scores (CMLt, AMLt) in beat and downbeat tracking tasks across both genres.

result, meaning that not much gain in performance is expected with the increase of annotations for such datasets. An end-user could annotate less that a minute of data and yet obtain decent performances. The same holds for downbeat in *candombe*, but not in *samba*. In the latter, there is a clear gain in adding more data, which has to do with the differences between the two rhythms, as discussed below.

Differences between *candombe* and *samba*. Observing the results in Figure 1, we see that the models tend to require more data to achieve better performance on *samba* than on *candombe*, and the uncertainty about the performance for *samba* is larger. Our intuition behind this result is that, as mentioned in Section 1.2, because *samba* has a bigger combination of timbres and pitches than candombe, the decision of what snippets to annotate (i.e., the sampling) might be more critical for the former than for the latter, e.g., ensuring timbre representation.

Best model configuration. The best performing configuration for beat and downbeat tracking in both music traditions is the fine-tuned TCN model with data augmentation (FTA). Particularly, data augmentation produced significant improvement in performance for downbeat tracking in samba. Interestingly, for the adaptive setting concerned in this work, the BayesBeat baseline is competitive with the TCN model, especially considering the computational cost (see Section 3.2).

Comparison with off-the-shelf benchmarks. Table 1 shows the performance of the TCN and the BayesBeat baseline for different data subsets, namely the smallest and largest subsets, and the full dataset. It also shows the performance of the three off-the-shelf baselines explained in Section 2.5. In alignment with previous works [12, 21], the models trained with Western music (TCN-BL and Böck [4]) perform very poorly in *candombe*, and reach only about 66% F-measure in *samba*, both significantly lower than the performance of the same models in Western music genres. The model of Ellis [32] scores considerably better, but is not consistent in both datasets. This shows the necessity of adapting meter tracking models to these music genres, as even the models trained with the smallest subsets of data (0.67 min) outperform the baselines.

3.2 How much time do the models take to train?

Our analysis is motivated by the adaptation of meter tracking models in real-world use cases. For this adaptation to make sense it has to be done quickly. In this regard, we estimate the time each model configuration takes in training, and contrast it with the BayesBeat baseline. Figure 2 shows how the train duration varies with the size of the train set for *samba* (very similar results were obtained for *candombe*). The TCN takes about the same time in both *samba* and *candombe*, with a minimum of about 100 s for the smallest subset. Among the TCN configurations, the most expensive ones use data augmentation. This makes sense given that more data is used for training. As expected, the BayesBeat trains significantly faster than the TCN, taking on average 1.62 s to train with 0.67 min of data, and being in the order of 50 to 150 times faster than the TCN when data augmentation is not used. This big gap in computing time, together with the results of Figure 1 and Table 1, makes BayesBeat an overall good alternative for adapting meter tracking to these Latin American music. We observed that all configurations take about the same inference time, around 25 s for the full test set.

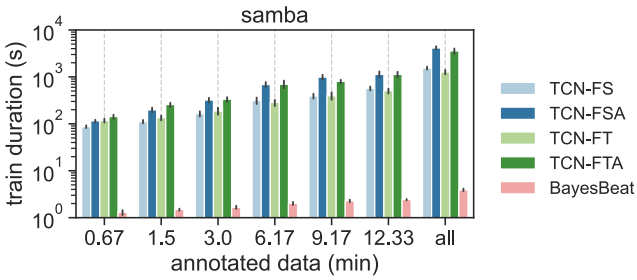

Figure 2: Training time for the different amounts of data.

3.3 When can we train with small data?

Our intuition is that the more variability in the data (in terms of meters, rhythmic patterns and instrumentation), the harder it is for a model to learn with small data. This aligns with our experiments in the adaptability of these methods to *samba* and *candombe*, and also agrees with the musicological insights of Section 1.2. To have a more

quantitative understanding of this, we derived a bar profile for each type of music. First we extract a feature map from each excerpt using the beat/downbeat annotations to time-quantize a locally normalized onset strength function [36] at the tatum scale — this was done with the *carat* [37] toolbox, considering the tatum duration as one quarter of the time-span between successive beats. Then, for each dataset, we summarize these feature maps across time, which results in a distribution of feature values per tatum. To allow an analysis of these profiles in different regions of the spectrum, we compute the onset strength in two frequency bands (20 Hz to 200 Hz; and > 200 Hz). We present these distributions as violin plots in Figure 3 for *candombe*, *samba*, and for the Ballroom dataset.

In Figure 3, we verify that for some tatums strength distributions are concentrated around 1 or 0, indicating a strong characteristic accent or lack thereof at that point of the bar respectively. High variance, in its turn, means "fuzzyness" in the rhythm pattern, which could justify the difficulty in learning that rhythm, specially with small data.

Samba, which has eight tatums per bar (2/4 meter), is known for having a strong metrical accent at beat 2, which we may readily identify in its low-frequency channel at tatum 5. The first beat also has a high median value but is less "deterministic" due to its high variance. In turn, the low-frequency profile of *candombe* displays a high-variance downbeat, no accent on beat 2, and strong accents on beats 3 and 4, but also a strong contrametric accent at tatum 4. These characteristics could help explain why the off-the-shelf beat tracking models, which expect beats to be accented, perform worst on *candombe*. Looking back at *samba*, we see that tatums 2 and 3 show small standard deviations and correspond to "off" tatums; together with beat 2, they make three out of eight tatums that exhibit very small variance in the low channel. In *candombe*, besides tatum 4, tatums 2, 3, 7, 8, 9, 14, and 16 also present small variance. This abundance of "anchor" points could justify why adaptation in *candombe* came with little data.

In Ballroom, we clearly see that beats are distinct for having high strength and low variance in both channels, whereas the rest of the tatums show no clear trend. Its few reference points could pose a challenge for learning models. Furthermore, beat patterns (the combination the four tatums in-between beats, including the beat itself) are also indistinguishable from one another, which could aggravate this matter. To test these observations, we trained a set of models from scratch for Ballroom using the same methodology that for *samba* and *candombe*. Results are depicted in Figure 4. The performance results correlate with the intuition that Ballroom is a more challenging dataset given that it comprises multiple genres, and also that for learning beat and downbeat more data would be needed.

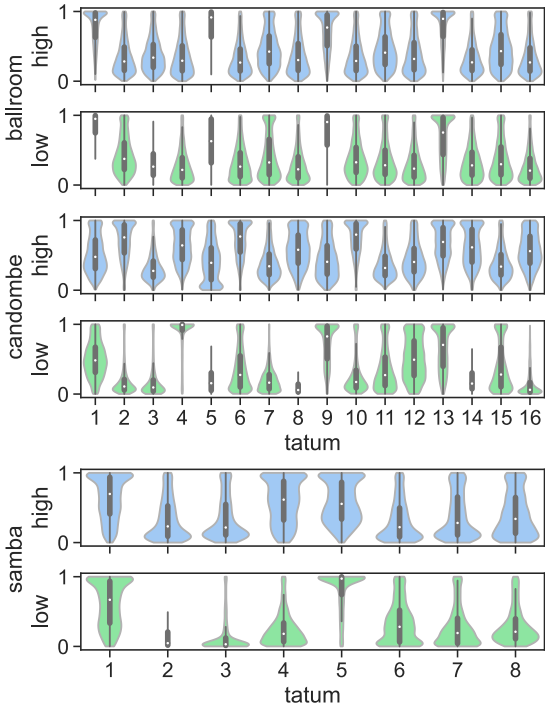

Figure 3: Tatum strength distribution per frequency band for Ballroom (just 4/4 tracks), *candombe*, and *samba*.

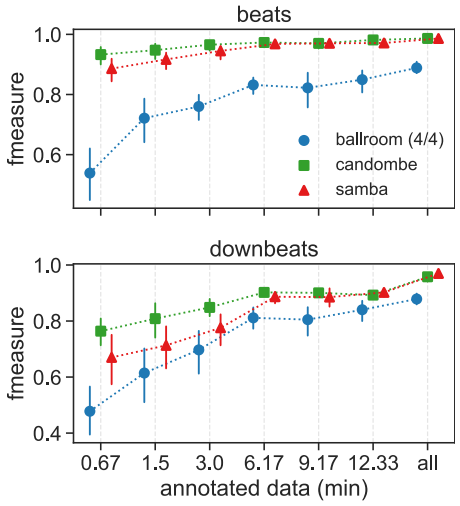

Figure 4: TCN-FS performance in Ballroom.

4. CONCLUSIONS AND FUTURE WORK

We adapted a meter tracking model using small quantities of data to work in particular Latin American music traditions, namely *samba* and *candombe*. We showed that, under certain homogeneity conditions, it is indeed possible to train such models with a few minutes of annotated data and training cycles, and obtain almost full-dataset performance. This result has promising consequences in real-world applications, as it opens the possibility of adapting such models to other music genres with modest labeling efforts. The most competitive model is a fine-tuned TCN with data augmentation, whereas BayesBeat is a good option under computational cost constraints. In the future, we will investigate rhythm complexity metrics that could serve to predict the amount of annotated data needed to adapt meter tracking models to particular music genres.

ABSTRACT

Computational Musicology and Music Information Retrieval (MIR) address the core musical question under study from a different perspective, often combining top-down vs. bottom-up approaches. However, the evaluation metrics for MIR tend to capture the model accuracy in terms of the goal. [1] For instance, mode recognition is implemented with a goal to evaluate and compare melodic analysis approaches, but it is worth investigating if at all it lends itself as one befitting proxy task. [2] This is particularly relevant in non-Eurogenetic music repertoires where the grammatical rules are rather prescriptive. We employ methodologies that combine domain knowledge and data-driven optimisations as a possible way for a comprehensive understanding of these relationships. This is tested on Makam, one of the understudied corpora in MIR. We evaluate an array of feature-engineering methods on the largest mode recognition dataset curated for Ottoman-Turkish makam music, composed of 1000 recordings in 50 makams. We also address (ethno)musicology-driven tasks with a view to gathering more profound insights into this music, such as tuning, intonation, and melodic similarity. We aim to propose avenues to extend the study to makam characterisation over the mere goal of recognizing the mode, to better understand the (dis)similarity space and other plausible musically interesting facets.

1. INTRODUCTION

The melodic framework in many music traditions is often governed by the system of modes. A mode can be viewed as falling somewhere between a scale and a tune in terms of its defining grammar, which includes the tonal material, tonal hierarchy, and characteristic melodic movements [1–3]. While the function and the understanding of these frameworks are distinct from a culture-specific perspective, in a broader sense, they may be considered as the modes of the studied music culture. Some music traditions that can be considered modal are Indian art (raga) music, the Turkish/Arabic makam/maqam traditions, and the Gregorian church modes. Concerning the relevance of musical mode in non-Eurogenetic music repertoires, there are two contrasting viewpoints on whether to rethink or reject modal structure. While the former advocates for adapting the concept of mode as an underlying framework to systematise musical patterns, the latter tends to nullify the syntactic jargon of using a foreign language grammar (e.g., mode) to interpret literature in another (e.g., makam).

Makam/maqam is the melodic framework that consists of a system of scales defined by successive intervals, habitual melodic phrases, modulation pathways, ornamentation techniques and aesthetic conventions. It is used in Turkish (and Arabic, including the Middle East and Western Indian Ocean) music, providing a complex set of rules for compositions and performance. A typical subset of the repertoire — Ottoman-Turkish makam music (OTMM) — is well-established as a classical music tradition. Historically, there are a few hundred makams, whereas in practice, most of the repertoire is composed in one of the top 20 makams [4, 5]. In OTMM, melodies typically revolve around an initial tone and a final tone [6], where the final tone is referred to as being synonymous with tonic. There is no definitive reference frequency to tune the tonic. Recognizing makam is in itself a much more difficult task due to various characteristics such as heterophony and high variability in interpretations by musicians [6]. Moreover, from the pedagogy and practice perspective, recognizing the underlying makam with a unary label may not be interesting enough. A knowledge seeker (e.g., from the perspective of an anthropologist or ethnomusicologist) would rather gain wisdom on the characterisation of a makam and its discriminatory aspects to differentiate it from seemingly similar-sounding neighbouring makams.

In the realm of music information retrieval (MIR), mode recognition as a task has been given considerable importance from the purview of this, lending itself as one befitting proxy to evaluate and compare melodic analy-

† Equal contribution; corresponding authors.
[1] We define goal as optimization of evaluation metrics, e.g., accuracy.
[2] We define task as what a model is intended to learn, e.g., modal features such as intervals, note sequence, relative salience, etc.

Guedes, "Critiquing Task- versus Goal-oriented Approaches: A Case for Makam Recognition", in *Proc. of the 23rd Int. Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

sis approaches. Such a list is lengthy, ranging from automatic transcription, tuning analysis, music discovery, music similarity and recommendation to computational (ethno)musicology applications [7, 8]. However, in most practical scenarios, mode recognition is not the central theme but just the first step evidencing the robustness of acoustic features and/or statistical models. In such a setup, the recognition accuracy tends to become just another optimisation function. This simply indicates that the ethos of mode recognition does not remain a task anymore but a 'goal'. In this work, we aim to critically address how such an approach can mislead the uninitiated audience by attributing the complexity of the musical characteristics to the shortcomings of computational models.

It is inevitable to have thorough interdisciplinary collaboration to address the specifics in their entirety. However, we will approach the first study in this direction from a corpus-based computational musicology paradigm. This means developing culture-aware music technologies combing data- and knowledge-driven methods. We aim to benchmark the reported state-of-the-art literature, improve baseline features and simulate intuitive models to contest them. Once the potential of our approach in achieving the 'goal' accuracy is established, we break away from supervised (classification) to unsupervised (clustering) learning to appreciate the nuances and facilitate a comprehensive understanding of the same realm, this time as a 'task'. The byproduct of such a work is to provide tools for several musicologically-relevant subtasks such as tuning and intonation analysis, temporal modelling, and so on. While musicological studies latch on qualitative and limited representative examples, empirical methods work at the level of larger corpora and are, therefore, particularly useful for information retrieval-based tasks where scalability and reproducibility are highly regarded, if not mandated. The extracted features facilitate the curation of large audio corpora not only by greatly reducing the time and effort spent on manual annotations but also by providing automatically extracted, reliable and reproducible information. It is to be noted that we are limiting the scope of this work to building on past work pertaining to aggregated feature representation disregarding any time information. Hence, sequence models or sophisticated deep learning models (e.g. [9]) are not included in the current discourse.

However, in such corpus-based studies that too are underrepresented in MIR, the features extracted from the data, [3] source code and the experimental results are not always shared, making it more inaccessible to reproduce or build on the literature. Thus the unavailability of public tools, datasets, and reproducible experimentation are major obstacles to computational music information research, especially if such relevant tasks have not been applied to studied music traditions earlier. The CompMusic project [4] contributed towards bridging this gap by creating open corpora and computational tools for several non-Eurogenetic music repertoires. This work builds on the dataset introduced in MORTY (MOde Recognition and Tonic Ydentification toolbox), which is the largest mode recognition dataset curated for OTMM, composed of 1000 recordings in 50 makams [10].

In this work, our contribution is two-fold. Firstly, we adapt a new feature called time-delayed melody surfaces (TDMS) from raga recognition to makam recognition that shows comparable results to that of the current state-of-the-art [11]. The second contribution is to establish a similarity space of makam melodic features that characterise the root cause of erroneous cases. The structure of the paper is as follows. Section 2 discusses relevant literature on mode recognition at large and a detailed review of makam recognition, more as a goal and not a task. Section 3 describes the methodological details on audio preprocessing, the dataset(s), and feature extraction/modeling. Next, the experimental details regarding the model architecture and evaluation strategies are discussed in Section 4.1. This essentially engulfs the 'goal'-oriented approaches and comparison with the state-of-the-art, followed by the discussion of an alternative paradigm of unsupervised learning. The latter aids in the 'task'-based approach and highlights the gained musicological insights from this study and possible avenues of extending to makam characterisation over merely recognizing the label. Finally, Section 5 summarises the contributions and poses the scope for further developments in the current study.

2. MODE RECOGNITION

There has been extensive interest in mode recognition in the last two decades; a good summary is presented in [12]. Most of this work focuses on culture-specific approaches for music traditions like OTMM [10, 11, 13, 14], Carnatic music [15–17], Hindustani music [18–20], Dastgah music [21–23] and medieval chants [24, 25]. A considerable portion of these studies is based on comparing pitch distributions [13, 15, 16, 18, 19, 26], which are shown to be reliable in the respective mode recognition task or, for that matter, goal per se. There also exist recent approaches that are based on characteristic melodic motif mining using network analysis [17, 20], aggregating note models using automatic transcription [27–30], or audio-score alignment [31, 32]. All of these methods have been designed specifically to address the studied music culture (with the exceptions of [20] and [10]), and they are not generalisable to other music cultures without considerable effort. Next, we present some of the specific literature on mode recognition that we base our analyses on.

Pitch Distributions (PD) and Pitch Class Distributions (PCD) have been the state-of-art feature for mode recognition tasks for a very long time [10, 12, 13, 19], irrespective of the fact that they completely disregard the temporal aspects of the melody, which are essential to a mode characterisation [33]. Karakurt et al. [10] applied a joint recognition of makam and tonic using PDs and PCDs. In the training phase, the authors used kNN classifiers with either single or multiple distributions per mode. Their best performing model achieved an accuracy of 71.8% on the OTMM

[3] Commercial audio recordings are generally difficult to be made public due to copyright issues.

[4] https://compmusic.upf.edu/

recognition dataset (explained in Section 3.1). Gulati et al. [20] proposed a novel feature for mode recognition in the context of Hindustani and Carnatic ragas, called the time-delayed melody surface (TDMS), which we will use in this study. Authors reported that TDMS-based models outperform PCD-based models of [10] in the raga recognition task.

Yeşiler et al. [14] used a Multilayer Perceptron (MLP) on pitch distribution of first and last sections together with overall distributions using a feature vector of 159 attributes (53-TET * 3 octaves). The highest accuracy reported is 75.6% on the OTMM recognition dataset with additional insights on relevant segments for better discriminability. Demirel et al. [11] advocate the advantage of using chroma features for the mode recognition task as it discards the need for automatic melody extraction of polyphonic audio, hence getting away with the imperfections thereof. Authors created makam templates from annotated data and used template matching using support vector machine (SVM) classifiers. The best performing model achieved an accuracy of 77% on the OTMM recognition dataset, which, to our knowledge, is the state-of-the-art in makam recognition applied to the OTMM corpus. Other works are not strictly mode recognition but use the framework of representation-cum-distance-measure for discriminating between allied raga-pairs [34, 35]. Section 4 discusses aspects we borrow from this methodology to quantify the classification errors from a clustering viewpoint.

3. METHODOLOGY

In [10], mode recognition is formally defined as classifying the mode of an audio fragment from a discrete set of modes. In the context of OTMM, the problem reduces to classifying the makam. Given that the mode recognition framework is already established and that we are benchmarking on literature applied to OTMM, we save some real estate assuming that the data (pre)processing and partial feature extractions will be exactly reproduced.

3.1 The OTMM Corpus and the Dataset

Considering the lack of open data sources for makam music, the CompMusic project gathered audio recordings, music scores and relevant metadata, and published in the public domain the *Dunya Ottoman-Turkish Makam Music Corpus* [5, 36], which is currently the most representative corpus for OTMM available for computational research purposes. From the corpus, [10] curated a test dataset of audio recordings with annotated makam and tonic, called the *Ottoman-Turkish makam music recognition dataset*. The dataset covers 20 commonly performed makams [5] composed of 1000 audio recordings. A single makam is performed in each recording (i.e. there are 50 recordings per makam). To the best of our knowledge, this dataset is the largest and the most comprehensive dataset for the evaluation of automatic makam recognition. Finally, the dataset has been used by other researchers [10, 11, 14] to demonstrate their methods, including the current state-of-the-art makam recognition approach [11].

We use the latest version of the dataset. [6] We use the pre-computed melody time-series (termed as "predominant melody" by [36]) provided in CompMusic Dunya. [7] The pitch is detected at a hop-size to sampling-rate ratio of 0.023 that translates to 23 ms intervals for 44.1 kHz sampled audio [37]. To compare across performances, it is crucial to normalise the melody with respect to the tonic frequency. For this study, we use manually curated tonic frequencies linked from the *Ottoman-Turkish tonic dataset*. [8] To avoid the effect of nonlinearity in the logarithmic Hz scale, we normalise the pitch time-series to a log-linear cents scale.

3.2 Feature Extraction and Modeling

The next step is to synthesise derived features from the raw predominant melody. These mid- or high-level features can be interpreted and mapped to musicological inferences. We follow an approach akin to Krumhansl's [38] to compute the histogram of pitch samples to construct the pitch-class distribution. The pitch values are octave-folded (0 — 1200 cents) and quantised into p bins of equal width. The bin centre is the arithmetic mean of the adjacent bin edges. The salience of each bin is proportional to the accumulated duration of the pitches within that bin. A probability distribution function is constructed where the area under the histogram sums to unity. Even though we use the equivalent of a PD method attributed to the high bin resolution, we converge to a PCD [18]. The PCD configuration is given in Section 4. The first row of Figure 1 shows PCDs computed from each Mahur, Rast, and Acemşiran in the dataset, with the average pitch at each bin drawn as a dashed line.

The next step is to construct a two-dimensional surface based on the concept of delay coordinates (also termed phase space embedding) [20]. The time-delayed melody surface (TDMS) is a compact representation that captures both the tonal and the temporal characteristics of melody, is robust to octave errors, also partially nullifies the relevance of melody transcription. We experiment with different parameters (See Section 4). The second row of Figure 1 shows TDMS averaged from the TDMS of all recordings in Mahur, Rast, and Acemşiran makams in the dataset. The horizontal and vertical trajectories indicate pitch transitions between the pitch classes. The isolated square shape-formation indicates a separation between the higher and lower tetrachords in the course of the melodic progression. In both PCD and TDMS features, makams Rast and Mahur are similar to a high degree. The PCD of makam Acemaşiran bears relatively small differences from the prior two; however, the TDMS representation manages to significantly differentiate itself via dif-

[5] Namely: Acemaşiran, Acemkürdi, Bestenigar, Beyati, Hicaz, Hicazkar, Hüseyni, Hüzzam, Karcığar, Kürdilihicazkar, Mahur, Muhayyer, Neva, Nihavent, Rast, Saba, Segah, Sultanıyegah, Suzinak, and Uşşak.

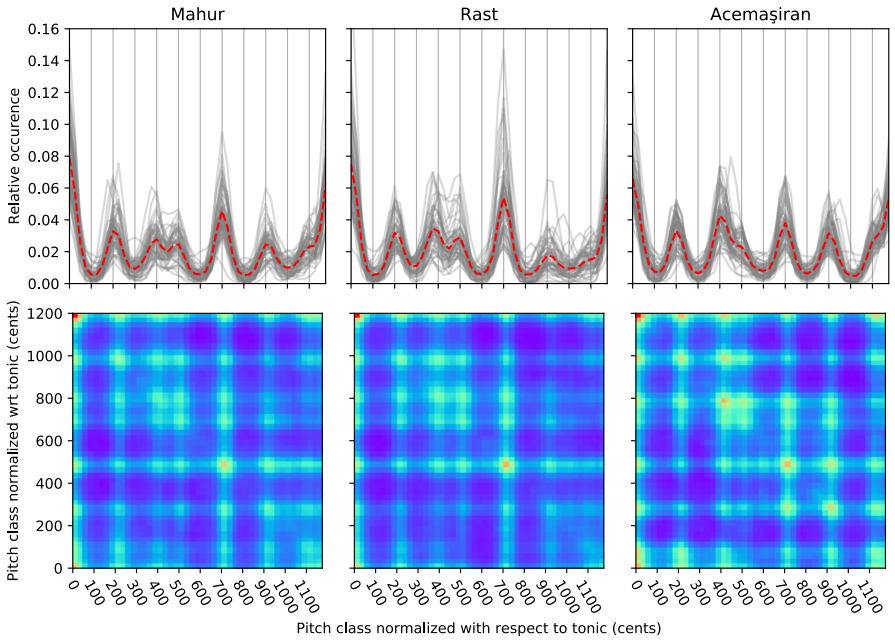

Figure 1. PCD (top row) and TDMS (bottom row) representations of Mahur (left column), Rast (middle column), and Acemaşiran (right column) makams.

ferences in melodic progression, captured through the delay coordinates. For example, in the TDMS representation, makams Mahur and Rast show clear transitions between 6^{th} (900 cents), 7^{th} scale degrees (1100 cents), and the tonic pitch class, whereas makam Acemşiran exhibits a progressions between 3^{rd} (400 cents) and 6^{th} scale degrees (900 cents).

4. EXPERIMENTS

Akin to the title of the paper, one of the main goals of the study is to treat makam recognition as a task and not a goal in itself. Our experiments are divided into two parts. The former addresses the 'goal'-oriented aspect, i.e., the best combination of features and classifiers in order to achieve the *optimal* accuracy. We also stress on intuitions why certain configuration of train-test partitioning would make more sense than others or why certain classifier is meant to 'learn' and not be totally data-proximity dependent. We report and discuss a subset of the results relevant to the optimal settings; the full experimental results are made available. [9]

For PCDs, we use the empirical "optimal" parameters for OTMM reported by [10], namely a bin resolution of 25 cents and Gaussian smoothing applied using a kernel width of 25 cents. We set the bin resolution of TDMS to 25 cents to compare with PCD, and grid-search time delay indices ($\in \{0.25, 0.5.1, 1.5, 2.5, 5\}$ seconds), compression exponents ($\in \{0.1, 0.25, 0.5, 0.75, 1\}$) and Gaussian smoothing kernel widths ($\in \{0, 12.5, 25, 50\}$ standard deviation in cents) in the classification experiments below to find the optimal configuration for OTMM.

[9] https://sertansenturk.com/work-research/ismir-2022-makam/

4.1 (Supervised) Classification

In line with the objective of supervised learning, i.e., to model the intra-class similarity and inter-class differences, the inherent 'goal' is to maximise classification accuracy. However, we carefully choose the feature set and classifier in order to suit the music theory. That is to say, we aim to incorporate knowledge constraints into mainstream data-driven computational models. We restrict ourselves to k-nearest neighbors [10, 12, 13, 19, 20], support vector machine [11, 12], multilayer perceptron [14] and logistic regression [12] that were extensively used in past mode recognition work.

Past studies used different cross-validation (CV) techniques such as leave-one-out CV [13], 10-fold CV [10, 19, 20] and nested k-fold CV [11, 14]. In our initial experiments, we compared nested 10-fold CV, 10-fold CV (without any unseen test set), and 10-times repeated shuffle split CV with 10% of the recordings reserved as test set for each repetition. We used stratified splits in all our experiments to keep the makam classes balanced and repeated each experiment 10 times. We report the mean & standard deviation of classification accuracy reported on the test set. We also compute a confusion matrix for each test set and aggregate it across all test sets in each repeated experiment per model. We report the results of the 10-times repeated shuffle split CV in the rest of the Section. Similar to [20], we observed that TDMS is robust in different time delay indices (between 0.5 and 2.5 seconds), kernel width (less than 25 standard deviations in cents) and compression exponent (above 0.25). For the rest of the experiments, we report results for TDMS with an "optimal" configuration of 1-second time-delay index, 12.5 cents of smoothing kernel width and a compression exponent of 0.5. Table 1

Model	PCD	TDMS
Support Vector Machine	$71.0 \mp 3.2\%$	$\mathbf{77.2 \mp 3.5}\%$
Multilayer Perceptron	$70.9 \mp 3.8\%$	$74.6 \mp 5.0\%$
k-nearest Neighbors	$68.2 \mp 3.4\%$	$70.2 \mp 3.1\%$
Logistic Regression	$66.8 \mp 3.9\%$	$75.5 \mp 4.1\%$

Table 1. Average $\mp$ standard deviation of classification accuracy for all feature-classifier combinations.

shows the mean and standard deviation in classification accuracy for PCD and TDMS using different models. In sum, TDMS with SVM works the best at par with the current state-of-the-art [11]. TDMS consistently performs better than PCD; statistical significance results are kept out of the scope of this work.

The associated confusion matrix for the optimal performing system is shown in Figure 2. Makams {Acemaşiran, Hicaz, Hüzzam} and {Bestenigar, Rast, Uşşak} are examples of highly discriminable and highly confused pairs respectively. The inferences from the confusion matrix are, however, limited to qualitative evaluation of the confused cases and a count of them. In the next Section, we propose a new approach to compute the pairwise distances in a clustering scenario which facilitates a quantitative evaluation of the proportion and magnitude of the confusions. This is, in a way, a manifestation of the recognition task wherein we model the inherent complexity in the data rather than the limitations of the method.

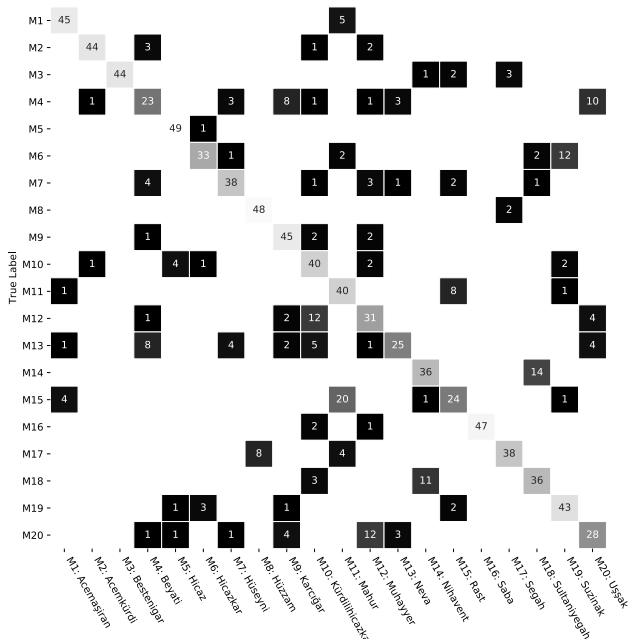

Figure 2. Aggregated confusions matrix for the optimal performing system: TDMS with SVM.

4.2 (Unsupervised) Clustering

To address the second half of the experiments, our focus moves to the 'task'-oriented results. This, we believe, is the highlight of the current contribution in terms of gaining/reconfirming musicological knowledge/concepts from the computational model that can feed back into the pedagogy and practices to further enrich the repertoire.

A typical mode recognition study would stop at this point after the goal accuracy is achieved [10, 11, 20]. Even though we report comparable results to that of the current state-of-the-art accuracy, we are keen on evaluating how much the representation-cum-distance-measure attribute to musicological insights. Over and beyond the error analysis, we stress validating the gap and reinforcing other possible avenues, so the complexity of the musical characteristics is not attributed to the shortcomings of computational models. One such way is to disregard the makam labels and study the melodic similarity space of relevant predictor features. Through these methods, we aim to verify whether the machine learning models indeed 'learn' what they are intended for. We present three complementary and supplementary retrieval scenarios to corroborate the 'task' details and bridge the gap that the best classification could achieve.

Hierarchical clustering: In the presence of theoretical grouping of makams, yet not having a prescription on the counts, it is practically impossible to set a k for a k-means clustering algorithm. However, hierarchical clustering seems to offer a dynamic solution in such scenarios. Here, each element is treated as distinct clusters at the lowest threshold, whereas there is a single giant cluster at the highest threshold. We present, in part of Figure 3, the dendrogram representation to capture the melodic similarity/grouping space across the 20 makams obtained from the hierarchical clustering of the TDMS features averaged from the 50 recordings per makam using Canberra distance. We use the Canberra distance to contrast with the hierarchical clustering reported in [14, see Figure 2] that was calculated from averaged pitch distributions, and keep the empirical experimentation of different distance metrics out of the scope. The groupings are shown in different colours, and the relative height where the tree elements merge is indicative of the normalised threshold. At the highest threshold, makam Saba isolates itself from the rest 19; this is indicative of the distinct nature of the pitch distribution captured through TDMS. Makam-pair (Rast, Mahur) show a very low distance, indicating high similarity in the feature space. A high distance between the (Hüzzam, Hicaz) pair, as shown in other figures, is also evident.

Cluster purity matrix: One supplementary way to capture all pairwise distances is through an unconventional method of computing a distance matrix with the salience function of cluster purity. This is broadly a homogeneity measure that evidences the quality of clustering. Any value close to 1 indicates perfect clustering, while 0.5 signifies random clustering. Out of the $\binom{20}{2} = 190$ distinct makam-pairs, 115 pairs show a cluster purity score ≥ 0.85, 73 other pairs bear cluster purity values in the range of (0.5,

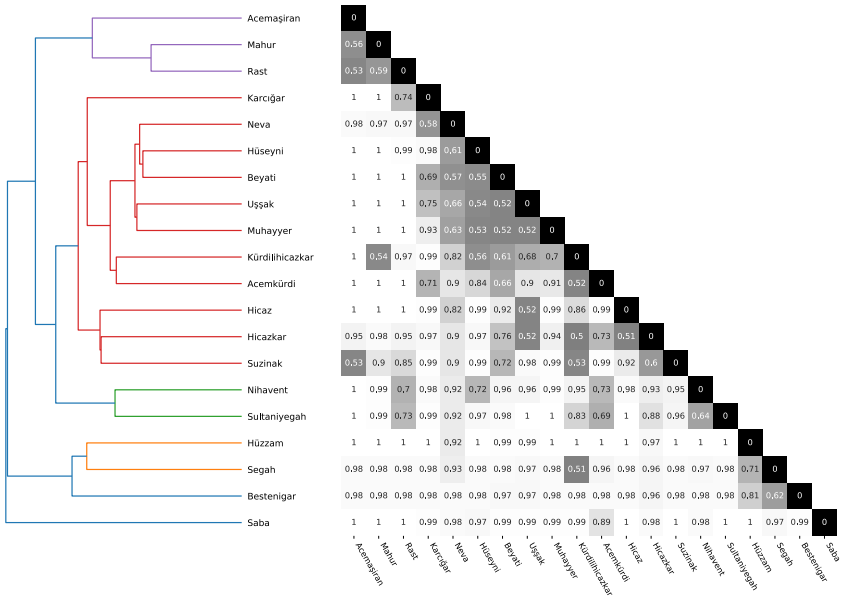

Figure 3. Left: dendrogram representation to capture the melodic similarity space across the 20 makams obtained from the hierarchical clustering of the TDMS. Right: the cluster purity matrix capturing the homogeneity of pairwise distances.

0.85), and none below a score of 0.5. We plot the pairwise purity scores partly in Figure 3, this representation has an intuitive inverse proportionality with the confusion matrix. The makam indices obtained from the dendrogram are aligned with that of the current matrix. It is intuitive to follow that the row corresponding to makam Saba (which is the most distinctive) has got the highest cluster purity (mode=1) with many other pairs, whereas the aforementioned confusable pairs yield a random clustering. This visualisation provides a complementary view of what is aggregated in the dendrogram.

Query retrieval score: The third scenario we present complementary to the clustering is the receiver-operated characteristics (ROC). We use the same two makam-pairs in the context of a query search for all possible matching and non-matching pairings out of each makams-pair. The ROCs in Figure 4 show the true positive rate versus the false positive rate achieved in the detection of non-matching makam pairs for the PCD (we consciously chose PCD over TDMS to introduce diversity) representations for four unique distance measures, inspired from [34]. The subplots correspond to makam-pairs (Hüzzam, Hicaz) and (Rast, Mahur), which are examples of highly discriminable and highly confused pairs, respectively. The ROC curves, the area under the curve (AUC) and equal error rate (EER) clearly indicate a better retrieval for the former, while the latter almost grazes the diagonal. We have inferences on why certain distance metric works better, but discussion on their relative performance is not directly related to the main narrative of this work and hence omitted [34, 39].

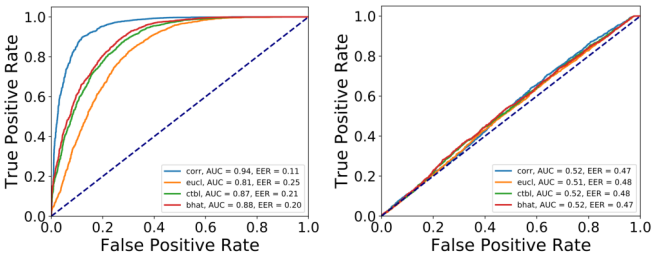

Figure 4. ROCs obtained using correlation (corr), euclidean (eucl), city-block (ctbl), and Bhattacharyya (bhat) distance from PCDs. Left: (Hüzzam, Hicaz) and right: (Rast, Mahur) makam-pairs.

5. CONCLUSION

We employed methodologies that combine domain knowledge and data-driven optimisations with a view to understanding the makam recognition 'task' in depth. We report comparable accuracy (77.2%) with the state-of-the-art [11] using the newly adapted TDMS feature with SVM. This achievement evidences the credential in our approach that provides us with a solid ground to argue the critique on goal- versus task-oriented approaches by comparing and contrasting. We have reported only the best-performing configuration in this paper [10] which will eventually be expanded to include temporal features and sequence models. In sum, we advocate that good supervised learning performance is a necessary but insufficient condition for a computational representation-cum-distance-measure to be considered informative for all purposes. As future work, we will incorporate convolutional networks and transformers to reproduce makam recognition on OTMM corpus to understand the potential of deep learning and the trade-off between goal and task involved. The application of such an approach aids in understanding music and other forms of sound culture and developing methodologies for cross-cultural mapping and comparing these materials.

ABSTRACT

Studying under-represented music traditions under the MIR scope is crucial, not only for developing novel analysis tools, but also for unveiling musical functions that might prove useful in studying world musics. This paper presents a dataset for Greek Traditional and Folk music that includes 1570 pieces, summing in around 80 hours of data. The dataset incorporates YouTube timestamped links for retrieving audio and video, along with rich metadata information with regards to instrumentation, geography and genre, among others. The content has been collected from a Greek documentary series that is available online, where academics present music traditions of Greece with live music and dance performance during the show, along with discussions about social, cultural and musicological aspects of the presented music. Therefore, this procedure has resulted in a significant wealth of descriptions regarding a variety of aspects, such as musical genre, places of origin and musical instruments. In addition, the audio recordings were performed under strict production-level specifications, in terms of recording equipment, leading to very clean and homogeneous audio content. In this work, apart from presenting the dataset in detail, we propose a baseline deep-learning classification approach to recognize the involved musicological attributes. The dataset, the baseline classification methods and the models are provided in public repositories. Future directions for further refining the dataset are also discussed.

1. INTRODUCTION

Traditional music of Greece is under-represented in available datasets, despite the fact that this music offers unique perspectives that combine characteristics of Western and Eastern music. The development of a traditional Greek music dataset is interesting to study in its own right, while it is also expected to provide a more complete picture of the music in the Mediterranean and Europe. Computational methods have been extensively studied in the past decades for carrying out ethnomusicological studies, constituting the field of Computational Ethnomusicology. A review of such methods is presented in [1], where it is evident that there are many benefits in compiling datasets of traditional music that can readily be used in computational models.

Several such datasets have been developed. For instance, an enormous database of Dutch melodies and songs that allows studying multiple musicological aspects is presented in [2]. Similarly, a dataset of Indian art music was presented in [3], where various MIR-related tasks were adjusted and applied therein. The employment of standard MIR tools has been evaluated in Arab-Andalusian music [4] and Flamenco music with the COFLA dataset [5]. Iranian Dastgah classification has been studied with MIR tools in [6]. A dataset of Georgian vocal music from historic tape recordings of three-voice songs was presented in [7], where the aim was to preserve cultural heritage and also to apply and examine existing MIR methods (e.g., for pitch and onset detection) in data of this form. Such datasets also provide opportunities for studying idiosyncratic musical instruments, e.g., in the case of Chinese music [8], where many instruments are employed that are not related to the ones used in Western music.

In several cases, off-the-shelf MIR tools are not well-suited for tasks that include traditional musical types. For instance, studying melodic similarity of Turkish non equally-tempered makam phrases in symbolic format required the development of a novel representation based on MIDI [9]. Similarly, rhythmic attributes of makam music with new models that integrate note transition rules for this music had to be developed for lyrics-to-audio alignment [10]. In addition, a novel method, based on audio signal processing, was created for identifying asymmetric rhythms in Greek traditional music [11].

The "Lyra" dataset of traditional and folk Greek music aims to contribute to all the aforementioned fields, from data-driven (computational) ethnomusicology to shaping new directions of research for MIR tools. The majority of available datasets that concern Greek music are unsuitable

Potamianos, "A Dataset for Greek Traditional and Folk Music: Lyra", in *Proc. of the 23rd Int. Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

for computational analysis due to their unstructured nature. An exception is the Greek Audio Dataset (GAD) [12], which includes 1000 pieces with audio content (YouTube links), lyrics and annotations for genre (coarse categories including traditional, pop, rock), mood (valence-arousal plane coordinates) and pre-computed audio features; this dataset was later expanded in the Greek Music Dataset (GMD) [13], consisting of 1400 audio pieces with the aforementioned data. However both the GMD and the GAD are not focused on traditional and folk music, while the quality of audio recordings is varying significantly between genres.

The Lyra dataset presented in this paper, in contrast to the GMD, includes mainly traditional and folk Greek music with fine-grained labeling, focusing on musicological aspects of interest. Additionally, the recording quality is homogeneous across all pieces. Musicological soundness and high quality content are ensured by the fact that data has been collected and annotated from a documentary series that was presented by academics in Greek television. Some baseline classification tasks that are of particular interest in this dataset are presented, namely classification of pieces in genres, instruments and places of origin. In all cases, the results show that computational analysis can provide useful insight about musicological relations and phenomena in traditional and folk music of Greece – and, possibly, of other places.

2. DATASET EXTRACTION AND DESCRIPTION

2.1 Challenges and Methods

Large amounts of clean data is fundamental for current AI models to achieve their full potential. In this paper, we walked all the way, from the "data in-the-wild" multimedia content of a TV show to a fully annotated dataset, through a combination of machine automation and human evaluation/annotation processes. The consistency of the dataset and the richness of information it provides are tested by developing and training models that perform three different classification tasks.

In the case of Greek traditional and folk music, there are few cases where metadata is combined with recordings in a structured manner. Additionally, there is a matter of quality of recordings as it is significantly affected by various factors, including the equipment used, the social occasion (e.g., during a festival or inside a studio) and the time period in which it took place, i.e., older recordings tend to be of lower quality.

An integration of dissimilar recordings, in terms of quality, can introduce significant deficiencies towards studying the musicological characteristics of world music with computational tools. In order to truncate the effect of the audio quality factor, we decided to incorporate the episodes from the Greek documentary series "To Alati tis Gis - Salt of the Earth" broadcasted by ERT (Hellenic Broadcasting Corporation), where primarily traditional and folk music is presented. The episodes were filmed during a 10 year period under strict production-level specifications, resulting to very clean and homogeneous audio content while significant wealth of information is provided by the presenter and the guests in the form of narrations between music performances.

The presented dataset consists of both the multimedia content and the annotations of interest. The multimedia content is provided as start and end timestamps that correspond to a single music piece, as parts of a longer episode, which is available online. Regarding the annotations, a taxonomy of labels is defined, based on the potential purposes of studies that might involve this dataset, considering also what metadata information can be retrieved either directly from the source or be integrated by volunteer annotators during the data collection process.

The study of Greek traditional and folk music involves knowledge about (i) the instrumentation, (ii) the genres, (iii) the places of origin and (iv) the way listeners perceive this music in terms of "danceability", among others. While musical instruments, genres and geography are semantically well-defined, the same can not be claimed for listeners' perception. Having at hand the multimedia content, i.e., audio and video, can be helpful to this end. Annotation about whether a music piece is being danced during its live performance can reveal cultural characteristics regarding the way this piece is perceived by the community, because body movements play an important role in music perception [14].

As a result, the taxonomy consists of (i) the musical instruments participating in the performance of each music piece (singing voice is considered an instrument), (ii) the musical genres and sub-genres that are identified by musicologists in Greek music, (iii) the places of origin and (iv) whether the music piece is being danced during its performance.

Volunteer annotators, students of the Department of Music Studies, undertook the task of separating each episode in music pieces and also labeling each one of them according to the specified taxonomy. A helper website was utilized where the respective category labels were added. An account was created for each annotator for the label assignment task. Every piece was labeled by two annotators and the final labels are the set of them where both annotators agree. At the end, the dataset that contains the aforementioned annotations along with the timestamps and the respective video id for each music piece was extracted from the database of the helper site.

2.2 Dataset description

Lyra dataset is organized into a single table where each row corresponds to a music piece while the columns include the various metadata information. Table 1 demonstrates the metadata categories.

Beginning with the simplest metadata categories, in terms of description, "id" is a unique identifier for each piece, generated by its title, replacing Greek with Latin characters and spaces with dashes. As expected, the number of unique values will be the same with the number of pieces, namely 1570. The same stands for "start-ts" and

name	# unique	multi-label	description
id	1570	No	unique identifier of each music piece
instruments	32	Yes	instruments participating in performance
genres	32	Yes	music style annotations
place	81	Yes (to contain regions)	full hierarchy of the place of origin
coordinates	81	No	latitude and longitude
is-danced	2	No	binary value (0 or 1)
youtube-id	74	No	id of the episode available online
start-ts	1570	No	start timestamp of the piece
end-ts	1570	No	end timestamp of the piece

Table 1. Metadata contained in the dataset.

"end-ts" that denote the exact time (second) that a song starts and ends in the corresponding video. The duration of the music pieces sums to approximately 80 hours.

The column "youtube-id" contains the id under which the video of the full episode is available online. The count of unique values are essentially the number of episodes that were used for the creation of the dataset. A typical duration of an episode is roughly a hundred minutes. The "is-danced" binary label informs about whether a music piece is being danced by the guests of the show. The music pieces annotated with "1" are approximately 51% while in the rest of them no dance performance occurs.

The classification of Greek music in "genres" is a work that requires one to take into account a number of socio-cultural and anthropo-geographical criteria. At an abstract level, we can distinguish the music of urban centers in contrast to the music of rural areas of Greece, with the former including rebetiko, laiko, urban-folk among others, while the latter, the music of rural areas, is what we generally call traditional music. Figure 1 shows the frequencies of the genres in the dataset, with "traditional" being the dominant one constituting almost 78% of the total. Depending on the place of origin, the style of a traditional music piece varies accordingly and, thus, several sub-genres flourish, such as Epirotic for the songs originated from Epirus. The 32 unique values in this metadata category are separated into 5 distinct genres and 27 sub-genres.

From a musicological perspective, Greek traditional music can be divided into two large geographic areas, i.e., the island and the mainland Greece. Each one creates a

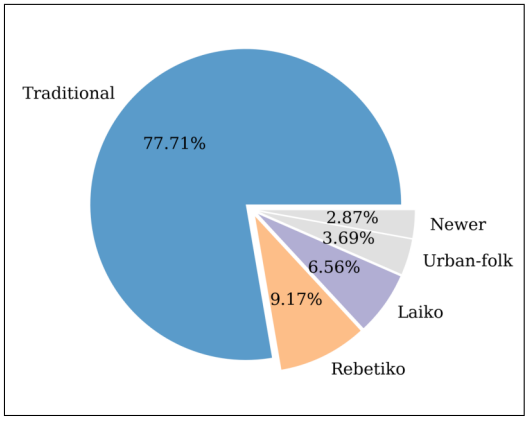

Figure 1. Relative frequencies of the music genres in the dataset.

distinctive musical feeling as there are large variations both on the rhythmic approach and the scales that are commonly used. For example, in islands we frequently come across music pieces with simple, fast rhythms while in the mainland more complex, slow rhythms are the norm.

The "place" (of origin) metadata category can be annotated with (i) a single label when the region from which a song derives is known, (ii) two labels when both region and a specific place are known and (iii) "None" denoting that there is not a specific place of origin for this piece. As an example, a music piece can be annotated with the region "Aegean sea" or with both "Aegean sea" and "Naxos", an island of the Aegean sea, if this knowledge is available. Specifically, from the 81 unique places in the dataset, 20 are regions and only half of them include the remaining 61. The most represented regions can be seen in Figure 2.

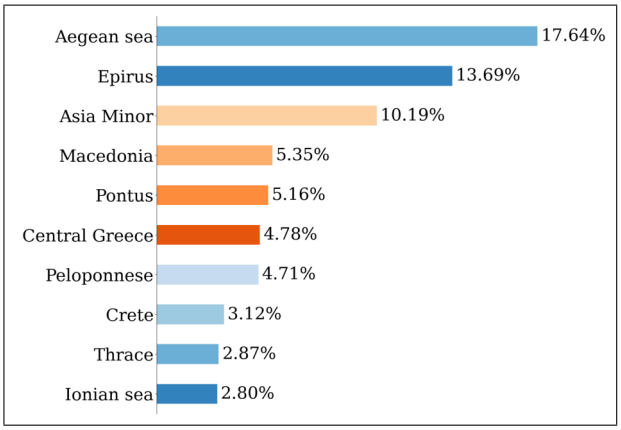

Figure 2. Relative frequencies of the most represented regions in the dataset.

The exact latitude and longitude of each place is also available at the "coordinates" column. The music pieces that do not have an explicit place of origin, such as the ones that belong to the "laiko" genre, are accounted for approximately 23% of the total. Figure 3 shows the location of the 81 places that exist in the dataset. We may notice the constant ability of music to excess the borders; places where Greek culture thrived in the past and neighboring countries

that share the same tradition, form a mosaic of people that communicated freely with each other in a musical way that has reached towards us.

Figure 3. Map of all the places of the dataset.

Analogous connections, like the ones between genres and places, one expects to be observed between places and instruments as well. Indeed, for over 100 years, the established music ensembles of Greek traditional music are generally two, namely (i) those with the violin as leading instrument (often substituted by lyra and santouri), which have a greater presence in island Greece and (ii) those with the klarino (Greek clarinet) as the leading instrument, which is dominant in the mainland.

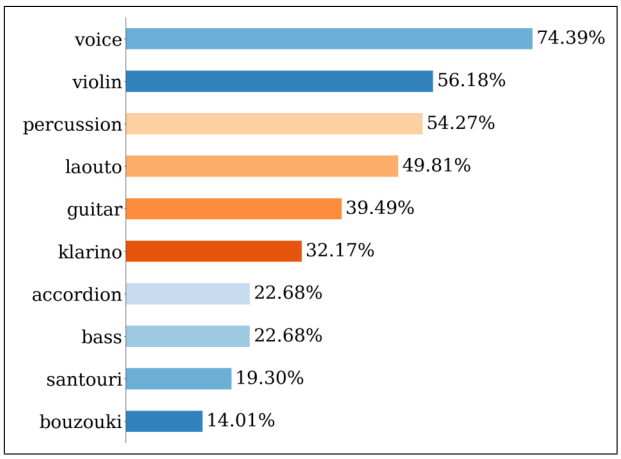

Figure 4. Relative frequencies of the most common musical instruments in the dataset.

In the popular and modern music domain, there is a great variety of instruments, but in most cases bouzouki, guitar, accordion and bass are common members of a laiko or rebetiko music ensemble. In the traditional music groups, the percussion and the laouto (Greek lute) are permanent companions of the leading instruments, offering melodic-harmonic background and rhythmic support. Of course, voice holds the main role in all kinds of performances.

In Figure 4 one can see the frequencies of the most popular instruments in the dataset. Singing voice is evident in almost 75% of it and instruments like violin, percussion and laouto, that have presence in both islands and mainland as well, are following.

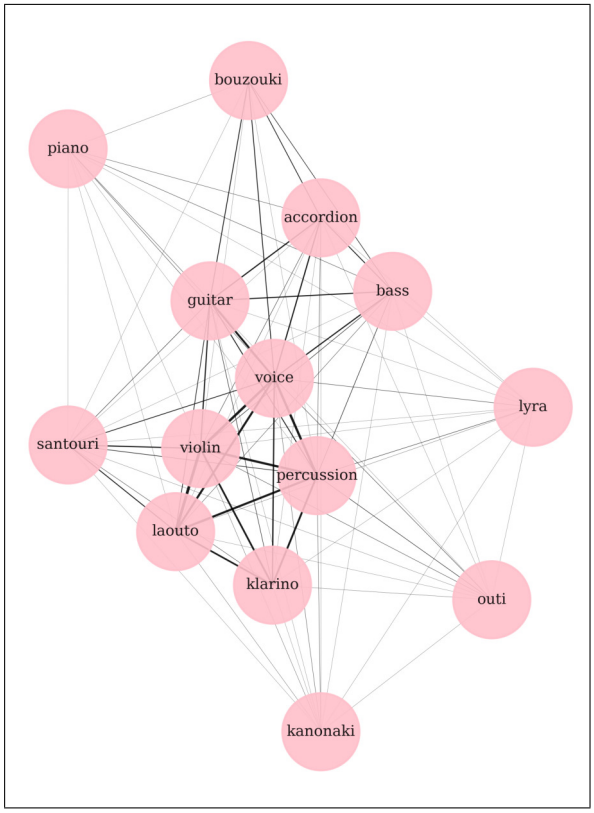

Figure 5. Graph that shows the co-occurrences of the fourteen most common musical instruments. The edge width is proportional to the number of music pieces a pair of instruments co-occur.

With regards to the music ensembles, it should be noted that 296 unique groups of instruments exist in the dataset, with the one constituted by voice, violin, percussion, laouto and klarino being by far the most popular by participating in the performance of around 12% of the music pieces. The co-occurrences of the most popular instruments can be seen in Figure 5 where the width of the graph edges is proportional to the number of pieces a pair of instruments co-occur in the dataset.

Sample rows of the dataset can be seen in Table 2. The dataset along with the baseline classification methods and the trained models are available online. [1]

The shared metadata should be considered as the version 1.0 of the dataset. In the next versions, it will be evolved towards two main directions, namely (i) the incorporation of more metadata categories such as annotations according to the content of the lyrics, the lyrics themselves as well as information about the types of the dances that occur and (ii) the addition of more music pieces by following the same process either for next episodes of the same documentary series or for other series that have a similar theme.

3. BASELINE CLASSIFICATION

The audio recording of each music piece is represented using a Mel-scaled Spectrogram (mel-spectrogram): this is

[1] https://github.com/pxaris/lyra-dataset

id	instruments	genres	place	coordinates	is-danced	youtube-id	start-ts	end-ts
alexandra	voice|violin| percussion| laouto| klarino	Traditional| Epirotic	Epirus| Zagori	39.8648| 20.9284	0	qrOwc1mLFUk	749	927
choros-tik	percussion| lyra	Traditional| Pontian	Pontus	40.9883| 39.7270	1	Aws0Y3aLaIs	1731	1886
agiothodo-ritissa	voice|violin| santouri| percussion| laouto|guitar	Rebetiko	None	None	1	0cj8BNcAhg4	2632	2853
einai-arga-poly-arga	voice|piano| guitar|bass| bouzouki| accordion	Laiko	None	None	0	zkoqg3VRVLA	2365	2614

Table 2. Sample rows of the dataset. Pipe "|" is used to separate values in a field.

a spectrogram whose frequencies are converted to the mel scale according to the equation:

$$m = 2595 \log_{10}(1 + \frac{f}{700}) = 1127 \ln(1 + \frac{f}{700}) \quad (1)$$

where **m** is the frequency in Mels and **f** is the frequency in Hz. Mel-spectrograms are calculated per fix-sized segment duration of 10 seconds. A non-overlapping window of 50 milliseconds has been applied, therefore the Mel-spectrogram size is 200 windows $\times$ 128 frequency bins.

As a baseline classification approach, each 10-second Mel-spectrogram is classified to the aforementioned tasks (genre, place and instruments) using a Convolutional Neural Network (CNN). CNNs have been widely used in general audio [15], speech [16, 17] and music [18] classification tasks. In particular, we have adopted the following architecture: 4 convolutional layers of 5 $\times$ 5 kernels, single stride, and max pooling of size 2. The number of convolutional kernels (channels) are for the first layer 32, for the second 64, for the third 128 and for the fourth 256. The final output of the convolutional layers is passed through 3 fully connected layers, with the first having an output dimension of 1024, the second 256 and the third equal to the number of classes.

Note that fix-sized duration of segments is necessary, since audio recordings do not share the same size. Adopting a much longer segment would require zero padding for several mel-spectrograms and probably more CNN parameters. In addition, splitting the song into non-overlapping segments achieves some type of data augmentation. For two of the adopted classification tasks (namely genre and place), we have trained the CNNs using a multiclass, single-label setup, while for the instrument task, which is multi-label, we have trained multiple binary CNNs, one for each instrument, which have been evaluated separately.

After the training and validation procedure of each of the aforementioned CNNs, final testing was applied on the respective test recordings. For the test set, to avoid spreading pieces from the same broadcast across data splits, we separate training and test data on an episode level. From the 74 unique episodes, we randomly split 20% of them and use all the music pieces they include, namely 330, to form the test data. Obviously, this final testing needs to be carried out on a "song-level", not a 10-sec segment level. Towards this end, a simple aggregation method was adopted, by just averaging the posteriors of the individual segment decisions of the CNNs. This aggregated estimate was used as the final prediction and evaluated in the final testing.

4. RESULTS

The performance results during the training of the baseline classifiers are shown in Table 3, computed on a validation subset that corresponds to 20% of the segments. For the multi-label task (instrument recognition), we show the F1 metric for each binary subtask separately, while for the single-label tasks (genre and place) we show the overall macro F1 for all classes. We remind that this evaluation is performed on the validation split of the 10-second data.

Classifiers type	Task	F1 (%)
Multiclass classifiers	Genre	82.3
	Place	85.5
Binary classifiers for Instruments	voice	75.8
	violin	86.3
	percussion	97.1
	laouto	96.7
	guitar	80.2
	klarino	95.0

Table 3. F1 scores of the classifiers on the 10-second segments of the training data using a 20% validation subset.

As soon as the 10-second classifiers are trained, they are applied on the whole recordings of the testing data, and a simple majority aggregation is performed to extract the final decision, as described in the previous Section. For the instrument classification task, we compute the Area Under the Curve (AUC) metric per label (binary classification subtask). The results are shown in Table 4.

Finally, the confusion matrices along with the respective F1 measures for the multiclass, single-label classification tasks of "genres" and "places" are shown in Figures 6 and 7. All genres have been taken into account for the respective classification, but not the sub-genres. On "places" task, the pieces have been classified to the 10 most common regions (including "None") plus the "other" category for the remaining. Genres classifier macro F1-score

Instrument	AUC (%)
voice	68.9
violin	85.2
percussion	95.1
laouto	93.8
guitar	73.5
klarino	90.9

Table 4. Area Under the Curve (AUC) scores of the instrument classifiers on the test data.

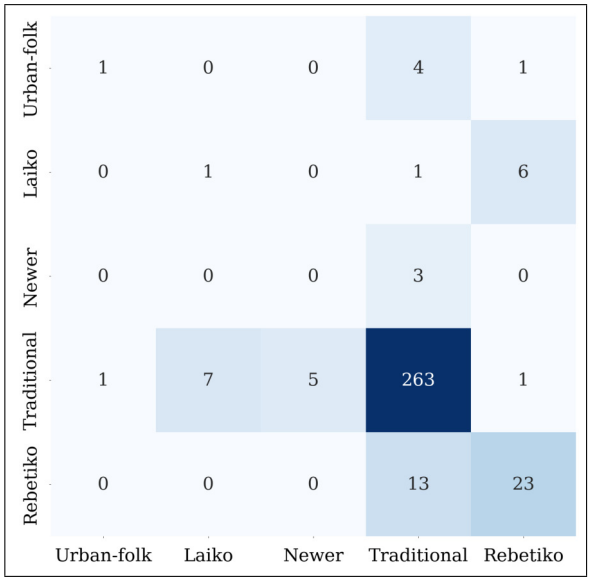

Figure 6. Confusion matrix for "genre" classes on the test data. **Macro F1-**score: **39.9**% and **Micro F1-**score: **87.2**%.

is 39.9% and micro F1-score is 87.2%, while for the places classifier the macro F1-score is 34.4% and the micro F1-score is 42.4%.

5. DISCUSSION

A reason that the "voice" classifier has lower performance compared to the other ones may be of a musicological character. Indeed, while the presence of the rest of the instruments can depend significantly on the music style of a piece, the same does not apply to "voice" as it is the dominant musical instrument in any genre. Given the fact that the binary classifier is trained to recognize an instrument (evident in a part of a music piece) in each of the 10-second segments, regardless if it is present on it or not, we expect to move towards a space with latent musical features such as the music style, where "voice" may not be as discriminative as the rest of the instruments are.

With regards to confusion matrices, the misclassifications can be either due to imbalance between classes or statistical correlations across them. Specifically, for the "places" task, the confusions between regions that are geographically near may be justifiable, while for "genres" task the imbalance between the classes seems to have significantly affected the performance of the model at the least represented ones.

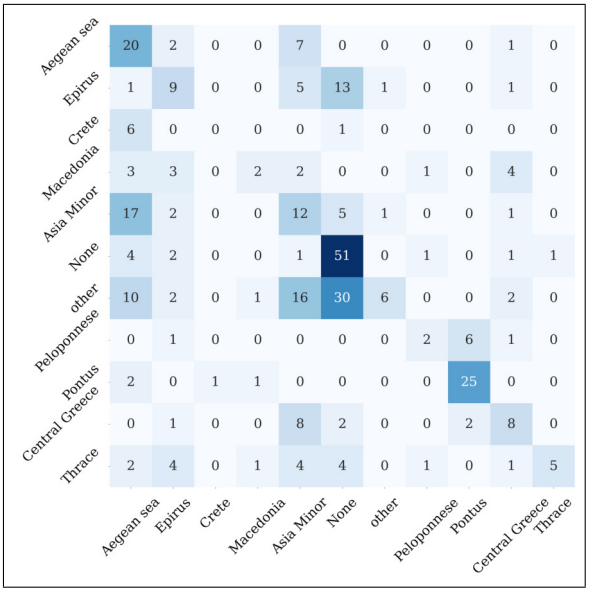

Figure 7. Confusion matrix for "place" classes on the test data. **Macro F1-**score: **34.4**% and **Micro F1-**score: **42.4**%.

We intend to improve models performance and conduct a more in-detail analysis in order to examine hypotheses such as the aforementioned ones in a follow-up study.

6. CONCLUSIONS

Greek traditional and folk music integrates components of Eastern and Western idioms, providing interesting research directions in the field of computational ethnomusicology. This paper presents "Lyra", a dataset of 1570 traditional and folk Greek music pieces that includes audio and video (timestamps and links to YouTube videos), along with annotations that describe aspects of particular interest for this dataset, including instrumentation, geographic information and labels of genre and subgenre, among others. The advantage of this dataset is that the entire content is harvested from web resources of a Greek documentary series that was produced by academics with specialization in this music and, therefore, includes high-quality and rich annotations extracted from the content of the shows. Additionally, the production of recordings and video material is professional-level, providing a common ground in terms of audio quality. Three baseline audio-based classification tasks are performed, namely instrument identification, place of origin and genre classification.

The presented results indicate that specialized tasks, that use the audio signal, can potentially provide valuable insight about several aspects of this music. The combination of video and audio signals allows possible experimentation on methods that process multimodal data. The Lyra dataset includes material that readily allows MIR tools to be employed for reaching valuable musicological results. This dataset can also, potentially, foster the expansion of the MIR methods altogether.

7. ACKNOWLEDGEMENTS

The authors would like to thank Professor Lambros Liavas, the producer, researcher and presenter of the documentary series "To Alati tis Gis - Salt of the Earth". His work not only provides a fruitful source of knowledge and art but also acts as an inspiration for new researchers. This work would not have been possible without the help of the volunteer annotators. A big thank to the students of the Department of Music Studies of National and Kapodistrian University of Athens. Finally, we would like to thank the reviewers for their valuable and constructive comments.

ABSTRACT

In this paper, we focus on singing techniques within the scope of music information retrieval research. We investigate how singers use singing techniques using real-world recordings of famous solo singers in Japanese popular music songs (J-POP). First, we built a new dataset of singing techniques. The dataset consists of 168 commercial J-POP songs, and each song is annotated using various singing techniques with timestamps and vocal pitch contours. We also present descriptive statistics of singing techniques on the dataset to clarify what and how often singing techniques appear. We further explored the difficulty of the automatic detection of singing techniques using previously proposed machine learning techniques. In the detection, we also investigate the effectiveness of auxiliary information (i.e., pitch and distribution of label duration), not only providing the baseline. The best result achieves 40.4% at macro-average F-measure on nine-way multi-class detection. We provide the annotation of the dataset and its detail on the appendix website [0] .

1. INTRODUCTION

A singing voice is one of the most essential elements of music. It provides impactful emotional expressions through melody and lyrics. In particular, in popular music, the role of the singing voice is more important, as the vocal quality and unique style of singers are critical in attracting people. Vocals mainly consist of singer individuality (i.e., vocal fold vibration and vocal tract resonance) and singing expressions (i.e., fine control of pitch, timbre, and loudness). Singing techniques, as the name suggests, are extended techniques in human singing. It characterizes singing voices as a component of expressions in vocal performances. In particular, many professional singers in popular music use singing techniques to make a performance more expressive, each in a different manner.

Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

The singing voice is an important subject in the field of music information retrieval (MIR), and there are many prior works that extract quantitative or objective information as in the task of singing transcription [1], lyric identification [2], and singer identification [2]. Computational analysis of singing techniques based on MIR can contribute to the clarification of singing styles and can be applied to music discovery, vocal training, consumer-generated media and so on. Singing techniques have been of keen interest, especially in J-POP, both among singers and music creators; the singing style of J-POP singers has a wide variety, and their singing techniques are diverse. In addition, singing techniques are one of the evaluation criteria in Japanese commercial karaoke systems with scoring systems. Meanwhile, as for music creators, *VOCALO* songs, whose singer's voice are created by a singing voice synthesis software such as VOCALOID [3], have been established as a music genre in Japan. Many VOCALOID creators manually manipulate the voice of VOCALOID to make it more expressive, sometimes while referring to how the actual singer produce the singing voice, like how singing techniques are applied. Therefore, J-POP is an attractive research target for singing technique analysis and computational singing technique analysis may bring benefits to real-world applications.

In this regard, we present a case study of singing technique analysis in J-POP. We first introduce a new dataset, including the annotation of singing techniques for J-POP recordings. We analyze the dataset using descriptive statistics to illustrate the technique distributions and singer styles. Finally, we conduct singing technique detection based on machine learning methods, which can be beneficial to analyze the one side of the singing voice automatically. We demonstrate the detection of various singing techniques (i.e., identifying the singing technique type with its starting time and duration) and report baseline results using existing methods. Finally, we investigate the effect of the identification model with auxiliary information derived from the statistics of the dataset and pitch information.

2. RELATED WORKS

2.1 Singing Technique Analysis

Analyzing the acoustic patterns of singing expressions has been a long-standing research topic. Research on vibrato

dates to the 1930s [4]. Later, computer-based methods allowed a more quantitative analysis of vibrato parameters [5,6]. In addition to vibrato, other singing techniques, such as growling [7], portamento [8], voice registers [9,10], and extreme vocal effects [11] have also been investigated. An analysis of singing techniques was also conducted for J-POP. Migita et al. investigated the vibrato parameters of the imitated singing voices of J-POP vocalists [12]. Yamamoto et al. conducted an exploratory analysis of singing techniques that imitate the singing style of J-POP singers [13]. They found 13 types of singing techniques from 48 tracks and analyzed them with annotations. Because singing techniques in J-POP cover wide repertoires [14], such exploratory analysis is also important for the purpose of singing performance analysis. As our interests are handling and detecting multiple singing techniques rather than specifying a single technique, we annotated the label as in the manner in [13] but on the original real-world tracks of J-POP. Therefore, our new dataset consists of labels for multiple singing techniques.

2.2 Singing Technique Datasets

There are a handful of datasets that focus on the analysis of singing techniques. The Phonation Mode dataset consisted of four vocal modes (neutral, pressed, breathy, and flow) of sustained sung vowels from four singers [15]. Although the dataset includes a wide range of pitches, they are discrete, and thus lack a melodic context. VocalSet [16] handles the issue by having voices sung in contexts of scales, arpeggios, long tones, and excerpts. In addition, it covers a broader range of singing techniques, such as vibrato, trill, vocal fry, and inhaled singing. Because audio samples in the two datasets were newly recorded, they were collected under controlled conditions. Therefore, their characteristics of singing techniques might be different from those appeared in songs.

However, several datasets have been annotated for real-world vocal music. The KVT dataset was originally built for vocal-related music-tagging tasks in K-POP music [17]. It contains 70 vocal tags, of which six are related to the singing technique (whisper/quiet, vibrato, shouty, falsetto, speech-like, and non-breathy). The annotation was conducted using crowdsourcing. The MVD dataset was built to analyze screams in heavy metal music, and has four different types of screams (high fry, mid fry, low fry, and layered) [18]. The regions and types of screams in the audio files were manually annotated. Similar to these studies, we are interested in versatile singing techniques in real-world music and thus we chose commercial music to build the dataset.

2.3 Singing/Playing Technique Identification on MIR research

Studies have been conducted on the automatic identification of singing techniques beyond computational analysis. There are two scenarios for identifying a singing techniques. One is classifying sung vocal audio into singing techniques. Several studies have conducted singing technique classification on VocalSet [19] and phonation modes [20, 21]. These works identify singing techniques but do not provide time-related information, such as start time and duration. The other method is to detect the singing technique in time. Miryala et al. [22] identified the singing expressions of raga, classical music in India. They created 35 recordings in eight ragas sung by six singers and showed a classification accuracy of 84.7% using a rule-based classifier. Yang et al. [8] proposed AVA, an interface for analyzing vibrato and portamento based on the filter diagonalization method (FDM) and hidden Markov model (HMM), respectively. They also provided a case study of the analysis of vibrato and portamento in the Beijing opera. Ikemiya et al. [23] provided rule-based parameterization of four singing expressions (vibrato, kobushi, gliss-up, gliss-down), extracted them from recorded vocal tracks to transfer to other vocal tracks, and demonstrated them on two sung excerpts. Kalbag et al. [18] provided scream detection for heavy metal music. They also built the MVD dataset and demonstrated classification, including non-scream singing and non-vocal music. Since singing techniques appear locally on sung vocals, we adapted these temporal detection strategies for identification.

3. DATASET

In this section, we describe the organization of our new dataset used for the analysis of this study. Due to the limit of the space, more details are described in the appendix site [0] .

3.1 Song Selection

To cover a wide range of singing techniques, the dataset should include various types of vocalists, considering gender, genre, tempo, and mood. We first listed 42 solo singers (21 males and 21 females), and four famous hit songs were selected from each singer to be as different as possible. Each song was performed as solo performance in Japanese. We collected audio tracks from commercial CD recordings of the J-POP songs. We trimmed the collected audio tracks and annotated only the first consecutive section (i.e., verse-A, verse-B and Chorus). Since we prioritized including various songs in our dataset rather than fully annotating multiple verses in a single song, we could collect a diverse set of singing styles.

When using popular commercial songs for academic research, copyright is always an issue. The works by Kim [17] on K-POP and Kalbag [18] on heavy metal music are good examples of developing datasets using commercial music, which distributes only labels about the performed music but not the audio signals or score information. We followed their solutions and made our dataset that consists of singing technique and pitch (frequency) contour labels.

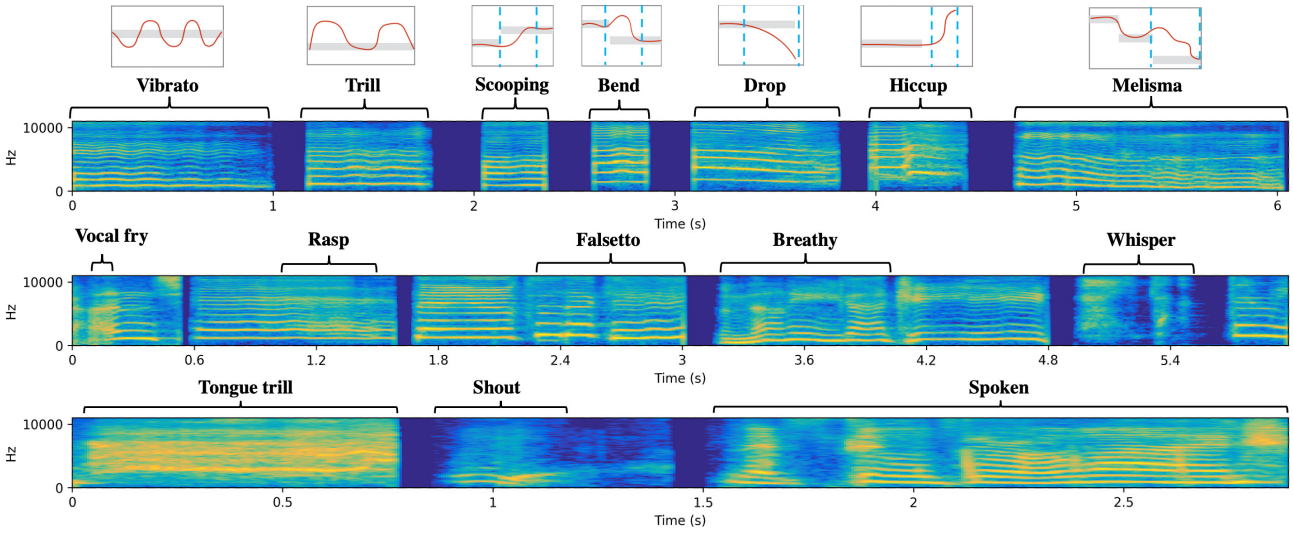

Figure 1. Singing techniques included in the dataset. (upper) Pitch techniques with a sketch of pitch contour. Gray is the target vocal note, the red line is the pitch contour and blue dotted lines are boundary of each technique. (middle) Timbral techniques. We also show the non-technique extracted from the same track. (lower) Miscellaneous techniques.

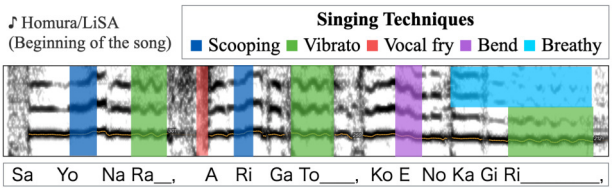

Figure 2. An overview of annotation. (middle) an excerpt spectrogram with singing technique (colored area) and vocal melody (orange curve).

3.2 Data Pre-processing

The dataset contains two types of annotations: vocal melody and singing techniques. We illustrate the annotation result in Figure 2. All annotations were conducted on isolated vocal tracks after vocal separation using Demucs v3 [24], which is a state-of-the-art model for musical source separation. During the annotation process, we confirmed that there was no dropout of vocal regions by comparing the original mixed track. Instead, we observed that the separated vocals tends to retain the back-chorus or sometimes instrumental sounds that are similar to the singer's voice (e.g., electric guitar, synthesizer).

3.3 Singing Technique Annotation

We thoroughly surveyed singing techniques based on instructional books [14, 25] and other conventional scientific research related to singing techniques [7, 13, 16, 17, 26–29] and defined the labels for the major techniques that appear in these references. We manually annotated songs using these labels.

Although many other singing techniques still exist, we considered the following 15 singing techniques in this study. We show the description of each singing technique in Table 1. The pitch contour sketches of these techniques and spectrogram examples are illustrated in Figure 1.

We note that these label names are not unique in the real-world (e.g., scooping is also called 'portamento,' 'glissando,' 'gliss-up,' 'shakuri' (in Japanese)). We made

Technique	description	type
vibrato	a periodic oscillation of pitch.	pitch
scooping	an upper continuous picth change	pitch
drop	a lower continuous picth change	pitch
bend	a short tremolo or U/inverted-U shaped pitch change	pitch
hiccup	a short hiccuping on attack/release of note	pitch
melisma	a musical arrangement in which several notes are applied to one syllable of a lyric.	pitch
trill	a continuous pitch change between two notes	pitch
falsetto	sung by falsetto register.	timbre
breathy	sung by breathy sound.	timbre
whisper	sung like whispering.	timbre
rasp	sung by a creaky voice with subharmonics.	timbre
vocal fry	sung by a creaky voice and pulse register phonation.	timbre
spoken	singing like rapping, *sprechgesang* [1], and some other styles like speaking.	misc.
shout	shouting.	misc.
tongue trill	a rolling tongue, occurred on [r] consonant.	misc.

Table 1. The description of each singing technique appeared in the dataset.

[1] A vocal style between singing and speaking.

[2] Although discarded in the analysis, we also annotate 'unknown' labels if the region seems to represent a singing technique but is difficult to classify them into any of the techniques above and found 24 unknown techniques in total. In the techniques, there are some sounds akin to coughing and pig squeals, for example.

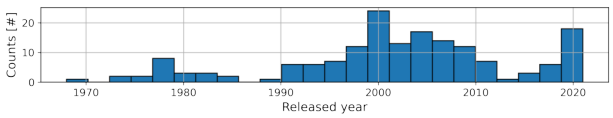

Figure 3. Distribution of song year of release.

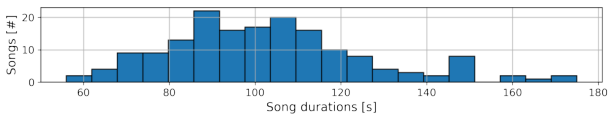

Figure 4. Distribution of song length in seconds.

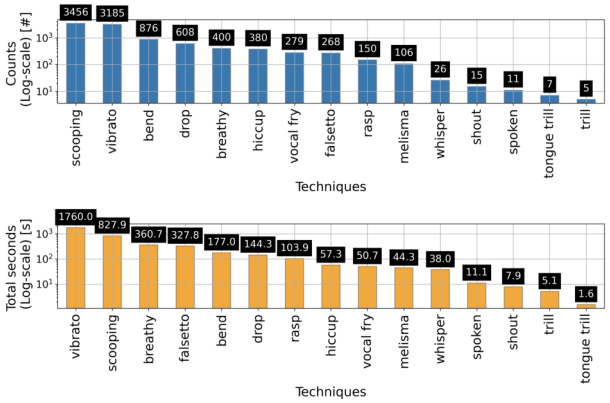

Figure 5. Statistics of the labels. upper: counts, lower: total duration.

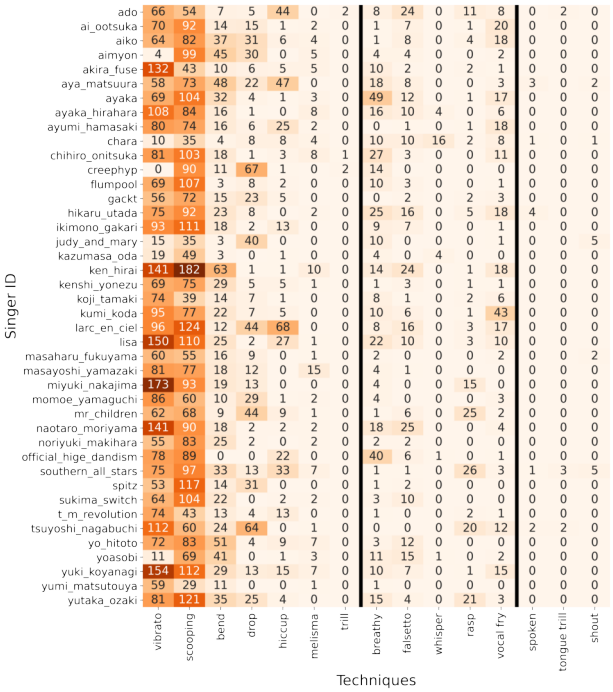

Figure 6. Occurrence distribution of singing techniques by singer. The vertical black line divides each category.

frame-level annotations on the audio tracks collected based on the vocabulary. Singing techniques were carefully annotated by an experienced vocalist (i.e., the first author of the paper) with the helps of sound playback and visualizing the spectrograms and pitchgrams. The annotation process is conducted on Sonic Visualizer [30].

3.4 Melody Annotation

Since pitch is an essential component of singing technique analysis, we further annotated melodic pitch using Tony [31], followed by manual correction such as removing the unvoiced parts and reverberation tails.

4. DESCRIPTIVE STATISTICS

4.1 Song Statistics

The distribution of songs selected for the dataset based on the year of release is shown in Figure 3. Songs can be collected from various eras, ranging from 1968 to 2021. The distribution of the songs in the dataset is shown in Figure 4. The overall length was 4h 47m 39s, and the average length of a song track was 1m 43s. The ratio of technique regions per song track was 22.8%.

4.2 Label Statistics

We present the statistics for the annotated labels as a histogram at the upper side of Figure 5. The most frequent technique is 'scooping'. It is followed by 'vibrato', 'bend', and 'drop'. This indicates that such techniques are relatively common in J-POP. These techniques are also used in Japanese commercial karaoke systems for vocal assessment [32]. 'scooping', 'bend' and 'drop' are portamento, whose frequent use is sometimes considered undesirable in classical singing [25]. It can be said that this frequent use of portamento is a characteristic of J-POP.

We show the distribution of techniques by each singer in Figure 6 and find that the occurrence frequency of the techniques is different for each singer. We also confirmed that scooping appears more than 29 times for every singer, whereas several singers tend to not use vibrato frequently (e.g., 'creephyp', 'aimyon', and 'yoasobi').

The lower side of Figure 5 and Figure 7 shows the total duration and distribution of each technique using a boxenplot, respectively. Figure 7 shows that most of the techniques are relatively short (that is, the range between 0.1s and 1s.), especially for 'drops', 'scooping', 'bend', 'hiccup', and 'vocal fry'. The average length of the singing techniques was 0.4s.

5. SINGING TECHNIQUE DETECTION

In this section, we describe the detection of the singing techniques. We conducted experiments on a multi-class detection scenario, which handles classification and localization simultaneously. The problem setting is the same as that in sound event detection (SED) [33]. Figure 8 illustrates the proposed method. We investigated the performance of the CRNN model in a singing technique detec-

[3] https://seaborn.pydata.org/generated/seaborn.boxenplot.html

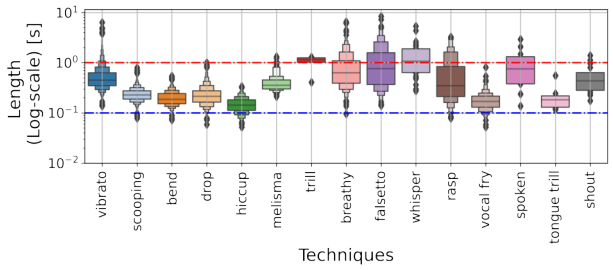

Figure 7. Distribution of each technique. Red and blue horizontal lines indicate 1 s and 0.1 s, respectively.

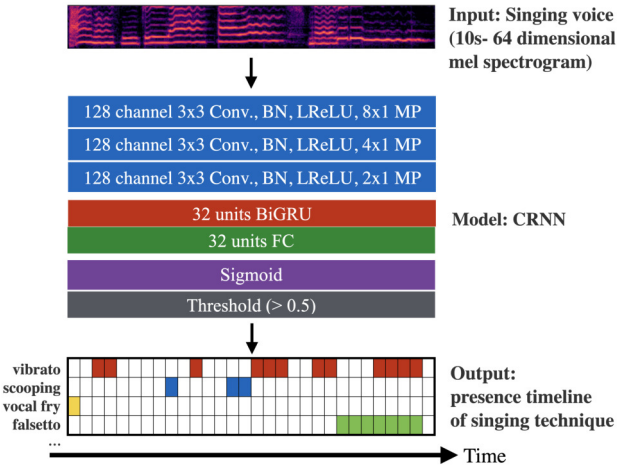

Figure 8. An overview of the singing technique detection. The configuration of the CRNN model is also shown.

tion task. In addition to running the simple setting, we also investigated how the considerations of the characteristics of the dataset improve the performance (i.e., label sparseness and pitch information). Thus, through the experiment, we attempted to answer for the following three research questions: 1) To what extent can we detect singing techniques using machine learning? 2) Can modification of the loss function treat the problem of label sparseness? 3) Can auxiliary pitch information help improve the detection performance?

5.1 Experimental Conditions

We performed singer-wise seven-fold cross validation during the experiment. We first split the singers into seven groups. Then, in each run, one group is left out for test set, another one group is for validation set , and the rest are used for training set. Owing to the label imbalances of techniques between singer, we used the 9 most common classes (i.e., 'bend,' 'breathy,' 'drop,' 'falsetto,' 'hiccup,' 'rasp,' 'scooping,' 'vibrato,' and 'vocal fry'), which appear on every fold. We divided the singer fold to balance the amount of each technique as much as possible.

We segmented the vocal tracks, which are separated by Demucs v3 [24] in advance, into 10s audio clips and non-overlapping parts at a sample rate of 44.1 kHz. Therefore, they were converted into 64-dimensional log-mel spectrograms. For experiments that involve the computation of short-time Fourier transform (STFT), we used a Hann window with 2048 samples to compute the discrete Fourier transform (DFT). The hop size was set to 10 ms in every experiment.

We used a CRNN model, which is widely used as a baseline system for SED. We adapted the settings of the model of Imoto et al. [34], which treated a similar issue (i.e, label sparseness) of ours in SED. The model configuration is shown in Figure 8. The model consists of three convolutional layers, one layer of bidirectional GRU cells, and one fully connected (FC) layers. The input was the aforementioned log-mel-spectrogram, and the output was a multi-hot vector representation of the singing technique for each time frame. All experiments were conducted using a batch size of 16, and the model parameters were optimized using an Adam optimizer with a learning rate of 10^{-4}. The model stopped training if the value of the loss function on the validation set did not improve over 10 epochs.

The model was optimized using the binary cross-entropy (BCE) loss. Performance was evaluated using segment-based recall (R), precision (P), macro-F-measure (Macro-F), and micro-F-measure (Micro-F) [35] using sed_eval. The macro-F-measure and micro-F-measure denote the class-wise and instance-wise average of the F-measure, respectively. We set the segment length to 50 ms.

5.2 Model Improvement

5.2.1 Label-frame sparsity

As mentioned in Section 4.2, most singing techniques have a short duration (i.e., shorter than 1 s). This can cause label imbalance between non-technique frames. To alleviate the problem, we investigated the effect of *focal loss* [36], which was originally proposed for image object detection. The focal loss can be represented as follows:

$$L_{fl}(p_t) = -\alpha(1-p_t)^{\gamma}\log(p_t) \quad (1)$$

where $\alpha \in [0,1]$ is a weighting factor for balancing the importance of positive and negative examples, and the term $(1-p_t)^{\gamma}$ is a modulating factor, with γ controlling the rate of dominant examples. We set $\alpha = 0.2$ and $\gamma = 2$ for all conditions in the work that used focal loss.

5.2.2 Pitch information

We demonstrated that some of the techniques, such as vibrato and scooping, have a pattern of the shape to certain extent. Therefore, it is possible that explicitly feeding the pitch helps in the detection. We further investigated the effect of the auxiliary information. Under this condition, we considered two ways of obtaining pitch in our experiment. One is the ground-truth (GT) pitch annotation mentioned in Subsection 3.4. However, when used in real-world applications, it is difficult to obtain correct pitch annotation. Hence, we also used pitch estimation predicted by CREPE [37] on a separated vocal track. As CREPE can compute pitch confidence, we adopted the pitch value

[4] https://tut-arg.github.io/sed_eval/index.html

	Macro-F	Micro-F	P	R
BCE	37.7%	56.6%	40.2%	41.7%
Focal	39.6%	57.7%	40.3%	42.6%
BCE-GT	39.1%	57.1%	41.4%	42.8%
BCE-CREPE	39.1%	57.1%	40.2%	41.7%
Focal-GT	**40.4%**	**58.3%**	**43.1%**	42.2%
Focal-CREPE	40.3%	57.9%	42.7%	**43.3%**

Table 2. The results of singing technique detection.

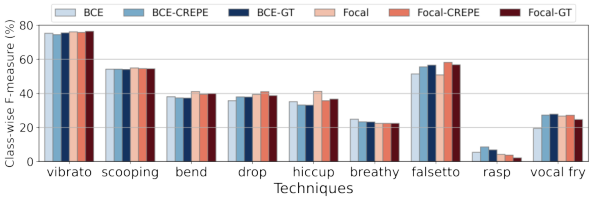

Figure 9. Class-wise F-measure

where the confidence value was higher than 0.5, whose overall accuracy was 78.0% evaluated by mir_eval [38]. We converted the pitch contour to a mel-band pitchgram that has the same frequency dimensions as the input mel-spectrogram, as in the work of singer identification [39]. Therefore, we stacked it on a mel-spectrogram along the channel axis.

5.3 Experimental Results

5.3.1 Baseline

The first row of Table 5.3 shows the results of the CRNN model compiled by BCE: 37.7% for Macro-F and 56.6% for Micro-F. The fact that Macro-F is much lower than Micro-F indicates that the model failed to identify minority rather than majority classes. Actually, the class-wise F-measure, as shown in Figure 9, indicates that detection of the minority techniques (e.g., 'rasp' and 'vocal fry') is more difficult than the majority techniques (e.g., 'vibrato' and 'scooping').

5.3.2 Effect of focal loss and pitch information

First, we show the results for the effect of *focal loss* in the middle part of Table 5.3. The detection performance improved by 1.9% in Macro-F. We further studied the class-wise F-measure, as shown in Figure 9, and confirmed that the performance of short techniques, such as 'bend' (38.0% $\rightarrow$ 41.1%), 'drop' (35.7% $\rightarrow$ 39.3%), and 'hiccup' (35.1% $\rightarrow$ 41.2%) are especially improved. This indicates that *focal loss* can adapt to the sparsity of the label.

Next, we showed the results of the effect of the auxiliary pitch information in the middle part of Table 5.3. A remarkable finding is that the F-measure of 'falsetto' was particularly improved (51.3% $\rightarrow$ 56.5%). We also confirmed that the recall value of 'falsetto' is raised more (64.7% $\rightarrow$ 74.1%) rather than the precision value (45.1% $\rightarrow$ 48.3%). This indicates that pitch information hint at the relationship between the sung pitch value and the occurrence of falsetto (i.e., falsetto can appear only at a higher pitch). We also confirmed that the input of CREPE pitch shows the similar tendency.

We further investigated the effects of combining these two types of auxiliary information. As shown in the bottom part of Table 5.3, the combination of GT pitch and focal loss is the best condition in terms of both macro- and micro-F values. We can confirm that both effects of each auxiliary information occur under this condition (red and dark-red bars in Figure 9). This indicates that the condition is robust to techniques that have a short duration or some relationships with pitch.

[5] The other metrics were following; 85.9% for voice recall, 29.9% for voicing false alarms, 94.5% for raw pitch accuracy.

5.3.3 Challenges

The remaining challenges in the task are detected unnatural region lengths and singers' identity. We confirmed that one of the common mis-detection cases is from the detection of too short or frequently switching regions. It might need to consider post-processing, such as temporal filtering or probabilistic model (e.g, hidden Marcov model, hidden semi-Marcov model, etc.). As for singer identity, it can affect the performance of the timbral techniques. We labeled timbral techniques when the sung voice transformed from the ordinary voice of the singer, and it caused the confusion. For example, the 'rasp' from a singer who has clean voice and ordinary voice from a singer who has raspy voice can be confusing. Therefore, there is still an issue of disentangling singers' identity and singing techniques.

6. CONCLUSION AND FUTURE WORK

This work presented an analysis and identification of the singing technique in J-POP music as a case study. In addition, we built a new dataset consisting of 168 J-POP songs with annotation of pitch contour and singing techniques. The contributions of this study are summarized as follows: 1) we constructed a dataset with frame-level annotations of singing techniques on 168 famous J-POP vocal songs, 2) conducted a descriptive-statistical analysis of the dataset, 3) proposed a CRNN-based singing technique detection model as a baseline, and confirmed that both auxiliary pitch information and focal loss help the detection performance.

As we showed the appearance of singing techniques relates to some other factors (e.g., difference of singing technique distribution by singer, pitch information helps the detection of falsetto, etc.), we are planning further investigations of relationships or joint identification between other musical factors (e.g. musical note, lyrics, beat and tempo, etc.) or higher level information (e.g. singer, songs' emotion, mood, etc.) with making more types of annotation. Although this work focuses only on J-POP, the knowledge can be applicable to other types of singing. Similar study on other style of vocal such as K-POP, western pops or non-popular vocal and comparison between them are other interesting topics for future work.

7. ACKNOWLEDGEMENTS

This work was supported by JST SPRING, Grant Number JPMJSP2124. Dr. Maiko Murai (Associate Prof. at the University of Tsukuba) gave advices on copyright law. Yoshihide Ishikawa, Sayori Takayama and Karolina Shi helped the preparation of the metadata. We are grateful to above all.

ABSTRACT

Rhythm quantisation is an essential part of converting performance MIDI recordings into musical scores. Previous works on rhythm quantisation are limited to the use of probabilistic or statistical methods. In this paper, we propose a MIDI-to-score quantisation method using a convolutional-recurrent neural network (CRNN) trained on MIDI note sequences to predict whether notes are on beats. Then, we expand the CRNN model to predict the quantised times for all beat and non-beat notes. Furthermore, we enable the model to predict the key signatures, time signatures, and hand parts of all notes. Our proposed performance MIDI-to-score system achieves significantly better performance compared to commercial software evaluated on the MV2H metric. We release the toolbox for converting performance MIDI into MIDI scores at: https://github.com/cheriell/PM2S.

1. INTRODUCTION

Performance MIDI-to-Score (PM2S) conversion aims to convert a performance MIDI, usually recorded by electronic MIDI keyboards, into musical scores in computer-readable score format such as MIDI, MusicXML [1] and Lilypond [2]. PM2S covers a list of subtasks including rhythm quantisation, note value prediction, key estimation, voice separation, and possibly score typesetting such as beaming and playing techniques annotation. PM2S can be used in various scenarios such as music improvisation [3], complete music transcription [4–7] in combination with multi-pitch detection, music alignment [8], music education, music performance analysis [9], and building music archives.

Although research on the various subtasks on PM2S dates back to earlier decades [10–13], the first academic paper that fully formulated this task was published in 2016 [14]. The paper works on converting a performance MIDI recording into a LilyPond score. The authors firstly fixed spurious overlapping notes according to a defined note overlapping ratio, then applied a probabilistic model using Hidden Markov Models (HMMs) based on a tactus-root combination concept [15] for meter, harmony, and stream estimation. After that, the note onsets and offsets are quantised to beat subdivisions. Note spellings and staves are determined from the predicted harmony and streams.

Following the use of conventional methods for solving subtasks such as rhythm quantisation, recent years have seen some advances on statistical methods [5, 16–19]. Nakamura et al. [16] proposed an improvement for rhythm transcription using a merged-output HMM to solve the problem introduced by multiple voices. A note value prediction method using Markov random fields was proposed in [17]. The two methods were further improved for automatic music transcription by combining multi-pitch detection [5, 19]. Mcleod and Steedman [18] proposed an HMM-based meter detection method for aligning MIDI performances.

Over the past two years, researchers have published papers using deep learning methods on PM2S. Hiramatsu et al. [20] proposed to use a recurrent neural network for joint estimation of note values and voices from note pitches and onset times, which in combination with multi-pitch detection and rhythm quantisation, outperformed previous methods [14, 19] for automatic music transcription. The Score Transformer [21] provided a solution to generating human-readable scores from quantised MIDI files.

From previous works, we observe that the problem of PM2S is usually solved through a combination of different methods for subtasks. Moreover, although there are attempts on applying deep learning methods for the task, they do not cover the rhythm quantisation step.

To address the limitations mentioned above, we propose to use a deep learning method for PM2S. We develop a CRNN model that directly converts a performance MIDI into a MIDI score. We pay special attention to the rhythm quantisation step, and propose to solve the problem by tracking beats on a MIDI note sequence. We then expand the CRNN model to predict a compact output for generating a quantised MIDI score, including quantised onset times and note values, time signatures, key signatures and hand parts. To better capture our method's ability in modelling expressive performances, we train and evaluate our proposed model on a set of classical piano music datasets [22, 23]. In a comparison with two commercial software

products MuseScore [24] and Finale [25], our proposed method achieved significantly better performance based on the MV2H metric [26].

2. METHODOLOGY

2.1 Problem definition

Our proposed method aims to predict a MIDI score from a performance MIDI using a deep learning model. Assume a performance MIDI note sequence $\mathbf{X}$ where notes are ordered firstly by time and secondly by pitch. Each note in the sequence is represented by a tuple:

$$\mathbf{X} = \{(p_n, o_n, d_n, v_n)\}_{n=1}^{N} \tag{1}$$

where p_n, o_n, d_n, v_n are the MIDI pitch number, onset and duration in seconds, and velocity for the n-th note, N is the number of notes. We aim to predict the transcribed MIDI score annotations including

$$\mathbf{Y_n} = \{(mo_n, nv_n, h_n)\}_{n=1}^{N} \tag{2}$$

$$\mathbf{Y_t} = \{(t_i, tn_i, td_i)\}_{i=1}^{T} \tag{3}$$

$$\mathbf{Y_k} = \{(t_i, k_i)\}_{i=1}^{K} \tag{4}$$

$$\mathbf{Y} = (\mathbf{Y_n}, \mathbf{Y_t}, \mathbf{Y_k}) \tag{5}$$

where $\mathbf{Y_n}$ covers the musical onset time mo_n, note value nv_n and hand part h_n for all notes; $\mathbf{Y_t}$ and $\mathbf{Y_k}$ are the time signature and key signature changes, where t_i is the time and tn_i, td_i and k_i are the time signature numerator, time signature denominator, and key signature respectively. T and K are the numbers of time signature changes and key signature changes. A MIDI score can be obtained by combining information from $\mathbf{X}$ and $\mathbf{Y}$.

2.2 From beat tracking to rhythm quantisation

Considering rhythm quantisation as a fine-grained tracking of beats and beat subdivisions, we propose to do rhythm quantisation by combining beat tracking and the prediction of musical note onset times in subdivisions within a beat. We use a deep learning model for both beat tracking and musical onset time prediction. Adding the beat tracking component allows the two components to learn from each other. It also allows us to use training data such as [23] that has beat-level annotations, but do not provide fine-grained alignment in subdivision level.

We define mo_n in Eq. (2) as a ratio of:

$$mo_n = s_n / S \tag{6}$$

where s_n is the musical note onset time in subdivisions within a beat, and S is the number of subdivisions per beat in rhythm quantisation.

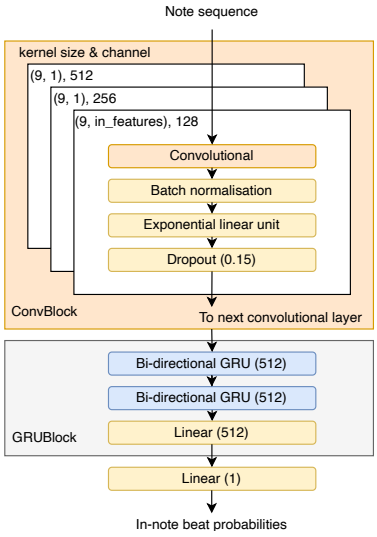

Figure 1. Model architecture for in-note beat prediction.

2.3 Neural beat tracking on note sequences

2.3.1 In-note and out-of-note beats

To match the model input data in note sequence format, we separate beats into two groups:

- *In-note*: beats concurrent with at least one note onset;
- *Out-of-note*: beats not concurrent with any note onset.

In our proposed approach, we first train a deep learning model to predict in-note beats in a binary classification task, and then use dynamic programming to infer out-of-note beats from the in-note ones.

2.3.2 In-note beat prediction

Let the ground truth in-note beat labels for each note in the note sequence be $\mathbf{B}_n \in \{0, 1\}$. We define a binary classification model that predicts the in-note beat probabilities for each note given the note sequence $\mathbf{X}$, that is:

$$P_n = P(\mathbf{B}_n | \mathbf{X}) \tag{7}$$

The model is trained to find the minimum binary cross-entropy loss defined as:

$$\mathcal{L} = -\frac{1}{N} \sum_{n=1}^{N} (\mathbf{B}_n * log(P_n) + (1 - \mathbf{B}_n) * log(1 - P_n)) \tag{8}$$

In order to acquire the beat and downbeat predictions, we use a CRNN with 3 convolutional layers and 2 bi-directional gated recurrent unit (GRU) layers. Figure 1 shows the model architecture. The predicted in-note beat probabilities are then converted to binary labels by dynamic thresholding. The dynamic threshold depends on the maximum predicted probability in a fixed segment length in seconds.

2.3.3 Out-of-note beat prediction

We assume there are in total N^i in-note beats and out-of-note beats are at subdivisions of their neighbouring in-note beats b_n^i and b_{n+1}^i where b_n^i means the n-th in-note beat

Algorithm 1 Out-of-note beat prediction

Input: List of in-note beats $\mathcal{B}^i$
Output: List of all beats $\mathcal{B}$ after adding out-of-note beats

$n \leftarrow 1$
for $K = 0, 1, 2, 3$ **do**
    Initialise objective function $\mathcal{O}_K \leftarrow 0$
    Initialise beat sequence $\mathcal{B}_K \leftarrow \{b_1\}$
end for
for $n = 1, 2, \ldots, N^i - 2$ **do**
    for $K_{cur} = 0, 1, 2, 3$ **do**
        Get out-of-note beats for current step by Eq. (9)
        if Tempo is beyond tempo range limits **then**
            Go to next K_{cur}
        end if
        for $K_{prev} = 0, 1, 2, 3$ **do**
            Update objective function by Eq. (11)
        end for
        Select the minimum objective among all K_{prev} values
        Add out-of-beats for current step to the beat sequence mapped to the selected K_{prev}
    end for
    for $K_{cur} = 0, 1, 2, 3$ **do**
        Update $\mathcal{O}_K$, $\mathcal{B}_K$ mapped with K_{cur}
    end for
end for
Return the beat sequence in $\mathcal{B}_K$ with the minimum objective function $\mathcal{O}_K$

and $n \in \{1, 2, \ldots, N^i\}$. We insert out-of-note beats b^o from candidates in:

$$b^o_{n,K} = \{b^i_n + \frac{k}{K+1}(b^i_{n+1} - b^i_n)\}^K_{k=1} \tag{9}$$

where $K \in \{0, 1, 2, 3\}$ is the number of out-of-note beats to insert for the current interval. We try to find a way that minimises the tempo change after adding out-of-note beats to the beat sequence. To describe the level of tempo change for a list of beats, we define an objective function as follows:

$$\mathcal{O}_1 = \sum_{n=1}^{N-2} \left| log\left(\frac{b_{n+2} - b_{n+1}}{b_{n+1} - b_n}\right) \right| \tag{10}$$

where N is the number of beats in the final beat sequence and b_n is the n-th beat. However, this function does not take into account adding too many out-of-note beats. We thus add a penalty associated with the number of out-of-note beats to the objective function, resulting in:

$$\mathcal{O} = \mathcal{O}_1 + \lambda \times N^o \tag{11}$$

where λ is the penalty coefficient applied to avoid adding too many out-of-note beats which is tuned based on experiments and N^o is the number of out-of-note beats added. In this way, we obtain an objective function $\mathcal{O}$ to be minimised in the out-of-note beat prediction process that encourages both a low level of tempo change and adds fewer out-of-note beats.

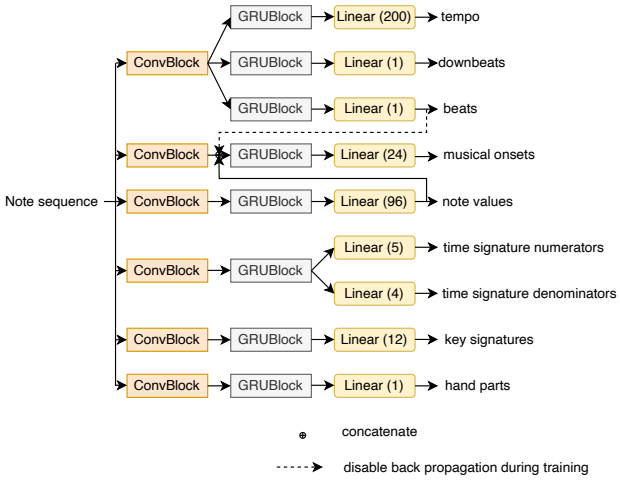

Figure 2. Model architecture for performance MIDI-to-score conversion.

We use a dynamic programming algorithm (defined in Algorithm 1) to find the optimal out-of-note beats while minimizing $\mathcal{O}$.

2.4 Performance MIDI-to-Score

Based on the problem definition in Section 2.1, we make some modifications to the prediction of time signature and key signature changes. In our proposed model, we define $\mathbf{Y_t}$ and $\mathbf{Y_k}$ in a way that the time signature and key signature values are mapped with each note by the note onsets. We also add beat b_n, downbeat db_n, and tempo tem_n prediction in note level. Beat probabilities are defined as in Eq. (7); similar definitions are used for downbeats. As a result, we define our model as $\mathbf{X} \rightarrow \mathbf{Y}'$ where:

$$\mathbf{Y}' = \{(mo_n, nv_n, h_n, tn_n, td_n, k_n, b_n, db_n, tem_n)\}^N_{n=1} \tag{12}$$

We then define a CRNN-based model that maps the input note sequence $\mathbf{X}$ with $\mathbf{Y}'$. Among the output elements, hand part h_n, beats b_n and downbeats db_n are defined as binary classification tasks; the others are defined as multi-class classification tasks, where

- Musical onset mo_n is defined as in Eq. (6), whose value is quantised by beat subdivisions;
- Note values nv_n are quantised by beat subdivisions;
- Time signature is defined to be $tn_n \in \{0, 2, 3, 4, 6\}$ and $td_n \in \{0, 2, 4, 8\}$, 0s indicate other values;
- Key signature k_n is defined to be in {C, Db, D, Eb, E, F, Gb, G, Ab, A, Bb, B};
- Tempo is quantised following a minimum inter-beat-interval of 0.01s.

Our proposed model structure is shown in Figure 2. The Convolutional blocks (ConvBlock) and GRU blocks (GRUBlock) have similar structure to the ones in Figure 1. Links between branches allow the output elements to learn from each other. The model is trained jointly using binary cross-entropy loss for binary classification output elements and negative log-likelihood loss for multi-task classification output elements.

A MIDI score can then be generated by combining the information given in the performance MIDI and the output

predictions from our proposed model.

3. EXPERIMENTS

3.1 Data

3.1.1 Datasets

To better demonstrate the ability of our proposed method on quantising expressive performance, we use a collection of classical piano music pieces from 1) The MAPS dataset [22] and corresponding metrical annotations from the A-MAPS dataset [27]; 2) The Classical Piano-Midi (CPM) database [28]; and 3) The ASAP dataset [23].

In order to avoid piece overlaps between train, validation and test splits, we use the distinct music piece labels for all piano performances given in the ACPAS dataset [29]. We use a real recording subset in MAPS (the ENSTDkCl subset) as the test set as in [5, 20]. Other music pieces not included in the test set are randomly split into training and validation based on their distinct music piece labels. In this way, we get a train/validation/test setup with no overlapping music pieces among splits. Table 1 shows the dataset statistics.

3.1.2 Annotation

Annotations are provided in different formats in the datasets we use. The A-MAPS dataset and the CPM database provide fully annotated MIDI scores with tempo and metrical information. Thus, we extract the annotations we need from the MIDI scores directly. Performances from the ASAP dataset come with two sets of annotations, MIDI scores and annotations in .tsv files. However, the MIDI scores were written by non-professionals and are not a good source of ground truth. Thus, we follow the authors' suggestion to use the provided annotations in the .tsv files, in which beat, downbeat, time signature and key signature annotations are provided. Due to the fact that the .tsv annotations do not cover precise fine-grained metrical and hand part annotations, we mask the ASAP data on musical onset time, note value, and hand part prediction during training. Moreover, when matching note onset times to beats or non-beats in our proposed model, we set a tolerance of $\pm$50ms to beat matching to comprise short-time variances introduced by human performance.

3.1.3 Data augmentation

Given the note sequence information defined in Section 2, we consider the following data augmentation methods:

- *Pitch shift*: Shift MIDI pitch values up or down for the whole music performance. The shifted pitch is defined as: $p_s = p_0 + p_{shift}$ where p_0 is the original pitch value and pitch shift $p_{shift} \in \{0, \pm1, \pm2, ..., \pm12\}$.
- *Tempo change*: Change the tempo to a ratio of the original tempo. The new tempo $tem_c = r_t * tem_0$ where tem_0 is the original tempo and $r_t \in [0.8, 1.2]$ is the ratio.
- *Note removal*: For polyphonic music, there should be little influence to the metrical structure of the music piece when removing some concurrent notes. Thus, for each group of M concurrent notes, we randomly remove 0 to M-1 of them from the MIDI performance.
- *Note introduction*: Contrary to note removal, we randomly select 0-100% of notes from the MIDI performance, and add new notes that are concurrent with the selected ones. We keep the velocity and duration the same, so as to preserve the original music structure as much as possible. The new note pitches are ±12 semitones apart from the original note pitches.

3.2 Evaluation metrics

3.2.1 Beat tracking evaluation

We define a *note-level F-measure* for evaluating in-note beat tracking, and a *beat-level F-measure* which follows the benchmark F-measure for beat and downbeat tracking [30] with a time tolerance of $\pm$70ms. In both cases, a true positive means a predicted beat is in the ground truth; a false positive means a predicted beat is not in the ground truth; and a false negative means a ground truth beat is missing in prediction.

For both F-measures, we report the precision p, recall r and F-score f. Similar definitions are used for downbeats.

3.2.2 Performance MIDI-to-Score evaluation

We use the MV2H metric [26] to evaluate the system performance on PM2S conversion. The metric covers five sub-metrics including multi-pitch detection (F_p), voice separation (F_{vo}), metrical alignment (F_{me}), note value detection (F_{va}), and harmonic analysis (F_{ha}). The final accuracy F is the average of all the sub-metrics.

3.3 Comparative experiments

Among the subtasks in PM2S, rhythm quantisation is a crucial and difficult part. It is also highly related to the estimation of time signatures, musical onsets, and note values. In our proposed rhythm quantisation method which combines neural beat tracking and musical onset time estimation, we consider beat tracking as a more important step since it works on drawing the skeleton of the metrical grid.

Thus, for the first part of our experiments, we investigate different input data configurations and data augmentation methods for the beat tracking part of our proposed method. To get rid of influences from out-of-note beat prediction, we use the note-level F-measure in our comparison. After that, we validate our beat tracking method on

beat-level F-measure combining out-of-note beat prediction in comparison with a baseline beat tracking model.

3.3.1 Input data encoding

Given the input data in note sequences, we consider the following ways of encoding the input elements:

- Pitches:
  - M: 128-dimensional one-hot vectors in MIDI pitch numbers;
  - C: 12-dimensional one-hot vectors in octave values.
- Onset times:
  - AR: the raw value in seconds;
  - AO: one-hot vectors quantised by 10ms resolution;
  - SR: onset time shift in seconds compared to the previous note onset ($o_i^{shift} = o_i - o_{i-1}$ for $i > 0$, $o_0^{shift} = 0$);
  - SO: one-hot onset time-shift quantised by 10ms resolution (with a maximum onset time shift of 4s, larger values are trimmed to 4s).
- Durations:
  - R: the raw values in seconds;
  - O: one-hot vectors quantised by 10ms resolution (similar to onset shift, large values are trimmed to 4s).
- Velocities are always normalised to 0-1.

For all possible input encoding combinations, we train and evaluate the in-note beat prediction part of our proposed model (excluding downbeat). The model learning rate is set to be 0.001. Since different input encodings can cause changes in the model convergence speed, we do not add learning rate decay in this comparison. The model is trained using a batch size of 32 over 4 GPUs with a dropout rate of 0.15. For each combination, we take the best model checkpoint on the validation set during training, and evaluate it over the test set. The performances of the model on all different input data encoding combinations are reported in Table 2.

From the results, we can see that in terms of pitch encoding, using the MIDI pitches tends to outperform using the chroma groups most of the time. For onsets, onset shift leads to better results than absolute onset across all encoding combinations. Using one-hot encoding for onset is better than using the raw values for most cases. 6 out of 8 encoding combinations result in better model performance with onsets encoded in one-hot format. However, an opposite preference is discovered for duration encoding, where duration in raw values ends up with better results for more cases.

Among all the 16 input data encoding combinations tested, the one with MIDI pitch, one-hot onset shift, and duration in raw value shows the best model performance. We use this input data encoding combination in our subsequent experiments.

Table 3. Note-level F-measure results on the ablation studies.

3.3.2 Ablation studies

Using the best input encoding combination observed in the previous comparison, we run an ablation study on the input features and different data augmentation techniques. We use all four input features when exploring different data augmentation methods.

Table 3 shows the ablation study results. From the table, we see that all four input features are helpful in beat tracking, among which the onset feature is the most beneficial one. This is consistent with the fact that onsets can be the feature to carry most metrical information in music performances. People can usually infer beat times from drum beats without knowing other information such as pitch or duration. Pitch and velocity are less important but still make a difference. That may be because pitch carries some harmony information that helps beat prediction. Velocity can provide useful information as well since beats are more probable to be concurrent with heavy notes. Finally, duration is of certain importance, suggesting it carries more metrical information than pitch and velocity.

Models (output data)	f_b	f_{db}
Baseline (b, db)	66.9	57.6
Proposed (b, db)	85.7	63.3
Proposed (d, db, t)	**86.2**	**69.8**

Table 4. Beat-level F-measure results on the baseline and proposed models. b: beat, db: downbeat, t: tempo.

Methods	F_p	F_{vo}	F_{me}	F_{va}	F_{ha}	F
Finale	82.2	54.6	9.9	92.2	86.2	65.0
MuseScore	10.0	65.0	15.3	95.0	84.5	54.0
Proposed	**99.8**	**87.0**	**61.7**	**99.9**	**91.1**	**87.9**

Table 5. MV2H evaluation on performance MIDI-to-score conversion.

Results on different data augmentation methods suggest that all four proposed data augmentation methods improve performance, among which tempo change is the most beneficial one. Not performing data augmentation does not result in the lowest note-level F-score. However, its low precision rate indicates a limitation on predicting more false positives, which is discouraged since we will be adding out-of-note beats based on the predicted in-note beats. It is possible that we can add the false negatives back when predicting out-of-note beats, but we cannot remove the false positives.

3.3.3 Proposed model vs. baseline model

Using the best configurations in previous experiment results, we combine the out-of-note beat prediction step and evaluate our proposed model performance on beat tracking using beat-level F-measure. We compare our method with a baseline model that is similar to a state-of-the-art audio beat tracking model [31]. We retrain the baseline model using a pianoroll input replacing the original audio spectrogram input, where the pianoroll is calculated from the performance MIDI, and let the model predict beat and downbeat probabilities. The probabilities are then passed to a dynamic Bayesian network [32, 33] to get beats and downbeats in seconds.

Table 4 shows the comparative results between the baseline and our proposed model. Results suggest our proposed model largely outperforms the baseline when jointly trained with beats and downbeats. This is possibly because that the baseline model is a general purpose system designed to operate on richer content than piano music alone, and that our proposed model can better handle tempo changes. By adding tempo to the output data, the performance of our proposed model can be further improved, which suggests a benefit of joint learning.

3.4 System performance evaluation

Using the best configurations found in the comparative experiments, we train and evaluate our proposed CRNN model defined in Section 2.4 on PM2S conversion. We report the model performance on the MV2H metric described in Section 3.2.2.

When looking for other methods for comparison, we realise that there are some difficulties in comparing our system with existing academic works. Cogliati et al. [14] evaluated their method in a subjective way by inviting five music theory students to rate the transcribed musical scores. Works such as [5, 19, 34] do provide a combination of methods to achieve PM2S conversion, however, the system performance was reported on audio-to-score transcription. Thus, we compared our proposed method with two commercial software products Finale v27 [25] and MuseScore v3 [24] that can do PM2S conversion.

Results in Table 5 suggest that our proposed model outperforms MuseScore and Finale across all MV2H submetrics. A significantly better performance can be observed in the metrical alignment sub-metric F_{me} which is highly related to the rhythm quantisation step. By checking outputs generated from MuseScore, we found that its low performance on F_p is caused by time shifts introduced when quantising notes according to a constant tempo estimated over the whole music piece. Constant tempo estimation also caused its low performance reported on F_{me}. A similar limitation can be found in output scores from Finale. On the contrary, our proposed method tracked tempo changes during rhythm quantisation and preserved the expressiveness of music performance as much as possible. This not only benefits metrical alignment, but also results in high accuracies on F_p and F_{va}. Still, the rhythm quantisation performance (F_{me}) is far from satisfactory. Some typical errors include double/half tempo error and errors introduced by missing/extra beat predictions.

To provide a better understanding of the performance of our proposed method, we provide some example outputs from our model together with their performance MIDI recordings [1] .

4. CONCLUSION

We described our proposed method for rhythm quantisation by using a CRNN beat tracking model that predicts whether notes are at a beat position or not. We explored different input data encoding and data augmentation methods on the beat tracking model. We found that note onset time is the most important input feature in beat prediction and it is best to encode it into a one-hot onset-shift vector. Tempo change benefits most among the data augmentation methods explored. We validated our model's beat tracking ability in comparison with a pianoroll-input baseline model. In the end, we report the performance of our proposed system on PM2S conversion in comparison with MuseScore and Finale.

Possible next steps include investigating more powerful model architectures such as the Transformer [35], expanding the output data to generate a machine-readable score [21], probing our system's ability in dealing with more genre and instrumentation [19, 36, 37], and exploring our method's potential in automatic music transcription by combining multi-pitch detection [38, 39].

ABSTRACT

Since most of music has repetitive structures from motifs to phrases, repeating musical ideas can be a basic operation for music composition. The basic block that we focus on is conceptualized as loops which are essential ingredients of music. Furthermore, meaningful note patterns can be formed in a finite space, so it is sufficient to represent them with combinations of discrete symbols as done in other domains. In this work, we propose symbolic music loop generation via learning discrete representations. We first extract loops from MIDI datasets using a loop detector and then learn an autoregressive model trained by discrete latent codes of the extracted loops. We show that our model outperforms well-known music generative models in terms of both fidelity and diversity, evaluating on random space. Our code and supplementary materials are available at https://github.com/sjhan91/Loop_VQVAE_Official.

1. INTRODUCTION

With the advance of generative models, many studies are trying to model sequential data such as language and speech. Music can also benefit from their previous works since it consists of a sequence of multiple notes to represent the composer's intention. Through the advancement, individuals can imitate the musical inspiration of artists without musical expertise.

Several works related to music generation have focused on generating long sequences by utilizing the expressive power of Transformer [1-4]. It is a promising approach because the Transformer with hierarchical layers can learn various types of repetitive structures on its self-attentions. However, it still has limitations, derived from the error accumulation and rhythmic irregularity, to achieve the ultimate goal which is to compose full-length music [1, 2]. To tackle that problem, we explicitly utilize recurrence properties in music, generating short and fixed-length music phrases that can be used as basic patterns of music.

Repeating musical ideas is a basic operation for music composition. This operation conceptualizes the loop, an essential ingredient for creating remixes or mash-ups [5]. With the concept, we can simplify the generation task into generating one distinctive pattern which consists only of a few bars. For loop extraction, previous works have attempted to detect autocorrelated peaks (it relies on an assumption that it is sufficient to detect the starting point of phrases) [5, 6], but we apply the knowledge of overall loop structures, obtained from a public audio dataset, to the MIDI domain.

Another intuition is that the musical ideas can be formed in combinations of finite symbols. It is known that learning discrete latent codes is sufficient to represent the continuous world since many modalities consist of sequences of symbols [7]. For example, objects in vision, words in language, and phonemes in speech may be candidates of symbols. Also, compressing raw data into discrete semantic units makes an autoregressive model easy to train by capturing long-range data dependency [8]. If we regard consecutive notes as symbols, it is natural to adopt discrete representation as the basis of our autoregressive generator. This process can emphasize pattern to pattern structures sacrificing the minimal loss of note details.

In contrast to using Inception Score (IS) and Fréchet Inception Distance (FID) for computer vision [9, 10], no consensus has been made for evaluating generated music. This is because the absence of pre-trained feature extractors prohibits the comparison of true and generated samples on feature space. Recently, Naeem has shown that random embedding can also be effective when the target distribution is far from pre-trained model statistics [11]. Using the random initialized networks, we evaluate our generative models on sample fidelity and diversity as firstly suggested in [12].

In this work, we propose symbolic music loop generation via learning discrete representations. It involves two main processes; 1) *loop extraction* from MIDI datasets using a loop detector and 2) *loop generation* from an autoregressive model trained by discrete latent codes of the extracted loops. The outputs of the generative model are loops consisting of 8 bars, which can be repeated seamlessly. Since we aim to generate polyphony and multitrack sequences, the bass and drum are chosen for our experiments, which are fundamental components of melody and rhythm. Additionally, we adopt an evaluation protocol from [11] to measure two-dimensional score which stands for fidelity and diversity. Our contributions are summarized as follows;

- We propose the framework of symbolic music loop generation, which involves loop extraction, loop generation, and its evaluations.

- For loop extraction, we design a structure-aware loop detector trained by external audio sources to extract loops of 8 bars from MIDI.
- For loop generation, we verify that an autoregressive model combined with discrete representations can generate plausible loop phrases which can be repeated.
- With randomly initialized networks for embedding, we evaluate sample quality in terms of fidelity and diversity.

2. RELATED WORK

We introduce several works related to the history of loop extraction and music generation, the effectiveness of discrete representations, and the development of evaluating generative models.

2.1 Loop Extraction

For symbolic music generation, some researchers have prepared their dataset by sliding a window with a stride of 1 bar [13, 14]. Although they have achieved good generative performance, this process does not consider relative positions within music, generating ambiguous phrases.

Some works have imposed structural constraints on music generation models [15, 16], or directly detect novel segments which are repetitive in time series [17, 18]. In the audio domain, there have been attempts to extract loops explicitly by capturing repeated phrases [5, 6]. They extract harmonic features such as chroma vectors or mel-frequency cepstrum and catch autocorrelation peaks to determine the starting point of loops. They also require a heuristic process to decide which features should be more weighted. In contrast, our loop detector works on a data-driven approach, so it does not require a manual process such as feature extraction and weighting strategies.

A recent work for drum loop generation has informed the availability of a human-created loop dataset from Looperman (https://www.looperman.com/) [19]. Although it consists of audio sources with various instruments and genres, we suggest a promising approach to combine them with Lakh MIDI Dataset (LMD) [20]. Concretely, we extract domain-invariant loop structures from Looperman and train a loop detector using them to extract loops from LMD.

2.2 Symbolic Music Generation

To make MIDI available in machine learning, two representation methods are prevalent; event-based representation and time-grid based representation [21]. Although the former can represent high time-resolution with a few event vectors, we choose the latter one to benefit from fixed-length and repetitive structures for music. There have been several works to deal with polyphony multitrack representation [1, 13, 22]. Especially for time-grid based representation, MuseGAN [22] has stacked five instruments each of which consists of 4 bars and 84 pitches. We follow their method while restricting to two instruments, the bass and drum.

2.3 Discrete Representations

As opposed to VAE [23] with continuous prior, Oord has proved that a finite set of latent codes is sufficient to reconstruct while it prevents posterior collapse [7]. Powerful autoregressive priors with the latent codes have shown promising performance not only in image generation [8] but also text2image [24], and video generation [25]. Loop generation can also benefit from discrete data compression by expressing long-range structural patterns.

2.4 Evaluation of Generative Models

Proper evaluation metrics for generative models are important to reduce human evaluation labor. Previous works of music generation have inspected model metrics (*e.g.,* log-likelihood) or musical metrics on data space to evaluate how much true and generated samples are similar [3, 22, 26]. Comparison on data space, however, is vulnerable to pixel by pixel phase difference, ignoring data semantics. Without available pre-trained networks, it has been reported that random embeddings are more robust for evaluation rather than using models trained by other data domains [11]. In this respect, we take randomly initialized networks as our feature extractor and evaluate our music samples on feature space.

The commonly used metrics in computer vision are IS and FID which compute a one-dimensional score. To distinguish fidelity and diversity from the score, Sajjadi has suggested precision and recall evaluating overlapped ratio between true and generated distribution [12]. After that, some works have proposed different ways of constructing data distribution using k-nearest neighbors (KNN) [11, 27]. We adopt KNN based evaluation protocol since it is not affected by its initialization and is robust to outliers.

3. PROPOSED METHOD

Our work starts with collecting MIDI loops using a structure-aware loop detector. Since we design the detector to take not the music itself but bar-to-bar structures, we can train it with a loop-labeled dataset from audio domain. After obtaining the MIDI loop set, we design a loop generator in two-stage; compressing data into discrete space and building an autoregressive model with them. Lastly, generated samples are evaluated on qualitative and quantitative metrics.

3.1 Data Preparation

3.1.1 Looperman Dataset

Looperman Dataset from the audio domain is collected and transformed for training our loop detector. We collect 1,000 loops of 8 bars from Looperman, a website allowing to upload and download free music loops. Formally, we denote one loop that is 1-D audio as $x_{WAV} \in \mathcal{R}$. The process of data transformation for the loop detector will be described in section 3.2.1.

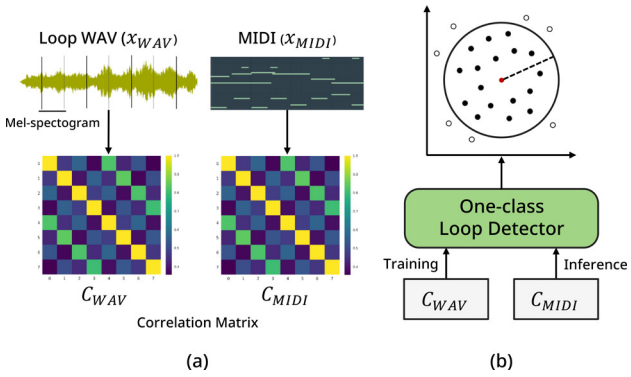

Figure 1. The process of loop extraction. (a) x_{WAV} and x_{MIDI} are transformed to each correlation matrix. (b) C_{WAV} are used to train the one-class loop detector and we extract loops from Lakh MIDI Dataset by forward passing C_{MIDI} to the detector.

3.1.2 Lakh MIDI Dataset

Lakh MIDI Dataset is a collection of MIDI files with various genres and tracks, so it is appropriate to conduct symbolic music experiments [20]. In this experiment, each note is quantized on the 16th note unit with binary representation so that 16 notes are placed in a bar. To verify the feasibility of multitrack polyphony generation, we extract two instruments; bass guitar (program=32~39) and drum (is_drum=True) which play crucial roles of melodic and rhythmic patterns in music. The bass pitches are clipped from C1 to B4 (48 pitches). If several pitches for the bass are played at the same time, we make only the lowest pitch alive for natural play. For the drum set, nine components (kick, snare, closed hi-hat, open hi-hat, low tom, mid tom, high tom, crash, and ride) are regarded as a standard set and the rest of the components are incorporated into the closest one or discarded. Formally, our pianoroll representation can be described as follows; $x_{MIDI} \in \{0,1\}^{(T\times B)\times P}$ where T is the number of time steps in a bar ($T = 16$), B is the number of bars ($B = 8$), and P is the number of pitches ($P = 57$). We collect 5,687,274 phrases of 8 bars by sliding a window with a stride of 1 bar, removing non-4/4 signature music. Using pretty_midi [28] and pypianoroll [29] in Python library, MIDI processing is conducted.

3.2 Loop Extraction

3.2.1 Data Transformation for the Loop Detector

We transform each the x_{WAV} and x_{MIDI} to $B \times B$ matrix indicating bar-to-bar correlation (Figure 1 (a)). For the x_{WAV}, we extract B mel-spectrograms each corresponding to B bars and compute a correlation matrix (C_{WAV}). For the x_{MIDI}, we compute normalized Hamming distance among bars and renormalize it to express correlation (C_{MIDI}). Only the upper triangle part of C is used. More details are described in Appendix B.3.

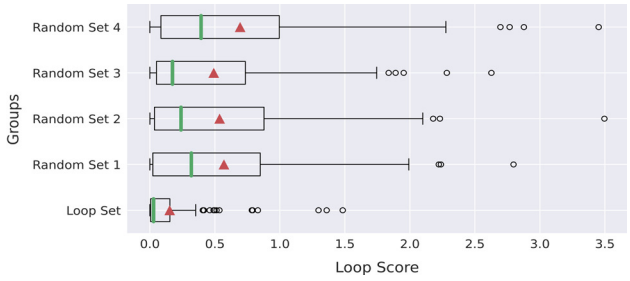

Figure 2. The evaluation of our loop detector. Green lines in the boxes indicate median values and red triangles for mean values.

3.2.2 Loop Extraction through the Loop Detector

Our loop detector is to classify loop and non-loop phrases, given only loop-labeled datasets. It is related to the problem of anomaly detection trained in an unsupervised way to construct normal data distribution. At inference time, outliers from the distribution are regarded as anomalous samples. Similarly, we treat C_{WAV} as normal samples (training set) and measure the likelihood of C_{MIDI} (test set) on C_{WAV} distribution. Among several ways, we choose One-Class Deep SVDD [30] as our loop detector, of which the training objective is

$$min\ \frac{1}{n}\sum_{i=1}^{n} ||f_w(x_i) - c||^2 + \lambda\Omega(W) \qquad (1)$$

where f_w is a neural network taking input x with learnable parameters W, n is the number of training samples, c is a center vector, and $\Omega(W)$ is a controllable regularizer. The objective can be thought as mapping all data samples close to center c, contracting a hypersphere. Initially, f_w is trained to reconstruct x with a decoder f_w^{-1} and center c is set to mean vectors acquired from f_w initial pass of the training data. f_w consists of 3 fully-connected layers with bias-off and LeakyReLU(0.1) to prevent hypersphere collapse as referred in [30]. During training, AdamW optimizer [31] is applied with cosine annealing from 1e-3 to 5e-6 for 1,000 epochs. At inference time, the loop score of C_{MIDI} can be obtained as

$$loop\ score = ||f_{w^*}(x) - c||^2 \qquad (2)$$

where w^* stands for optimized parameters of f (the process of loop extraction is illustrated on Figure 1 (b)). Samples with lower loop scores are considered close to the loop.

To evaluate the loop detector, we manually pick 100 loop samples from x_{MIDI} and compare them with 4 groups randomly picked (Figure 2). Although the randomized groups can contain subsets of loops, we can verify that the loop set group indicates the lowest loop score (0.153 ($\pm$0.282)). Also, paired t-test between the loop group and each other group shows the statistically significant difference with $p < 0.001$. When determining whether loop or not, we set a conservative threshold as positive one sigma of the loop score distribution (transformed by log to fit close to Gaussian distribution) from the training set. Consequently, we collect 751,935 x_{MIDI} to be used at loop generation stage.

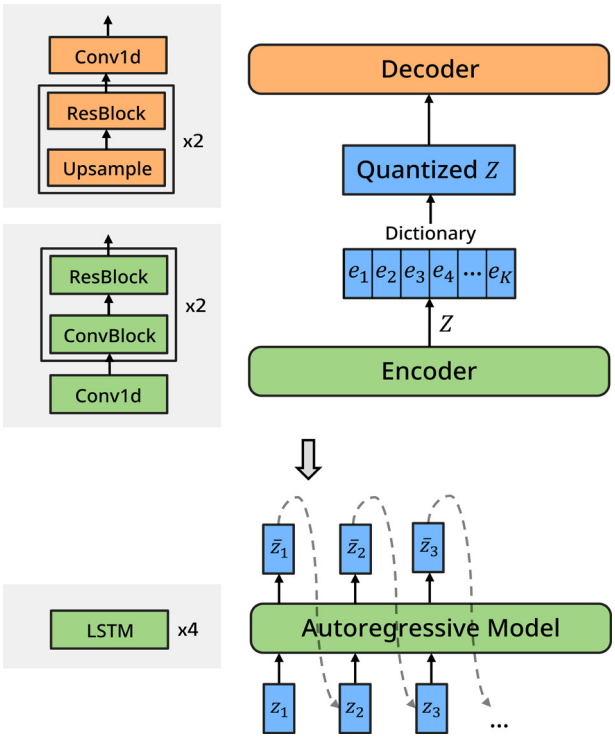

Figure 3. The process of loop generation. The upper denotes VQ-VAE and the bottom for LSTM based autoregressive model.

3.3 Loop Generation

3.3.1 Data Compression using VQ-VAE

VQ-VAE [7] maps a data sequence into discrete latent space and reconstructs it to the original data space. With an encoder $q_\phi$and a decoder p_θ, the objective becomes

$$max\ \mathbb{E}[log\ p_\theta(x|z)] - \beta||q_\phi(z|x) - sg[e]|| \quad (3)$$

where sg denotes a stop gradients operator for the dictionary embedding e. During forward pass, latent z from the encoder $q_\phi(z|x)$ is quantized to nearest embedding e. The second term above is responsible for the latent z not to diverge far from e. For every batch, the embedding dictionary is updated in the sense of centroids of K-means clustering.

Our VQ-VAE (Figure 3) encodes $\mathrm{x} = \{x_1, x_2, \cdots, x_{T\times B}\}$, $x_i \in \mathbb{R}^P$ into $\mathrm{z} = \{z_1, z_2, \cdots, z_S\}$, $z_i \in \mathbb{R}^D$ where S denotes the number of time steps ($S = 32$) in latent space and D denotes latent dimensions ($D = 16$). Starting from randomly initialized dictionary $\mathrm{e} = \{e_1, e_2, \cdots, e_K\}$, $e_i \in \mathbb{R}^D$ ($K = 512$), the latent z_i is mapped to the nearest embedding e_k where $k = argmin_j \|z_i - e_j\|$. After that, the embeddings are passed to the VQ-VAE decoder to reconstruct their original data. For the reconstruction objective, our data representation is regarded as multi-label for each time step (multiple 1s can exist on pitch P dimension at one time step), so cross-entropy loss with softmax is not suitable. Our objective for the reconstruction is described as

Model	Reconstruction Error
CNN-VAE	4.412e-3
VQ-VAE	6.643e-3

Table 1. The reconstruction errors. This is computed as the average of hamming distance between input and target samples of the validation set.

$$min\ -\frac{1}{nm}\sum_{i=1}^{n}\sum_{j=1}^{m} L\left(\sigma(o_{ij}), y_{ij}\right) \quad (4)$$

where L denotes binary cross-entropy, σ is sigmoid function, o is outputs of the VQ-VAE with m notes, and y for ground truth. When $\sigma(o_{ij}) \geq 0.5$, it predicts label as 1, otherwise 0.

The details of our VQ-VAE architectures (Figure 3) are described in Appendix B.4. Empirically, we have verified that a high compression ratio, especially along S dimension, severely deteriorates the reconstruction task of the VQ-VAE. The value of S has been determined to consider both the compression ratio and reconstruction quality. AdamW optimizer and cosine annealing from 1e-3 to 5e-6 is applied to the model training. As did in [32], random restarting is applied to less referenced e_i, replacing them with one of batch samples. After training, we forward pass the training set to obtain quantized embeddings z.

3.3.2 Generation through an Autoregressive Model

We design an autoregressive model $\prod_{i=0}^{S} p_\theta(z_i\,|z_{<i})$ over the quantized embeddings to generate unseen samples. The quantized indices k are used as inputs of 4-layers LSTM with an embedding layer. For each time step, softmax output predicts next step index k (validation accuracy 76.651% in teacher forcing mode). z_0 is sampled from multinomial distribution $p(z_0)$ of the training set. When sampling unseen data in full sampling mode, temperatures in softmax enable us to control sample diversity (temperature=0.7). We compare several sampling methods such as temperature sampling, top-k sampling [33], and nucleus sampling [34]. The generated indices are decoded by the VQ-VAE's decoder.

4. QUANTITATIVE EVALUATION

For quantitative evaluation of generated samples, we address three concepts; 1) *model metric* related to evaluating the capacity of generative models, 2) *musical style* related to measuring how much our intended properties of the loop are involved in generated samples, and 3) *similarity metrics* related to how much generated samples are involved in the training set on feature space (or vice versa).

4.1 Model Metric

Reconstruction Error: For VAE, the reconstruction error is part of the objective function that indicates how well the

Model	LS	UP	ND	P	R	D	C
Training Set	6.806e-3	5.769	14.383	-	-	-	-
CNN-VAE	3.496e-1	5.614	12.648	0.642±0.033	0.625±0.021	0.617±0.076	0.746 ±0.024
Music Transformer	7.200e-1	4.127	11.290	0.546±0.077	0.359±0.113	0.687±0.174	0.408±0.064
MuseGAN	2.307e-1	**5.790**	14.011	0.641±0.013	**0.689±0.012**	0.673±0.045	0.842±0.013
VQ-VAE+LSTM (temperature sampling)	2.275e-1	5.079	14.289	0.768±0.013	0.655±0.022	1.263±0.047	0.949±0.002
VQ-VAE+LSTM (top-k sampling=30)	**1.978e-1**	5.044	14.320	0.779±0.015	0.636±0.015	1.328±0.072	**0.952±0.004**
VQ-VAE+LSTM (top-p sampling=0.08)	2.037e-1	5.042	**14.341**	**0.783±0.017**	0.638±0.029	**1.337±0.075**	0.950±0.005

Table 2. The result table indicates all metrics explained at section 4.2 and 4.3. We compute P, R, D, and C from 10 different networks, so we denote mean values with standard deviations. Best values are marked in bold font.

Model	F_1 score (P & R)	F_1 score (D & C)
CNN-VAE	0.633	0.675
Music Transformer	0.433	0.512
MuseGAN	0.664	0.748
VQ-VAE+LSTM (temperature sampling)	**0.707**	1.084
VQ-VAE+LSTM (top-k sampling=30)	0.700	1.109
VQ-VAE+LSTM (top-p sampling=0.08)	0.703	**1.111**

Table 3. F1 score from Table 2 results.

model decodes its latent features to the original data. However, perfect satisfaction with the objective does not guarantee to generate high-quality samples (empirically, we have verified that original VAE has produced many noisy samples even after achieving the minimal reconstruction error when forcing Kullback-Leibler divergence term to 0).

4.2 Musical Style

The investigation of used harmonics and rhythm patterns indicates the musical style of our generated samples.

Loop Score (LS): Using the trained loop detector, we can evaluate how much generated samples are close to the loop.

Unique Pitch (UP): It computes the average number of used pitches per bar [22]. It reflects harmonic components on data space. It is desirable for generated samples to follow UP values of the training set.

Note Density (ND): It computes the average number of notes played per bar considering all instruments [26]. It reflects rhythmic components on data space. It is desirable for generated samples to follow ND values of the training set.

4.3 Similarity Metrics

Evaluating generated music samples on data space considers only musical features that humans can perceive. Here, we measure similarity of true and generated samples on latent space while indicating the sample fidelity and diversity.

Precision & Recall (P & R): The fidelity of generative models can be evaluated on precision which measures how much generated distributions are involved in true distributions. Likewise, the diversity can be realized by recall which measures how much true distributions are involved in generated distributions [12].

Kynkäänniemi have proposed improved P & R that count the presence of samples on the overlapped data manifold constructed by KNN [27]. In the case of precision, the data manifold is constructed from multiple spheres whose center is determined by true samples and whose radius is the distance between the true samples and their k-th nearest neighbors. All operations in the P & R should be conducted on latent space, so we use simple CNN networks initialized randomly for embedding [11]. For both P & R, we fix *k* of the KNN to 5 and get the average of the metrics from 10 different networks. To avoid extensive computation of the KNN, we use 10,000 samples for each network.

Density and Coverage (D & C): P & R are vulnerable to outliers overestimating data manifold. To remedy this, [11] have counted the average number of overlapped samples on a sphere. The concept and process of D & C are similar with P & R, except that the density can be greater than 1.

5. EXPERIMENTS

We evaluate our model by comparing it to 1) *training set*, 2) *CNN-VAE* similar structure with our VQ-VAE, 3) *Music Transformer* [3], and 4) *MuseGAN* [22]. All models have generated loop samples as many as the training set. Additionally, we apply several sampling methods for the VQ-VAE+LSTM and compare them. The experiment details of the baselines are explained in Appendix A.

5.1 Quantitative Evaluation Results

5.1.1 Model Metric Results

Due to the finite latent codes, our VQ-VAE is a little worse than the CNN-VAE for the reconstruction task (Table 1).

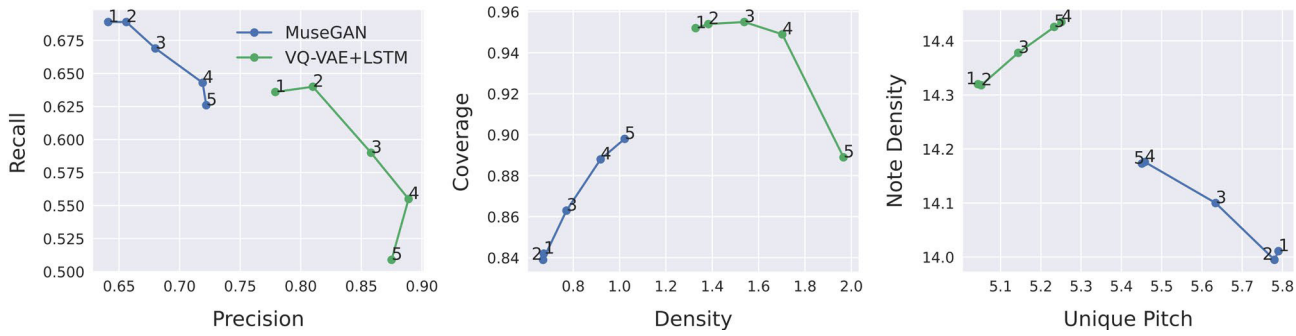

Figure 4. Rejection sampling results for the MuseGAN and VQ-VAE+LSTM. Each numbering markers indicates the various rejection rates (getting stricter from 1 to 5). The rates correspond to {no apply, 1, 0.1, 0.01, 0.001}.

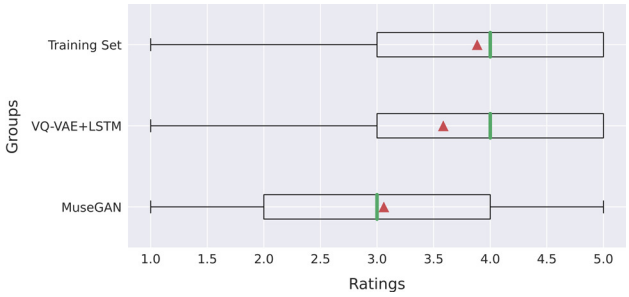

Figure 5. Human listening test. Green lines in the boxes indicate median values and red triangles for mean values.

As referred in [7], we have observed that β in the VQ-VAE objectives did not affect much to the task ($\beta = 0.25$).

5.1.2 Musical Metric Results

Our proposed model achieves the highest performance in terms of LS and ND (Table 2). The reason for poor performance in UP may be related to the VQ-VAE's reconstruction performance. Nevertheless, they can generate highly structural and rhythmic samples in a holistic view. Note that the Music Transformer fails to preserve the loop properties in its generated samples.

5.1.3 Similarity Metric Results

Except for the recall, our model achieves much better scores in terms of precision, density and coverage (Table 2). In MuseGAN, the recall may be overestimated by generated outliers. Depending on sampling methods and their parameters for full sampling mode, we can observe that there is a trade-off between fidelity and diversity. Even with the random embeddings, the all metrics show consistent performance (low standard deviations). A comprehensive evaluation (F_1 score) can be found in Table 3.

5.2 Rejection Sampling

It is promising that the loop detector can be used to control the trade-off between fidelity and diversity of generative models. This concept, rejection sampling, is to reject generated samples which do not meet our conditions. (loop scores in this context) [8]. If setting the rejection rate strictly, we can obtain music samples which are closer to the loop. For the experiments, we choose high-scored models that are MuseGAN and VQ-VAE+LSTM with top-k sampling. Figure 4 shows the P & R, D & C, and UP & ND results for various rejection rates. In P & R, the two models show similar trends while applying more strict rejection rates, but opposite trends for other metrics. Contrary to our assumption, both D & C of MuseGAN increase as we apply the stricter loop detector. It rather disproves that MuseGAN produces many outliers, so the loop detector may help to increase sample diversity close to the true distribution. In terms of ND, both models indicate minimal effect with the rejection sampling. However, they show contradiction about the aspect of UP changes.

5.3 Human Listening Test

We conduct a listening test for 20 people. We select the training set as a baseline and compare loop samples from two generative models (MuseGAN and VQ-VAE+LSTM with top-k sampling). Participants are asked to listen 10 samples for each group (total 30 samples) and evaluate how much the sample sounds like the loop music (which can be repeated seamlessly) on a Likert scale.

As Figure 5, the training set group achieves the highest ratings with an average rating of 3.885 ($\pm$1.045). For the generative models, VQ-VAE+LSTM achieves the highest average rating 3.585 ($\pm$1.141). It seems that the participants have felt them closer to the real music since loops from discrete representations are repetitive and structural (MuseGAN 3.060 ($\pm$1.172)). Additionally, we carry out Kruskal-Wallis H test which is non-parametric one-way ANOVA. The test shows a statistically significant difference among the test groups with $H = 49.811$, $p < 0.001$.

6. CONCLUSION

We leverage recurring nature of music by adopting the concept of the loop. To fulfill our objective, we address two processes; *loop extraction* and *loop generation*. First, we design a loop detector trained by a loop audio dataset to prepare loops from MIDI. Second, we adopt the two-stage generative approach, compressing data into discrete representations and designing an autoregressive model. Even without pre-trained feature extractors, we can evaluate our generative models on measuring fidelity and diversity. It is observed that our model outperforms well-known generative model for loop generation.

ABSTRACT

Music mixing traditionally involves recording instruments in the form of clean, individual tracks and blending them into a final mixture using audio effects and expert knowledge (e.g., a mixing engineer). The automation of music production tasks has become an emerging field in recent years, where rule-based methods and machine learning approaches have been explored. Nevertheless, the lack of dry or clean instrument recordings limits the performance of such models, which is still far from professional human-made mixes. We explore whether we can use out-of-domain data such as wet or processed multitrack music recordings and repurpose it to train supervised deep learning models that can bridge the current gap in automatic mixing quality. To achieve this we propose a novel data preprocessing method that allows the models to perform automatic music mixing. We also redesigned a listening test method for evaluating music mixing systems. We validate our results through such subjective tests using highly experienced mixing engineers as participants.

1. INTRODUCTION

Music mixing is a highly cross-adaptive transformation since the processing of an individual track depends on the content of all tracks involved. Apart from artistic considerations, it typically tries to solve the problem of unmasking by manipulating the dynamics, spatialisation, timbre or pitch of multitrack recordings [1]. This manipulation is achieved through a set of linear and nonlinear effects, which generally can be classified into five different classes: *gain, equalization (EQ), panning, dynamic range compression (DRC) and artificial reverberation* [2].

Several methods have been investigated to automatize this task [3]. For example, rule-based systems [4–6], cross-adaptive audio mixing effects [7, 8] and data-driven methods [9, 10]. A black-box approach is introduced in [9], where a *Wave-U-Net* is trained to perform automatic mixing of drums. Conversely, neural proxies of audio effects are used as a fixed signal processing path within a deep neural framework to perform automatic mixing of songs [10]. However, the lack of dry or unprocessed multitrack data has limited the performance of these deep learning approaches. Thus an unified approach has yet to be found that achieves results close to or superior to the quality of professional human-made mixes [11, 12]. It has been hypothesized that the bottleneck of performance can be resolved with a large enough dataset [10]. Nevertheless, collecting data is difficult, as it is unusual for musicians and record labels to provide multitrack dry recordings.

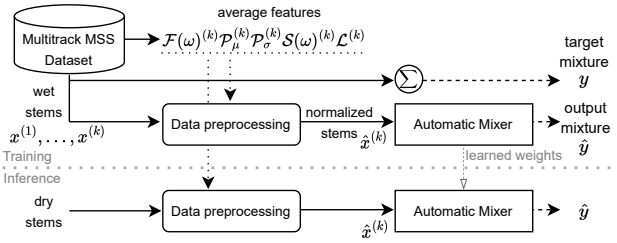

Figure 1: Our method uses data preprocessing by computing average features related to audio effects on an out-of-domain dataset (MSS data). This allows normalization of wet stems and supervised training of an automatic mixer. At inference, the same preprocessing is applied to dry data.

In this work, we consider the use of out-of-domain data in conjunction with a supervised deep learning approach to close such performance gap. To achieve this, we propose a novel method that performs a data normalization or augmentation procedure on each of the audio effect classes. Figure 1 depicts our method. We train deep neural networks to perform automatic loudness, EQ, panning, DRC and reverberation music mixing. Thus we present 1) a data preprocessing step that allows training with out-of-domain data, 2) a new deep learning architecture, 3) an exploration of stereo-invariant loss functions, 4) a design of a perceptual listening test targeting highly skilled professionals, and 5) listening test results showing that our approach is indistinguishable from professional human-made mixes. Audio samples and code can be found at https://marco-martinez-sony.github.io/FxNorm-automix/.

2. METHOD

2.1 Effect normalization and augmentation

One of the main challenges of deep learning models for automatic mixing is the lack of multitrack dry data. Since

Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

collecting a large dry multitrack dataset is inherently difficult, we believe it is possible to reuse existing datasets, such as music source separation (MSS) data. Music source separation has been heavily researched in the last decade [13] and a significant effort has been put into collecting training data, such as the well-known MUSDB18 dataset [14]. However, direct application of such data is infeasible, since the mixture is a summation of the wet stems, that is, mixing effects have already been applied.

Several methods have been shown to be capable of reverse engineering the effect parameters [15–17], however such approaches require the original dry multitrack recordings and target mix. There are also data-driven methods for removing effects [18, 19], although they only apply to specific effects and are prone to adding sound artifacts.

Instead of removing audio effects, we propose to normalize each stem based on audio features related to each class of audio effects. In this way, different data features are scaled or transformed to make an equal contribution across the dataset [20]. We propose normalization schemes for loudness, EQ, panning, DRC and reverberation, thus ensuring that all stems have been normalized to the same range of audio features. During training, we expect the models to learn how to undo or denormalize the input stems and thus approximate the original mix. At inference, we also normalize the real multitrack dry data thus allowing the model to perform automatic music mixing. This Section introduces how each effect is normalized and Section 2.2 the full data preprocessing procedure.

Loudness—To normalize loudness, we independently compute the average loudness $\mathcal{L}^{(k)}$ for the stem type k as

$$\mathcal{L}^{(k)} = \frac{1}{N}\sum_{i=1}^{N} \text{LUFS}(x_i^{(k)}), \tag{1}$$

where LUFS is the integrated loudness level in dBFS in accordance to [21], x is the ith stem waveform of k type, e.g. k=vocals, and N is the total number of available songs. Then, based on $\mathcal{L}^{(k)}$, each stem is loudness normalized using [22].

Equalization—EQ normalization is based on the average frequency magnitude spectrum $\mathcal{F}^{(k)}$ as

$$\mathcal{F}(\omega)^{(k)} = \frac{1}{N}\sum_{i=1}^{N} \Gamma(\omega)_i^{(k)}, \quad \Gamma(\omega)^{(k)} = \frac{1}{M}\sum_{j=1}^{M} X(\omega)_j^{(k)}, \tag{2}$$

where $\Gamma^{(k)}$ corresponds to the individual stem mean frequency magnitude, ω is the frequency index, $X^{(k)}$ is the magnitude of the Short-Time Fourier Transform (STFT) of each $x^{(k)}$ and M its total number of frames.

We then proceed to normalize each stem by performing EQ matching with respect to $\mathcal{F}^{(k)}$. EQ matching typically involves finding the optimal filter settings by designing and applying a filter based on the difference between the target and input frequency magnitudes [23]. The differential frequency magnitude $\mathcal{F}(\omega)_{\text{diff}}^{(k)}$ is computed as

$$\mathcal{F}(\omega)_{\text{diff}}^{(k)} = 10^{\log_{10}(\mathcal{F}(\omega)^{(k)}) - \log_{10}(\Gamma(\omega)^{(k)})}. \tag{3}$$

$\mathcal{F}(\omega)_{\text{diff}}^{(k)}$ is further smoothed with a Savitzky-Golay filter [24]. An FIR filter is designed using the window method [25], and applied using forward-backward filtering [26] to have a zero-phase response. Since forward-back filtering squares the magnitude response, we apply a square root to $\mathcal{F}(\omega)_{\text{diff}}^{(k)}$ before designing the FIR filter.

Panning—The panning normalization is based on the Stereo Panning Spectrum [27, 28], where we use the average panning as a reference then re-pan accordingly.

We compute the left and right channel similarity measure $\Psi(\omega)$, to approximate the panning gains assigned during mixing. We focus only in amplitude panning thus we calculate $\Psi(\omega)$ using only frequency magnitude as

$$\Psi(\omega) = 2\frac{X(\omega)_{\text{L}} X(\omega)_{\text{R}}}{X(\omega)_{\text{L}}^2 + X(\omega)_{\text{R}}^2}, \tag{4}$$

where $X(\omega)_{\text{L}}$ and $X(\omega)_{\text{R}}$ correspond to the left and right channel STFT magnitudes. $\Psi(\omega)$ denotes whether a frequency bin ω_0 is panned to the center ($\Psi(\omega)_{\omega_0}$=1), or whether is panned to either side ($0 \leq \Psi(\omega)_{\omega_0} < 1$). The stereo side can be determined with the difference $\Delta(\omega)$ between partial similarities $\Psi(\omega)_{\text{L}}$ and $\Psi(\omega)_{\text{R}}$ as

$$\Psi(\omega)_{\text{L}} = \frac{X(\omega)_{\text{L}} X(\omega)_{\text{R}}}{X(\omega)_{\text{L}}^2}, \Psi(\omega)_{\text{R}} = \frac{X(\omega)_{\text{L}} X(\omega)_{\text{R}}}{X(\omega)_{\text{R}}^2}, \tag{5}$$

thus $\Delta(\omega) = \Psi(\omega)_{\text{L}} - \Psi(\omega)_{\text{R}}$, where $\Delta(\omega)>0$ and $\Delta(\omega)<0$ correspond to signals panned left or right, respectively. The panning gains, $\Phi(\omega)_{\text{L}}$ and $\Phi(\omega)_{\text{R}}$, then can be estimated by choosing a panning law to approximate the panning coefficient $\alpha(\omega)$. We empirically found that a linear panning law, $\Phi(\omega)_{\text{L}}$=1-$\alpha(\omega)$ and $\Phi(\omega)_{\text{R}}$=$\alpha(\omega)$, yields better approximations. Thus we approximate the panning gains based on $\Delta(\omega)$ and assuming $\Psi(\omega)$=2$\alpha(\omega)$. We compute the average similarity measure $\mathcal{S}(\omega)^{(k)}$ across all $\Psi(\omega)^{(k)}$ computed from N stems and their STFT frames M. $\mathcal{S}(\omega)^{(k)}$ is also further smoothed with [24].

For each individual stem, re-panning is implemented by 1) computing $\Psi(\omega)$ and $\Delta(\omega)$, 2) estimating $\Phi(\omega)_{\text{L}}$ and $\Phi(\omega)_{\text{R}}$, and 3) estimating the reference panning gains, $\hat{\Phi}(\omega)_{\text{L}}$ and $\hat{\Phi}(\omega)_{\text{R}}$, using $\mathcal{S}(\omega)^{(k)}$ and $\Delta(\omega)$. Finally, we calculate a gain factor based on the ratio of panning gains which we apply to $X(\omega)_{\text{L}}$ and $X(\omega)_{\text{R}}$ as

$$\hat{X}(\omega)_{\text{L}} = \frac{\hat{\Phi}(\omega)_{\text{L}}}{\Phi(\omega)_{\text{L}}} X(\omega)_{\text{L}}, \hat{X}(\omega)_{\text{R}} = \frac{\hat{\Phi}(\omega)_{\text{R}}}{\Phi(\omega)_{\text{R}}} X(\omega)_{\text{R}}. \tag{6}$$

Panning normalization is performed per frame and the normalized audio is obtained with the inverse STFT of $\hat{X}(\omega)_{\text{L}}$ and $\hat{X}(\omega)_{\text{R}}$ with their original channel phase.

Dynamic Range Compression—DRC usually alters the transients of the input [29], thus we base our DRC normalization on the onset peak levels which are linked to such transient modification [30].

We first perform onset detection based on the High Frequency Content (HFC) method [31, 32]. HFC emphasizes the energy variation that occurs in the upper part of the spectrum which is typical of onsets [33]. We then select the maximum peak for each of the detected onsets.

The average peak level $\mathcal{P}_{\mu}^{(k)}$ and peak level standard deviation $\mathcal{P}_{\sigma}^{(k)}$ are defined as $\frac{1}{N}\sum_{i}^{N}\mu_{i}^{(k)}$ and $\frac{1}{N}\sum_{i}^{N}\sigma_{i}^{(k)}$, respectively. Where $\mu^{(k)}$ and $\sigma^{(k)}$ are the channel mean peak level and standard deviation in dB, which for a robust estimate are calculated from the top 75th percentile of detected peaks.

DRC normalization consists in upper bounding the peak levels of the audio. Thus, if $\mu^{(k)} > (\mathcal{P}_{\mu}^{(k)} + \mathcal{P}_{\sigma}^{(k)})$, we apply a compressor to the input audio by performing an incremental grid search of the *ratio* and *threshold* parameters until $\mu^{(k)} < (\mathcal{P}_{\mu}^{(k)} + \mathcal{P}_{\sigma}^{(k)})$. *Threshold* is the level above which compression starts, and *ratio* determines the amount of compression [29]. This is done with fixed *attack* and *release* values, i.e. the start and stop timing settings.

Artificial Reverberation—Due to the inherent characteristics of reverberation [29], an attempt to similarly normalize this effect is not trivial. Blind estimation of reverberation features, such as reverberation time (RT) or direct-to-reverberant ratio, is an open research area in itself, and considering that most of the research has been done for speech signals [34–36], its application to music is beyond the scope of this paper.

We propose instead a data augmentation approach where we stochastically add reverberation to already reverberated stems. Reverberation is added using a mixing method called the 'Abbey Road reverb trick' [37], where a chain of EQ and reverb effects is applied as a send effect, i.e. a copy of the input is processed and added to the input. Naively adding reverberation directly to the input audio has the potential to clutter the low and low-mid frequencies. In this manner, the process of learning how much reverberation is required for a given mix is carried out by the network by learning to filter out the additional reverberation that is present in the input stems.

2.2 Data preprocessing

Since most mixing effects are interrelated, applying the normalization methods separately yields inaccurate results, e.g. EQ normalization modifies the dynamics of the audio, thus modifying DRC features. To minimize this, we perform effect preprocessing progressively and based in the following order: EQ, DRC, panning and loudness. Since EQ and DRC normalization are done on a per channel basis, panning normalization is applied after the above to avoid further modification of the stereo features.

Thus, for each stem type k, average feature computation corresponds to 1) calculate $\mathcal{F}(\omega)^{(k)}$ and EQ normalize, 2) calculate $\mathcal{P}_{\mu}^{(k)}$ and $\mathcal{P}_{\sigma}^{(k)}$ and DRC normalize, 3) calculate $\mathcal{S}(\omega)^{(k)}$ and panning normalize, and 4) calculate $\mathcal{L}^{(k)}$ and loudness normalize.

We apply our reverberation preprocessing method after all the average features have been calculated. Considering that this procedure is based on a stochastic data augmentation procedure, for consistency we treat the added reverberation as noise for the normalization pipeline. The final data preprocessing method corresponds to applying reverberation augmentation followed by EQ, DRC, panning, and loudness normalization methods.

2.3 Architecture

We propose a new architecture based on [38] and [39]. It operates in the time-domain and processes raw waveforms in a frame-wise manner. The model can be divided into three parts: adaptive front-end, latent-space mixer and synthesis back-end. The model is depicted in Figure 2 and its architecture is summarized in Table 1.

The **adaptive front-end** is exactly the same as in [38], with the only difference that now the input $\hat{x}$ corresponds to K stereo tracks of length A. In the front-end, time-domain convolutions are applied to the input audio in order to learn a latent representation $\boldsymbol{Z}$ and a filter bank which output feature map $\boldsymbol{X}_1$ corresponds to a frequency band decomposition of $\hat{x}$. The **latent-space mixer** corresponds to the temporal dilated convolutions (TCN) separator block of [39], and to improve long-term dependencies learning, the TCN is followed by stacked Bidirectional Long Short-Term Memory (BLSTM) layers. Contrary to [39], the objective of the mixer is not to learn a mask for source separation, but rather to learn a mixing mask $\hat{\boldsymbol{Z}}$.

The **synthesis back-end** uses $\hat{\boldsymbol{Z}}$ to modify $\boldsymbol{X}_1$ based on the given mixing task and its design is motivated by [38]. It upsamples the mixing mask using nearest neighbor interpolation and via an element-wise multiplication applies it to each filter-bank channel source of $\boldsymbol{X}_1$ at each time step. We hypothesize that this frequency-based transformation is akin to the model learning and applying a dynamic equalization effect [40] while also filtering out the extra reverberant content of the normalized input stems.

The resulting feature map $\boldsymbol{X}_4$ is further modified via a Squeeze-and-Excitation (SE) block [41] implemented as shown in [38]. The SE layers scale the channel-wise information of $\boldsymbol{X}_4$ by applying an adaptive gain $\boldsymbol{s}_c$, and consequently, learning a loudness gain and panning transformation for each filter bank channel. The modified frequency decomposition $\boldsymbol{X}_5$ is then reconstructed using a non-trainable transposed convolution as shown in [38]. Finally, the resulting $2K$ stereo tracks are channel-wise summed into a stereo output and a hyperbolic tangent is used to avoid clipping. All convolutions use a stride of 1 to avoid ringing and filtering artifacts [42]. BLSTMs and SE layers are applied to the filter dimension.

2.4 Loss function

Based on the stereo-invariant loss function introduced by [10], we explore two variations of such loss. First, due to the perceptual nature of the mixing task and motivated

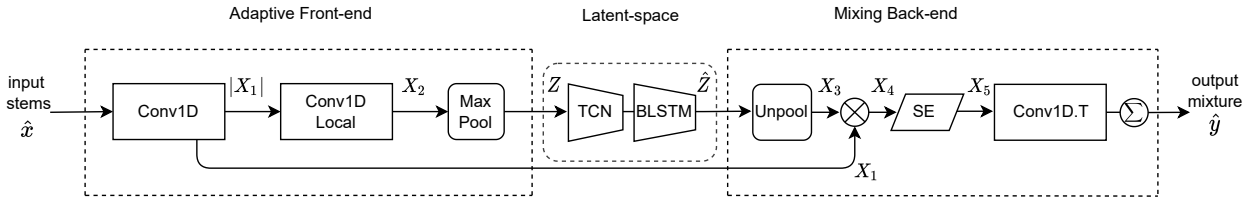

Figure 2: Block diagram of the proposed model

Table 1: Summarized architecture of the proposed model.

Layer	Output shape	Output
Input stems	$(2K, A)$	$\hat{\boldsymbol{x}}$
Conv1D	(N, A)	$\boldsymbol{X}_1$
Conv1D-Local	(N, A)	$\boldsymbol{X}_2$
MaxPooling	$(N, A/64)$	$\boldsymbol{Z}$
TCN	$(N, A/64)$	.
BLSTM	$(A/64, N)$	$\hat{\boldsymbol{Z}}$
Unpooling	(N, A)	$\boldsymbol{X}_3$
$\boldsymbol{X}_3 \times \boldsymbol{X}_1$	(N, A)	$\boldsymbol{X}_4$
SE (Abs)	(A, N)	.
SE (Global Avg)	$(1, N)$	.
SE (FC)	$(1, 16N)$	.
SE (FC)	$(1, N)$	$\boldsymbol{s}_c$
$\boldsymbol{X}_4 \times s_c$	(N, A)	$\boldsymbol{X}_5$
Conv1D.T	$(2K, A)$	.
Summation	$(2, A)$	$\hat{y}$

by [43], we apply A-weighting pre-emphasis and low-pass FIR filters (ρ) to the target and output audio frames y and $\hat{y}$, respectively. Then we compute the sum and difference signals y_{sum}=$\rho(y_{\text{L}})$+$\rho(y_{\text{R}})$ and y_{diff}=$\rho(y_{\text{L}})$-$\rho(y_{\text{R}})$.

The first loss follows closely [10] and is based on the Spectral Convergence (SC), magnitude-normalized Frobenius norm, and the L1-norm spectral log-magnitude (L1Log) as

$$\begin{aligned} L_{\text{a}} = l_{\text{SC}}(Y_{\text{sum}}, \hat{Y}_{\text{sum}}) + l_{\text{L1Log}}(Y_{\text{sum}}, \hat{Y}_{\text{sum}}) \\ + l_{\text{SC}}(Y_{\text{diff}}, \hat{Y}_{\text{diff}}) + l_{\text{L1Log}}(Y_{\text{diff}}, \hat{Y}_{\text{diff}}), \end{aligned} \tag{7}$$

where Y and $\hat{Y}$ are the respective 4096-Fast Fourier Transform (FFT) magnitude with a 25% hop size.

The second loss replaces the SC loss component with a less penalizing normalization such as the widely used L2-norm on the spectral magnitude (L2), defined as

$$\begin{aligned} L_{\text{b}} = l_{\text{L2}}(Y_{\text{sum}}, \hat{Y}_{\text{sum}}) + l_{\text{L1Log}}(Y_{\text{sum}}, \hat{Y}_{\text{sum}}) \\ + l_{\text{L2}}(Y_{\text{diff}}, \hat{Y}_{\text{diff}}) + l_{\text{L1Log}}(Y_{\text{diff}}, \hat{Y}_{\text{diff}}). \end{aligned} \tag{8}$$

We empirically found the perceptual-based pre-emphasis filter as vital when modeling a highly perceptual task such as music mixing. We also found an easier convergence during training when using a single frame-size loss rather than a multi-resolution magnitude loss.

3. EXPERIMENTS

3.1 Dataset

We first conduct experiments with a small dataset (S) which corresponds to the MUSDB18 dataset [14]. This dataset consists of wet stems for *vocals*, *drums*, *bass* and *other* (K=4), where the *mixture* is the summation of such stems. There are a total of 150 songs, of which 86 are used for training and 14 and 50 for validation and testing purposes, respectively.

We also use a private large dataset (L) for music separation which corresponds to 1,505 extra multitrack songs created in the same manner as MUSDB18. We incorporate the MUSDB18 training and validation sets into the large dataset, thus obtaining a total of 1,455+86=1,541 training songs and 50+14=64 validation songs. In both datasets, most of the songs correspond to mainstream western music, with rock and pop as the predominant genres.

To validate our method, we use a private set of 18 dry multitrack songs, where all songs have been produced by different musicians and mixing engineers. From this data we grouped the respective dry stems without applying any effect in the process.

3.2 Dataset preprocessing

We apply our preprocessing methods to both datasets independently. EQ preprocessing is computed with a 65,536 point STFT with hop size of 25% and a FIR filter of 1,001 taps. In order to avoid clipping, all audio stem channels are loudness normalized to -30 dBFS prior to the EQ feature computation and normalization.

For DRC preprocessing, to determine the timing settings of the compressor used during the normalization, we averaged the values found in mixing engineering best practices [8, 44]. *Attack* values correspond to 7.5, 10, 10 and 15 ms and *release* values to 400, 180, 500 and 666 ms, for *vocals*, *drums*, *bass* and *other*, respectively. For the incremental grid search we use *ratio* and *threshold* values within {4, 20} and {-40, -10} db respectively. For the HFC computation we use 128 mel bands of all stems with the exception of bass where we found better onset detection with 16 mel bands. Prior to the DRC preprocessing, all channels are peak normalized to -10 dB.

Panning preprocessing is done with a 2,048 point STFT with hop size of 50%. For all stems, frequency bins are re-panned until 16 kHz, with the exception of *drums*, which is re-panned until 16 kHz in order to avoid artifacts.

Reverberation augmentation is done by applying uniform random sampling on a set of 130 different impulse responses (IR) whose RT is within {2, 4} seconds (s). The

EQ used prior to the reverberation corresponds to a low-shelf and high-shelf with a fixed gain of -30 dB whose cut-off frequency is uniformly sampled within {500, 700} Hz and {7, 10} kHz, respectively. At inference, to simulate the reverberant characteristics of the training data, before applying the aforementioned augmentation, a "pre-reverb" is added in the same manner but from a different set of 400 IRs whose RT is within {1, 1.5}-*s*. A shorter RT is chosen, as high reverberation levels has been shown to have a more detrimental effect on subjective preference than low levels [45]. Reverberation augmentation is applied only to *vocals* and *other* stems. Reverberation and DRC effects are implemented using the Python package from [10].

3.3 Hyperparameters

The convolutional layers on the front-end have N=128 filters of size 64 and 128 respectively, and a 64-point window for max-pooling. In the mixer, the bottleneck layer has 256 channels, the skip connection paths have 64 channels, and the convolutional blocks have 128 channels of kernel size 3. We use 4 stacks of 6 convolutional layers with a dilation factor of 1,2,...,32. We stacked 3 BLSTMs with a hidden feature map of 64 channels. The FC layers in the SE block have 2048 ($16N$) and 128 channels respectively.

The input consists of $2K$ channels, each channel consisting of A=10-*s* audio frames at 44.1 kHz. The receptive field of the mixer is 505 samples, and taking into account the pooling operation, the overall network has a receptive field of 32,446 samples. Thus, the loss function is only calculated on a 8.52-*s* frame centered in the middle of the 10-*s* input. The network has in total 2.7M parameters. As a baseline, we use the modified *Wave-U-Net* (WUN) introduced by [9]. The same settings are used as in the original work which yields a network of 2.5M parameters.

3.4 Training

Regarding on-the-fly data augmentation, we apply a randomization of the order of the stereo channels, this is done consistently across the stems and the target mix. For the proposed network we use the pretraining from [38]. We train both models using a batch size of 4, an initial learning rate β=0.001, and the following learning rate schedule; β for 300 epochs, β/3 for 100 epochs, β/10 for 100 epochs, β/30 for 50 epochs, β/100 for 50 epochs and β/1000 for 25 epochs. An epoch consists of 1600 batches, L2 norm of the gradient is clipped by 0.2 and we use 10^{-7} for weight decay regularization. We select the model with the lowest validation loss.

4. RESULTS & ANALYSIS

We trained both networks with the preprocessed datasets S and L and the loss functions L_a and L_b, which yielded Ours-S-L$_a$, Ours-S-L$_b$, Ours-L-L$_a$ and Ours-L-L$_b$ for our proposed network, and WUN-S-L$_b$ and WUN-L-L$_b$ for Wave-U-Net. Convergence during training for WUN with L_a was unsuccessful, therefore it is excluded from the results.

	dry test set				MUSDB18 test set

Table 2: Objective metrics correspond to the average mean absolute percentage error by feature subgroup.

4.1 Quantitative evaluation

To measure how close the output mixes are to the reference mixes, we use the following audio features, spectral: centroid, bandwidth, contrast, flatness, and roll-off [46]; panning: the Panning Root Mean Square (RMS) [27]; dynamic: RMS level, dynamic spread and crest factor [47]; and LUFS loudness level [21]. All features are computed using a running mean of 0.5-*s* [27]. Table 2 shows the results for the dry test set and the MUSDB18 test set. As expected, the overall error values are larger for the dry test set. Also, the loudness, dynamics, and panning values show a closer match to the reference mix when compared to the Normalized mix, which is the sum of input stems after data preprocessing. Spectral values do not match in the same way, which could indicate that the generated mixes deviate in terms of EQ and reverberation.

4.2 Listening Test

We designed a the listening test using the Web Audio Evaluation Tool [48] and the APE interface [49]. The test is intended for professional mixing engineers only and we ask participants to rate the mixes based on Production Value, Clarity and Excitement as shown in [50]. Perceptual tests for mixing systems [9,10] often differ from MUSHRA [51] tests, as the reference sample is omitted in order to encourage a direct comparison between mixes. However, based on feedback from pilot tests, we decided to include the 4 dry stems in the test as references. In this way, the ratings may reflect the quality of transformation on each stem as applied by the mixing systems.

Fourteen participants with an average mixing engineering experience of 11.6 years took part in the test. In total there were six different songs and for each song six different mixes were presented. Each mix was 25-*s* taken from the chorus-to-verse transitions of the full mixes. The six mixes correspond to the Ours-S-L$_b$, Ours-L-L$_a$, Ours-L-L$_b$, WUN-S-L$_b$ and WUN-L-L$_b$ models plus a professional Human mix. Ours-S-L$_a$ was omitted from the test to allow more songs to be tested while avoiding listening fatigue [52]. A low-anchor was not used as it has been shown to compress the other ratings at the higher end [1]. All mixes were loudness normalized to -23 dBFS [53].

Figure 3 shows the results of the listening test and Table 3 shows the pairwise comparisons of mixes. For Production Value, there is no statistically significant difference between the Human mixtures and the models that were

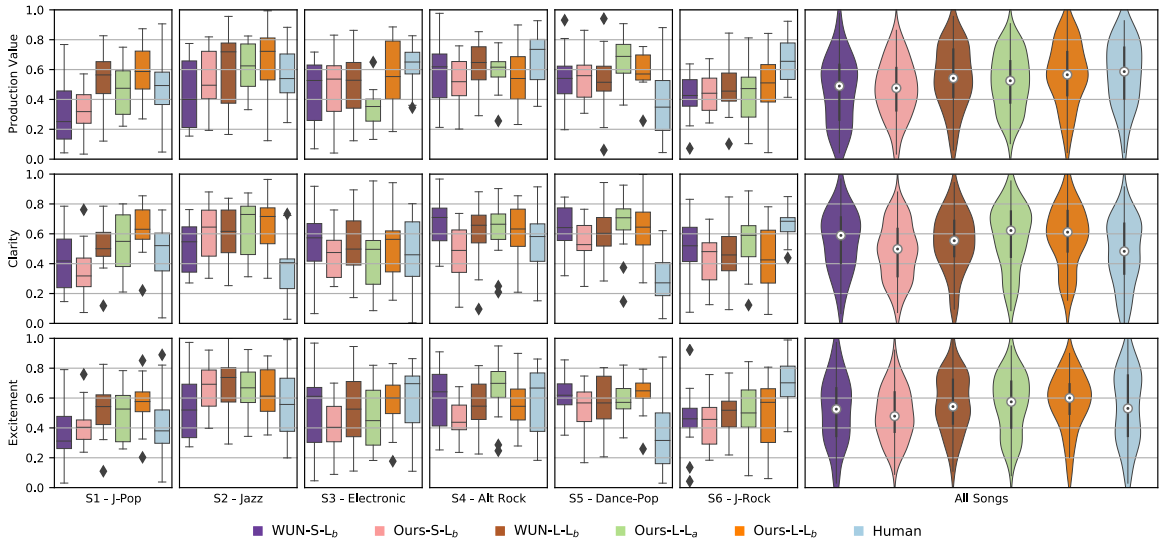

Figure 3: Listening test boxplots and violin plots for all individual six songs (S1 to S6) and all songs, respectively.

trained on the large dataset. For Clarity, Human mixes are rated lower than Ours-L-L$_a$, Ours-L-L$_b$ with a p-value of 0.008 and 0.013, respectively, indicating that our models generate mixtures with less masking. For Excitement, the null hypothesis is accepted, and therefore Human mixes are considered no different than any other mixture system. Although Ours-L-L$_b$ was among the best among all criteria, the null hypothesis is also accepted when compared to WUN-L-L$_b$. Thus, a further analysis is needed among both networks, e.g. in terms of long-term learned dependencies and ability to generate full-length coherent mixes.

In general, models trained with large datasets received the highest scores, which could confirm that lack of data has been the bottleneck of data-driven mixing systems. However, for Clarity and Excitement, the mixes by WUN-S-L$_b$ are not considered different from the rest, which might indicate that our data preprocessing method is both effective for small and large datasets.

It should be noted that, in general, none of the mixes is consistently considered as very good. This relates with other findings, where even commercial mixes made by renown engineers are not rated as high [1, 44]. This opens up a new research direction for evaluating mixing systems, as this type of test is too difficult for inexperienced participants, and when experienced participants do participate, they tend not to rate any mix as very good.

For individual songs, Human mixes have lower rates for Jazz and Dance-Pop. For the latter, low ratings on all criteria may be due to highly compressed drums. However, the high ratings in terms of Excitement and Production Value for the Human J-Rock mix might be due to hard-panned guitars. In contrast, the models are conservative when it comes to panning and are unlikely to hard-pan sources, however a further analysis is required. Furthermore, although we show the models successfully mixing multiple genres, an in-depth analysis of the genre distribution of the dataset with ratings by genre is needed.

Production Value	WUN-S-L$_b$	Ours-S-L$_b$	WUN-L-L$_b$	Ours-L-L$_a$	Ours-L-L$_b$	Human

Table 3: Post hoc Mann-Whitney test results of pairwise comparison with Bonferroni Correction. o > 0.05, $\star < 0.05$, $* < 0.01$, $** < 0.001$. E.g. when y-axis is compared to x-axis, $\overline{*}$ or $\underline{*}$ indicate y-axis is significantly better or worse than x-axis for a p-value < 0.01, respectively.

5. CONCLUSION

We present a novel data preprocessing approach that allows us to train deep learning networks with existing wet or processed multitrack data by reusing them to perform an automatic mixing task. During inference, we apply the same data preprocesing to dry multitrack data and we tested the generated mixes via objective and subjective tests. We introduced a new deep learning architecture designed for the proposed task, a perceptual-based loss function along with a redesigned listening test aimed at experienced mixing engineers. The results indicate that our approach successfully achieves automatic loudness, EQ, DRC, panning, and reverberation music mixing. Resulting mixes compared to professional mixes scored higher in terms of Clarity and are indistinguishable in terms of Production Value and Excitement. We believe that the proposed preprocessing can be applied to other data-driven MIR tasks.

6. ACKNOWLEDGMENTS

We would like to express special thanks to K. Gokan and S. Masui for their valuable comments and all the mixing engineers from Sony Music Entertainment Japan, Sony Europe and Queen Mary University of London who participated in the listening test.
