MUSIC-STAR: A STYLE TRANSLATION SYSTEM FOR AUDIO-BASED RE-INSTRUMENTATION

Mahshid Alinoori **Vassilios Tzerpos**
Department of Electrical Engineering and Computer Science, York University, Canada
{mahshida, bil}@yorku.ca

ABSTRACT

Music style translation aims to generate variations of existing pieces of music by altering the style-related characteristics of the original piece while content, such as the melody, remains unchanged. These alterations could involve timbre translation, re-harmonization, or music rearrangement. Previous studies have achieved promising results utilizing time-frequency and symbolic music representations. Music style translation on raw audio has also been investigated and applied to single-instrument pieces. Although processing raw audio is more challenging, it provides richer information about timbres, dynamics, and articulations.

In this paper, we introduce Music-STAR, the first audio-based translation system that translates the existing instruments in a piece into a set of target instruments without using source separation. To conduct our experiments, we also present an audio dataset that contains two-track pieces performed by two instrument sets alongside their stems. We carry out subjective and objective evaluations to compare Music-STAR with a variety of baseline methods and demonstrate its superiority.

1. INTRODUCTION

Music style translation is defined as transforming the style-variant components of a music piece to create variations that preserve the content. This can take several forms depending on how "music style" is characterized. Dai et al. [1] classify style into three categories: composition, performance, and timbre. Recent works have mainly focused on timbre translation [2–7] and composition style translation [8–12].

Timbre translation aims to alter the timbre information, which typically results in a change in instrumentation. Timbre translation models mostly use time-frequency representations [2–6]. Some of these [4–6] treat the spectrograms as images and apply GAN-based models [13,14] designed for image-to-image translation [15]. Timbre translation has also been explored by integrating classic signal processing and deep learning methods [16, 17].

The universal translation network [7] is the only model that works with audio waveforms directly. Inspired by the WaveNet autoencoder [18], it translates an arbitrary source piece to several specific timbre domains. Although one universal encoder is used to encode the domain-independent features, every domain needs to have a specific conditional WaveNet [19] decoder.

On the other hand, composition style transfer attends to tasks such as re-harmonization and music rearrangement. [1] Almost all works on composition style translation exploit symbolic representations, i.e., MIDI and piano rolls. Some of these models focus on music rearrangement by altering the accompaniments [8–10] where the style is associated with the genre. MIDI-VAE [9] is among the few cases that do not overlook the dynamics and account for note velocities. Wang et al. [11] has introduced the only GAN-based model that operates on symbolic representation to perform genre transformation. Hung et al. [12] approach music rearrangement by modifying the instrumentation, where they establish a correlation between rearrangement and transforming multiple timbres in a musical piece.

In this paper, we explore music re-instrumentation of audio waveforms that contain more than one instrument. We present several baseline solutions and then propose Music-STAR, a system designed explicitly for audio-based translation, which is built upon the WaveNet autoencoder [18]. To conduct our experiments, we also present a dataset called StarNet, in which every piece of music is performed by two different sets of instruments. The source code, audio samples, and supplementary materials are available at https://mahshidaln.github.io/Music-STAR.

2. DATASET

In order to train and evaluate Music-STAR and the baseline models, we need an audio dataset that contains multi-track pieces played with different sets of instruments alongside their stems. For this purpose, we have created the StarNet dataset, in which every piece is composed of two instrument tracks from two domains: strings-piano and clarinet-vibraphone. In other words, for every piece, the dataset includes strings-piano and clarinet-vibraphone mixtures as well as their corresponding isolated tracks.

We have chosen piano ↔ vibraphone and strings ↔ clarinet translations to preserve the type of excitation in

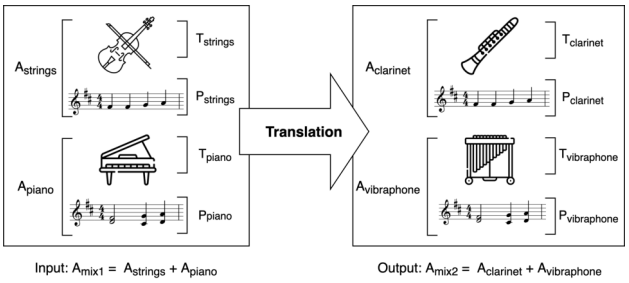

Figure 1. An example of multi-instrument translation where the timbre components of strings ($T_{strings}$) and piano (T_{piano}) are translated into clarinet ($T_{clarinet}$) and vibraphone ($T_{vibraphone}$), respectively, while retaining the corresponding pitch components ($P_{strings} = P_{clarinet}$ and $P_{piano} = P_{vibraphone}$).

the source/target instruments (discrete excitations in piano and vibraphone versus continuous excitations in clarinet and strings).

Accessing recorded music stems is often hard due to copyright limitations. Therefore, we select a variety of music pieces from MusicNet [20] and other freely available classical music MIDI collections. Instead of using their original instruments, we apply virtual instruments for the aforementioned combinations. The resulting dataset contains two domains, one for each instrument combination, adding up to roughly 11 hours of audio for each domain. The StarNet dataset is available at `https://zenodo.org/record/6917099`.

To conduct our experiments, we use two versions of StarNet:

1. Preprocessed StarNet: The preprocessed version of StarNet includes uncompressed stereo WAV files with a sample rate of 44.1 kHz and a bit depth of 16 bits. The preprocessing step includes detecting and removing the intervals where one or both instruments are silent to ensure their simultaneous presence for a considerable amount of time. After the silence removal, the dataset size shrinks to roughly 9 hours. Silence detection is done by indicating the minimum loudness and minimum silence duration.

2. Reduced StarNet: The reduced version of StarNet is obtained after resampling the preprocessed version at 16 kHz, merging the two audio channels and outputting mono audio, and finally quantizing the audio by 8-bit mu-law encoding.

3. METHODOLOGY

Pitch and timbre are among the fundamental acoustic properties of every audio track in a recorded mixture. As we address instrumentation changes in our work, timbre is regarded as the style component, while pitch constitutes the content we intend to preserve. Based on this definition, we introduce the following notation of a piano track and its style and content components:

$$A_{piano} := T_{piano} + P_{piano}$$

where A is an audio signal, T is the timbre component, and P is the set of pitch components and their embodied durations in that signal. Separating style and content components, also known as disentanglement, has been leveraged in previous music translation studies [7,9,12] and is mostly addressed by adversarial learning in encoder-decoder architectures. Note that T and P in the notations are conceptual terms, and the corresponding features will be extracted by the autoencoders and represented by the embeddings.

An example of single-instrument translation is shown below, where a piano track is translated to vibraphone in a way that the pitch component is retained, and the timbre component alters:

1. $Input = A_{piano} := T_{piano} + P_{piano}$
2. $Output = A_{vibraphone} := T_{vibraphone} + P_{piano}$

Our task is to tackle a more complex problem, i.e., dealing with multi-instrument pieces (Fig. 1). In the case of our dataset, the input audio signal will be one of the following:

1. $A_{mix1} = A_{strings} + A_{piano} :=$
   $T_{strings} + P_{strings} + T_{piano} + P_{piano}$
2. $A_{mix2} = A_{clarinet} + A_{vibraphone} :=$
   $T_{clarinet} + P_{clarinet} + T_{vibraphone} + P_{vibraphone}$

As a result, pitch-timbre disentanglement does not suffice here as we need to isolate two sets of timbre and pitch components.

In this section, we first introduce the baseline methods for performing multi-instrument translation, i.e., single-instrument translation pipeline and separation-based translation pipeline. Then we present our proposed methods, i.e., the embedding-supervised method and Music-STAR.

3.1 Single-instrument Translation Pipeline

The most simplistic approach to multi-instrument translation is to translate each instrument track separately and obtain the final output by mixing them. However, this is only possible when the music stems are available.

In order to implement this method, we employ an existing audio-based translation model [7], which is built upon the WaveNet autoencoder [18]. This model consists of a universal encoder and six decoders corresponding to six target domains, all collected from the MusicNet [20] dataset.

In this universal network, the temporal encoder maps the pitch components into an embedding space utilizing a WaveNet-like architecture. The decoders are conditioned on the pitch embeddings and generate audio samples that entail the specific timbre they have been trained for in an autoregressive manner. A domain confusion network is employed during training to ensure that no domain-specific information is included in the embeddings by imposing domain confusion loss [21]. The authors also emphasize the role of distorting the input by modulating the pitch locally

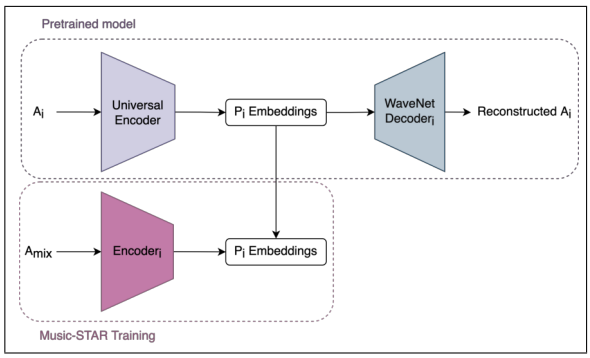

Figure 2. The embedding-supervised encoder is trained to generate the same embeddings as the universal encoder for every instrument *i* present in an audio mix (A_{mix}).

in every audio segment while training. This way, they ensure that the encoder does not memorize the content and drive it to capture meaningful features. In other words, the network is trained as a denoising autoencoder that learns to recover the original input by applying teacher forcing [22] while training the decoders. The teacher forcing technique is carried out by feeding the original input audio segment to the decoder instead of the generated samples.

3.2 Separation-based Translation Pipeline

The previous method does not apply to use cases where the instrument tracks are not available separately and where the system must take the audio mixture as input. One way to tackle this is to adopt a pipeline of audio source separation and single-instrument translation. The source separation module isolates each of the tracks so that a single-instrument translation model can transform each of them into a target instrument.

To perform source separation, we adopt Demucs [23], a state-of-the-art music source separation model that operates in the waveform domain, taking an audio mixture and outputting isolated audio tracks. These stems are then fed into the universal network described in Section 3.1 for the translation phase.

3.3 Embedding-supervised Method

Training source separation models to separate every instrument in a mixture is a demanding task, and thus we favor solutions that do not depend on it. We have investigated a potential solution that we refer to as the embedding-supervised method, which performs a semi-separation task through the encoding process. In this case, the embedding-supervised encoder learns to capture the pitch-related features of one of the two instruments in the mixture. In order to achieve this, we need a pre-trained encoder that can provide the desirable pitch embeddings for a single instrument and assist the embedding-supervised encoder in distinguishing between the instruments throughout the training step. Recall that the universal encoder in our baseline model learns to extract pitch-related information from the input. Thus the output of such an encoder can provide the embeddings we seek. Based on this, we can train the embedding-supervised encoder to mimic the output of the universal encoder when given a mixture as the input. (Fig. 2)

For instance, if we have the mixture as:

$$A_{mix} = A_{strings} + A_{piano}$$

we feed the piano track A_{piano}:

$$A_{piano} := T_{piano} + P_{piano}$$

into the universal encoder, and its output will represent piano track pitch information (P_{piano}). We then input the mixture A_{mix} to the embedding-supervised encoder and train it to output the same code, i.e., the embeddings for P_{piano}. Consequently, we have a piano-specific encoder to extract the piano pitch content from any mixture. Note that for such training, existence of the stems in the dataset is necessary. We can isolate the information corresponding to one instrument via this approach without applying actual source separation. We can train one encoder per instrument with the help of the universal encoder. The model strives to minimize the loss function below:

$$L(E^i_{es}(mix), E_u(x^i)) \quad (1)$$

where E_{es} is the embedding-supervised encoder, mix is the audio segment from the input mixture, E_u is the universal encoder, x^i is the fragment of the instrument track i that we want to extract from the mixture, and L is L1 loss.

During inference, a pre-trained WaveNet decoder can also be engaged to translate the code to an arbitrary target instrument.

3.4 Music-STAR

Our ultimate goal is to realize the idea of multi-instrument translation where we do not need to engage source separation modules or additional encoders, and in general remove the restrictions of the aforementioned techniques. To this end, we introduce Music-STAR, designed explicitly for audio-based multi-instrument translation as described below.

As mentioned in Section 3.1, the universal network is trained using a random local pitch modulation that distorts the input to ensure that the encoder does not memorize the input content. Since the encoder learns to extract pitch-related information, we expect the code to embody data from the distorted segments. However, the decoder is trained using the teacher forcing technique, where the original audio segment is fed into the decoder alongside the embeddings produced by the encoder. The benefits of this approach are two-fold. First, the decoder learns the timbre of the original segment that is not present in the latent space. Second, for the decoder to reconstruct the original audio with the right pitch, it forces the encoder to represent the original segment in the latent space by removing the distortion. We will employ a similar idea below.

To begin, we represent our input audio as:

$$A_{input} = A_{strings} + A_{piano} := \\ T_{strings} + P_{strings} + T_{piano} + P_{piano}$$

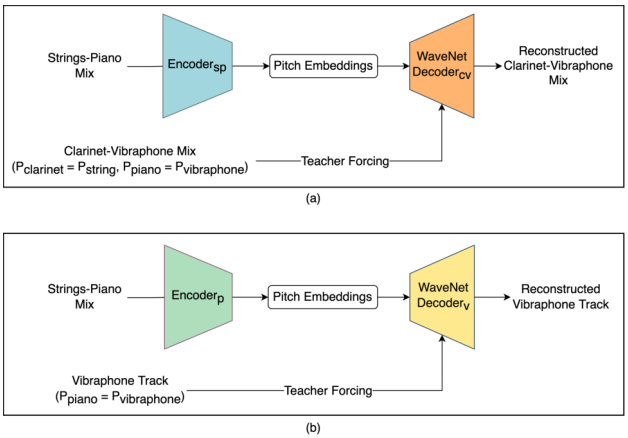

Figure 3. Training Music-STAR using (a) the mixture-supervised method to generated the target mixture, (b) the stem-supervised method to generate a single target stem. The modules subscripts *sp*, *cv*, *p*, and *v* corresponds to string-piano, clarinet-vibraphone, piano, and vibraphone, respectively.

The output we are looking for is:

$$A_{output} = A_{clarinet} + A_{vibraphone} := \\ T_{clarinet} + P_{clarinet} + T_{vibraphone} + P_{vibraphone}$$

where $P_{strings} = P_{clarinet}$ and $P_{piano} = P_{vibraphone}$.

To obtain this output, we should make sure that:

1. The encoder includes only the representations of P_{piano} and $P_{strings}$ in the embeddings, removing the information related to the other components of A_{input} (T_{piano} and $T_{strings}$), which has been proven possible when removing the distortion in [7].

2. The decoder generates the output signal by applying the target timbres that it has learned from the audio segments used for teacher forcing.

Accordingly, we conclude that the autoencoder will be able to extract the pitch-related features of the input mixture and translate it into target timbres if we train the model by:

1. Using the strings-piano mixture as the encoder's input, and

2. Using the clarinet-vibraphone counterpart of the input to apply teacher forcing to the decoder.

When the decoder is learning to translate the encoder's output to generate the clarinet-vibraphone segment, it inevitably guides the encoder to hand in helpful information for the task, which should be strings and piano pitch representations (see Fig. 3(a)). Since we train the model using the source and target audio mixtures, we name this approach the *mixture-supervised* method. The loss function for the mixture-supervised method is formulated as

$$\sum_{j} L(D(E(mix), t_j), t_j) \qquad (2)$$

where L is the cross-entropy loss, D is the decoder, E represents the encoder, mix is the input mixture segment, and t_j is the jth sample from the target mixture used for teacher forcing.

In our experiments, we also account for a variation of the mixture-supervised method where the target mixture (used in teacher forcing) is replaced by only one of its instrument tracks. We call the resulting method *stem-supervised*, in which we employ two autoencoders, each for translating one of the instruments in the mixture, and combine their outputs in the end to obtain the final mix (see Fig. 3(b)).

4. EXPERIMENTS

4.1 Single-instrument Translation Pipeline

We employ the universal network [7] to perform single-instrument translation. The network is originally trained on six classical music domains from the MusicNet dataset that includes mono audio segments with a sample rate of 16 kHz, which are later quantized by 8-bit mu-law encoding. The input files are randomly selected, and then a 0.75-second audio chunk is randomly segmented out of the file for every training input. A duration between 0.25 to 0.5 seconds of that segment is then selected for applying distortion by modulating the pitch.

In order to use this architecture as a baseline, we need to make sure that the decoders can generate the timbres included in the StarNet dataset. Therefore, we use the pre-trained universal encoder and finetune the decoders on the reduced StarNet dataset. Note that the data in reduced StarNet has the same properties as the data used for training the original model in terms of sample rate, bit depth, and the number of channels. Since the universal encoder has been trained using substantial computational resources on six domains and captures domain-agnostic features, it is powerful enough to successfully encode inputs from other domains. We finetuned the decoders with a batch size of 16, a learning rate of $1\mathrm{e}{-3}$, and a decay factor of 0.98 for 100 epochs.

4.2 Separation-based Translation Pipeline

We adopt Demucs [23] as the music source separation model, which is trained originally on MuseDB [24]. It is vital for our experiment that the network separates the two instruments present in the mixtures. Therefore, we train Demucs on preprocessed StarNet from scratch. We use the original learning rate of $3\mathrm{e}{-4}$ and Adam optimizer with a batch size of 32 for 250 epochs. The resulting model can take an arbitrary length of an input mixture and successfully separate the strings track from the piano or the clarinet track from the vibraphone.

The separated audio tracks are then post-processed to comply with the data configuration in reduced StarNet and fed into the finetuned models from Section 4.1 that correspond to their target instruments.

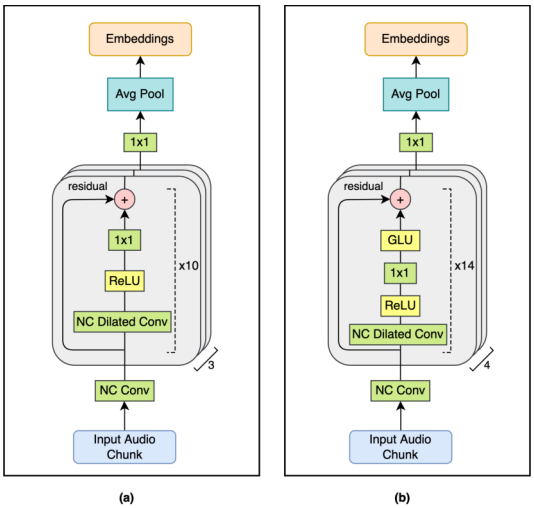

Figure 4. (a) The architecture of the universal encoder. (b) The architecture of the encoders used in the embedding-supervised and Music-STAR models.

4.3 Embedding-supervised Method

An autoencoder architecture builds the backbone of the model. This method focuses on training the embedding-supervised encoder with the help of the universal encoder. The architecture of the universal encoder is depicted in Fig. 4(a). Since the embedding-supervised encoder should learn to extract the same information as the universal encoder from a mixture rather than a stem, one would expect that a more complex architecture would be required for it. This was indeed confirmed by our pilot experiments.

The architecture we use as the embedding-supervised encoder is shown in Fig. 4(b). Similar to the universal encoder, it starts with a non-causal non-dilated convolution. The encoder consists of four blocks of 14-layer residual networks composed of non-causal dilated convolutions with a kernel size of 3, followed by ReLU nonlinearity and a 1x1 convolution. A GLU activation function follows the 1x1 convolution, and the output is summed with the input to form the residual connection. The result of this connection is then fed into the next layer of the encoder. The dilation increase factor of 2 and the 128 channels are identical to the universal encoder.

Unlike the baseline model that trains a universal encoder for all the domains in the training set, we need to train a single encoder for each instrument to extract content information from a mixture. The embedding-supervised encoders are trained on 0.75-second audio chunks randomly segmented out of the mixture files from reduced StarNet, and the same segments are extracted from the instrument tracks to be fed into the universal encoder. We adopt Adam optimization and exponential learning decay with a learning rate of $3e{-}4$, a decay factor of 0.98, and a batch size of 16 for a total of 100 epochs.

The finetuned WaveNet decoders described in Section 4.1 are then attached to the embedding-supervised encoders during inference to translate the code into the target instruments.

4.4 Music-STAR

We employ the WaveNet autoencoder architecture in the mixture-supervised method as well. The encoder we use for this method has the same architecture as the one used in the embedding-supervised method (Fig. 4(b)). The decoder's architecture is identical to the WaveNet decoders described in [7].

We train the models on the reduced version of StarNet. We pick random one-second audio segments of the input mixture and extract the same segment in the target mixture to apply teacher forcing to the decoder. Training is done using the Adam optimizer and exponential learning decay, where a learning rate of $3e{-}4$ and a decay rate of 0.99 are applied. The model is trained for a total of 100 epochs with a batch size of 16.

We use the same training configuration as above for the stem-supervised setting, except that two autoencoders are involved, each for transforming the source mixture into one of the target instruments.

5. EVALUATION

We conduct subjective and objective evaluations of the obtained audio and compare the re-instrumentation methods on three criteria:

1. Content preservation: how much of the pitch content of the input is retained in the output.
2. Style fit: How well the output presents the target timbres.
3. Audio quality: How clean and distortion-free the generated audio is.

5.1 Subjective Evaluation

The subjective evaluation provides a qualitative assessment of our models based on how users perceive the generated outputs. We carry out the subjective evaluation by distributing a survey among 30 participants, some of whom have a musical background. Each survey contains two different pieces, one from each domain (strings-piano and clarinet-vibraphone) selected out of 10 pieces in total. The target mixture is provided for each piece to demonstrate the gold standard, followed by corresponding translation outputs resulting from the five methods. The order of outputs is different for the two pieces, and the participants have no prior knowledge of the order.

Every piece in the survey is evaluated through three questions asking the participants to rank the five outputs based on:

1. How well they preserve the target musical content, which accounts for content preservation.
2. How well they present the instruments' tone colors (timbre) of the target piece, corresponding to style fit.
3. How clean and distortion-free they are, presenting the audio quality.

Method	Subjective			Objective	
	Content	Style	Quality	Content (Jaccard)	Style (Cosine)
Single-instrument	166	150	153	0.371	0.483
Separation-based	165	147	159	0.392	0.474
Embedding-supervised	161	157	149	0.350	0.472
Stem-supervised	154	190	183	0.323	**0.699**
Mixture-supervised	**254**	**256**	**256**	**0.426**	**0.698**

Table 1. Evaluation results on the three criteria of content preservation, style fit, and audio quality. The results from the subjective evaluation show the scores for each model according to the rankings provided by the surveys. Objective evaluation reports Jaccard similarity and cosine similarity for the first two criteria, respectively.

After collecting the surveys, we concluded the rankings for each question by scoring the models. For each criterion, the methods receive a score of 5 if one of their generated outputs is ranked first, a score of 4 if ranked second, a score of 3 if ranked third, a score of 2 if ranked fourth, and a score of 1 if ranked last. The aggregate scores are shown in Table 1. More detailed analysis is available online [1] .

5.2 Objective Evaluation

We aim to provide a quantitative quality assessment on content preservation and style fit using techniques employed in previous studies.

5.2.1 Content Preservation

Following the work by Cífka et al. [3], we assess the models on content preservation by calculating the Jaccard similarity between the pitch contours of the outputs and their corresponding gold standards. Since we are addressing multi-instrument music in our study, we extract the pitch contours using the multi-pitch Melodia algorithm [25] which provides the existing pitch frequencies in Hz. We round the frequency values to the nearest semitone. Then we express the similarity of the pitch sets of each time step in terms of the Jaccard index. Higher Jaccard similarity between the output and the gold standard signifies better content preservation.

5.2.2 Style Fit

We evaluate the style fit factor using the deep metric triplet network offered by Lee et al. [26]. The network consists of a backbone model, which provides embeddings for three inputs, and a triplet model that outputs a similarity score between those embeddings. The three inputs are called *the anchor*, *the positive*, and *the negative*. The network is trained to generate the embeddings in a way that the positive is closer to the anchor than the negative. During inference, a similarity score between the anchor and the other two will be reported.

Following Cífka et al. [3], we use MFCCs as the input features as they provide timbre-related information. We train the triplet network using the mixtures in the preprocessed StarNet dataset. For instance, the MFCCs of eight-second clarinet-vibraphone audio segments are used as both the anchors and the positive inputs in the training phase. At the same time, their counterparts from the strings-piano domain are regarded as negative inputs.

During inference, we presented the translation outputs from the five methods as the anchors, their corresponding gold standard as the positive, and the performance from the other domain as the negative. We report the average cosine similarity between the outputs of each translation method and their corresponding gold standards. Higher cosine similarity denotes more likeness to the target timbre and a better style fit.

5.3 Discussion

All evaluation results are presented in Table 1. The scores reported by the subjective evaluation are the total sum of the models' scores on both Clarinet-Vibraphone $\leftrightarrow$ Strings-Piano translations. Objective evaluation reports the average performance of models in translating the two domains. Both objective and subjective evaluations conclude that mixture-supervised Music-STAR is the predominant model in performing multi-instrument music translation. The mixture-supervised method outperforms the other methods in all the assessments except for objective style fit, where it reaches an almost equal cosine similarity with the stem-supervised method. An advantage that it has over the other methods is that the presence of the stems is not necessary for training the model. Mixture-supervised Music-STAR is, to the best of our knowledge, the only model capable of performing timbre translation on multiple instruments in a mixed signal.

The embedding-supervised method is, on average, the worst-performing model. The encoder used in this model is trained based on the universal encoder's outputs to extract the pitch information of one instrument out of a mixture. An imperfect ground truth places the model at the disadvantage of even more unsatisfactory performance. Also, the performance of single-instrument and separation-based translation models on different criteria are very similar.

6. CONCLUSION

This paper introduced Music-STAR, the first audio-based multi-instrument music translation system. Music-STAR tackles multi-instrument translation without applying explicit source separation to the input mixtures. We also introduce the StarNet dataset that includes two-instrument pieces performed in two domains alongside their stems. We explored a variety of possible solutions based on the WaveNet autoencoder, and finally reached a successful mixture-supervised method capable of performing simultaneous source separation and pitch-timbre disentanglement for two instruments.

Future work will target increasing the number of instrument tracks in the mixtures, and adding to the variety of instrument combinations. We also plan to develop a more ornate dataset in terms of the details on articulations and dynamics.

LEARNING UNSUPERVISED HIERARCHIES OF AUDIO CONCEPTS

ABSTRACT

Music signals are difficult to interpret from their low-level features, perhaps even more than images: e.g. highlighting part of a spectrogram or an image is often insufficient to convey high-level ideas that are genuinely relevant to humans. In computer vision, concept learning was therein proposed to adjust explanations to the right abstraction level (e.g. detect clinical concepts from radiographs). These methods have yet to be used for MIR.

In this paper, we adapt concept learning to the realm of music, with its particularities. For instance, music concepts are typically non-independent and of mixed nature (e.g. genre, instruments, mood), unlike previous work that assumed disentangled concepts. We propose a method to learn numerous music concepts from audio and then automatically hierarchise them to expose their mutual relationships. We conduct experiments on datasets of playlists from a music streaming service, serving as a few annotated examples for diverse concepts. Evaluations show that the mined hierarchies are aligned with both ground-truth hierarchies of concepts – when available – and with proxy sources of concept similarity in the general case.

1. INTRODUCTION

Music signals are challenging to interpret [1]. For instance, inspecting a spectrogram by parts – *e.g.* think of attention maps [2] – does not convey much meaning with respect to the high-level descriptions that are useful to humans – *e.g.* the mood of a song. Fortunately, a solution was proposed in a field that shares similar problems: computer vision. As pixels of images are too low-level to be understandable, *concept learning* was introduced to rationalise the abstractions steps involved in a feed-forward model (*e.g.* detection of colours, shapes, patterns, ...), which in turn can be used to describe the content of an image directly, and to align models with human reasonings better. Indeed, this field has had successful applications in explainability (XAI) – dissecting a model's predictions into human-grounded concepts [3–5], interactive learning [6] or knowledge transfer between tasks [7]. However, these methods have yet to be used for Music Information Retrieval (MIR).

Guigue, "Learning Unsupervised Hierarchies of Audio Concepts", in *Proc. of the 23rd Int. Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

Music has particularities that are not captured by the current formulation of concept learning. For instance, let us consider genres as common musical concepts we would like to detect from spectrograms. Genres are typically blended as they influence or result from other genres (*e.g. Punk Rock*). By contrast, most literature on concept learning has considered sets of few identified and disentangled concepts, which does not apply to genres. Moreover, one trend in MIR is to incorporate multiple types of descriptors into a shared space (*e.g.* mood, genre, instruments [8, 9]), thus requiring handling even more entanglements.

We thus propose to study a novel problem for concept learning that is relevant for music: **learning hierarchies of concepts**. Indeed, a hierarchy enables navigating thousands of non-independent concepts without cognitive overload by uncovering their mutual relationships with a structure, thus rationalising which concepts share the same class or are derived from one another. In addition, the use of taxonomy – *i.e.* hierarchy – is common in musicology and feels like a natural representation in this context [10, 11].

The problem we study is interesting for *music representation learning* because research is often limited by data labelling, which is labour-intensive and can be ambiguous or tied to a specific dataset. Meanwhile, concepts can be learned with few shots, which open the doors to new sources of music descriptors. In particular, we propose to leverage a dataset of playlists from a music streaming service as a folksonomy of concepts. Playlists are often built with a specific concept; there exists one for any genre, instrument, mood, and many more niche ideas. Yet, there is no overall ground-truth organisation of playlists, making their use cumbersome. That is why we propose to solve this task by first adapting a method from concept learning research to learn music concepts from playlists in a few-shot manner and then, building on top of this method, automatically derive a hierarchy from the learned concepts.

The paper proceeds as follows: we provide background on concept and hierarchy learning (section 2); we adapt the literature of concept-based explanations to the realm of MIR (3); we present a novel way to organise the detected concepts into a hierarchy in an unsupervised manner (4); finally, we experiment and discuss our attempt to provide a new audio concepts hierarchy with mixed types (5).

2. PRELIMINARIES AND RELATED WORK

We first present the literature on concept learning and hierarchy mining, then frame our problem through XAI to uncover common pitfalls to avoid when interpreting data.

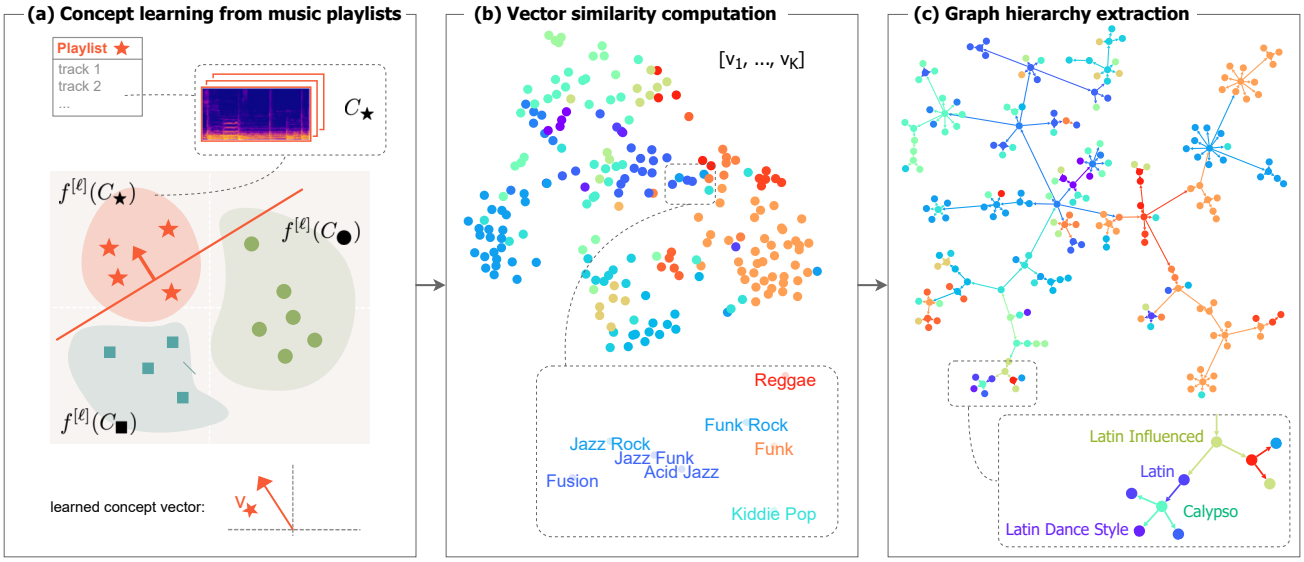

Figure 1. **Overview of our method** *(a)* CAVs learning (section 3.1); *(b)* t-SNE projection of concepts $\mathcal{V}_{\text{genre}}$ learned on a small dataset with 219 music genres; *(c)* resulting extracted hierarchy $H(S(\mathcal{V}_{\text{genre}}))$. Nodes colours denote ground-truth clusters. Experiments on a bigger concept dataset are conducted in section 5.

2.1 Concept learning

Concept learning has witnessed growing interest in recent years [4]. The introduction of concepts stems from the inadequacy of usual *explanation spaces* with human mental models of problems: tabular features, pixels, and words in sentences are sometimes too low-level to build relevant explanations or to interact with. This idea is far from novel from a purely technical standpoint: a stream of papers aim to learn a set of sub-attributes in a fully supervised manner (*e.g.* facial features [12], or animal attributes [13]), that are then combined to predict some end-task labels, typically through a linear regression to track the importance of each attribute. This idea has been revamped recently for *concept bottleneck* learning [14] and *prototypical part learning* [15]. In the same vein, *disentanglement techniques* [16] have sought to realign latent representations to interpretable attributes. All those works rely on the assumption that a somewhat complete set of useful concepts exists, well-defined and rather disentangled, and that a corresponding labelled dataset is readily available to train on.

This is rarely the case in practice. Kim et al. introduced CAVs for images [3] and demonstrated that concepts could be learned reliably from few annotated examples – technical details are provided in section 3.1. Going beyond the previously few datasets annotated for concepts, this work has led to new and diverse applications: skin lesion interpretations [17], emotion recognition [18], interactivity [6, 19], automatic concept learning [20], batch normalisation [21], sufficiency of explanations with shapley values [22, 23], causal inference [24]. To our knowledge, there exists no application in the music domain.

2.2 Unsupervised Hierarchy Mining

Using knowledge graphs and taxonomies is frequent leverage in MIR [25]. Unsupervised learning of hierarchy is, however, less so. Part of it lies in the difficulty of adequately defining the meaning of the hierarchical relations, learning the hierarchy in a tractable way, and evaluating the found hierarchy without ground-truth.

Fortunately, there is active literature coming from *natural language processing (NLP)* research. Many work proposed variants of *topic modelling* [26] to enable sampling hierarchised structures [27, 28]. However, these methods get computationally intractable as the number of nodes, topics, and hierarchical levels grows. Many successes thus came from scalable greedy methods such as hierarchical clustering [29, 30], rule-mining [31, 32] and graph-based analyses [33, 34]. Outside of NLP, hierarchies have been learned based on the latent manifold geometry [35], predefined structure [36], and for images [37, 38].

To our knowledge, these techniques have never been combined with concept learning, as we propose.

2.3 Explainability

Our end goal is to interpret music signals, which is linked to explainability (XAI). Before jumping into our method to learn a hierarchy of concepts, we need to acknowledge that many works have debated the sanity of explanation methods [39–43] and the fact that these methods largely disagree with one another [44]. XAI has vast boundaries, which has also percolated to its music sub-field for which there exists many explanation paradigms and evaluations [45]. Explanations for MIR are thus also prone to exhibiting pathologies that hamper knowledge mining: *e.g.* shortcut learning [46], lack of clear definitions [39, 47], flawed evaluations [48], out-of-distribution artifacts [49, 50] or misalignment with human reasonings [51–54].

Uncovering these failure cases sharpens our understanding of how models make decisions, and shows that we have to go beyond evasive considerations on explain-

ability to make them relevant [41] since trustworthy AI is not achieved automatically with XAI [55]. One taxonomic distinction we would like to underline is whether methods aim to explain models or data [56]. Our method is intended to belong to the latter category for which the purpose is not to explain how models work (*e.g.* troubleshooting learned filters) but rather to use them as proxies to gain new insights about reality (*e.g.* causal inference [57]).

With all these aspects in mind and based on previous literature, we formalise our three explanation goals:

1. **Attribution.** Identify musical concepts associated with a given track's audio signal.
2. **Transferability.** Detected concepts should be applicable to various settings and tasks.
3. **Generality.** The hierarchy should be independent of the signals and make sense for various settings.

Our first goal is linked to the traditional explanation literature supporting *transparency* [45, 47] and is common in concept-learning. We have defined our second and third goals to stress that the finality of our work is to be as universal as possible.

3. LEARNING MUSIC CONCEPTS

In this section, we first adopt the few-shot supervision setting of concept learning to learn the music concept $\vec{v}_C$ of each playlist, viewed as a set C of audio signals examples.

3.1 Background on CAVs

We review some essential notions from the concept learning framework we use to learn playlist concepts [3].

We denote $\vec{f}^{[\ell]}$ the output of the l-th layer of a trained neural network f taking as input some samples $x \sim X$. A "concept activation vector" $\vec{v}_C$ is defined for a set of positive examples C as the normal to a separating hyperplane between $\{\vec{f}^{[\ell]}(x) \mid x \in C\}$ versus negative examples – usually $\{\vec{f}^{[\ell]}(x) \mid x \notin C\}$, we provide an illustration in Figure 1(a). In practice, the hyperplane is learned through a logistic regression on a subset of C, while holding out the remaining samples for validation and testing [1] .

As additional insights, this setting is "sound" for few-shot learning because it uses a pretrained model f with prior knowledge on the domain – relating to transfer learning [58] – and learns a linear mapping on its space, hence reducing the risk of over-parametrisation and justifying why more complex mappings are not considered.

3.2 Sets of examples C

The work of Kim et al. [3] lends itself naturally to learning concepts from playlists. Indeed, playlists can be seen as small sets of positive music examples built around a particular musical idea. As it will be further detailed in our experiments, we can use data from music streaming services where playlists are abundant. We will denote $\mathcal{C} = \{C_i\}_i^K$ the set of K sets of music tracks that will enable to learn a CAV set $\mathcal{V} = \{\vec{v}_i\}_i^K$ discriminating $\mathcal{C}$ in the $\vec{f}^{[\ell]}$ space.

It must be noted that playlists are more than a set of tracks, we usually have access to textual data with a title and a description that help rationalise the learnt concepts.

3.3 Backbone model $\vec{f}^{[\ell]}$

As often in few-shot learning, CAVs learning makes use of a pretrained model f – referred to as *backbone* – to embed samples into a latent space with a higher level of abstraction. In this paper, our working hypothesis is that **music concepts can be described solely through audio signals**. We wanted to fully explore the potential of audio signals, which is a known challenging setting in MIR and recommendation [59], and leave its combination with other sources of features for future work. In addition, having audio inputs enables using our model with any music track from any dataset, hence supporting goal 2, while relying on features such as collaborative filtering or other usage data would have tied our model to a given dataset.

After having experimented with several models, as the recent self-supervised model *CLMR* [60], we have chosen to use *MusiCNN* [61] as the backbone since it had demonstrated consistent performances across various musical tasks, which we deemed on par with our goal 2 and 3. MusiCNN was trained on the *Million Song Dataset* [62].

3.4 Preliminary results

We provide some experimental observations to fix ideas and prepare the next section. If we train CAVs as in the original paper [3] – further detailed in section 5.2, we obtain a set of vectors $\mathcal{V}$ that allows to detect a set of K concepts given any music input spectrogram. An example result of learned concepts is given in Figure 1(b) for one of the studied datasets. Unsurprisingly, we find that many associated concepts end up having close vector weights [2] . If we were to use our concept detectors directly, we would have many concepts activated simultaneously, which could make predictions hard to read when K is very big. On the positive side, note that **vector proximity could be used as a means to quantify concept similarities**. With this idea, we go a step further and next present our method to build a hierarchy to help rationalise concept dependencies.

4. HIERARCHISING MUSIC CONCEPTS

Having learned numerous non-independent concepts $\mathcal{V} = \{\vec{v}_i\}_i^K$, we next elaborate on how to organise them with a structure to make them usable (goals 2, 3).

Many classes of structures are possible, and it would be a mistake to select one with purely theoretical considerations since cognitive and social sciences [63, 64] have underlined that explanatory preferences are shaped by diverse factors that cannot be reduced to a set of so-called golden explanation principles. Therefore, from an empirical standpoint, taxonomies seem to be frequent with music

[1] By definition, $\vec{v}_C$ is the learned parameter of a logistic regression.

[2] In the figure, proximity is defined as the cosine similarity.

concepts (*e.g.* genres [8], instruments [25]). We thus argue that this class of graph is rather natural for humans and chose to consider it only.

4.1 Similarity graph computation

Before mining a hierarchy, it is necessary to determine how concepts – now acting as graph nodes – relate to one another. Essentially, we are trying to define a similarity measure between concepts.

When sampling uniformly from a music dataset, concept activations are rare signals overshadowed by uninformative negative detection. The straightforward solution of estimating the empirical covariance of concept activations is thus not a well-behaved measure of similarity. Fortunately, there is another reliable, interpretable (and faster) way to do it. We propose to consider the positive examples of each concept playlist – embedded in $\vec{f}^{[\ell]}$, and to check on what side of other concept hyperplanes their centroid lies. Formally, given $\mathcal{V} = \{\vec{v}_i\}_1^K$, we compute the matrices of concept similarities S and adjacency A (*i.e.* A is a binarised matrix representing graph edges):

$$S_{i,j}(\mathcal{V}) = \mathbb{E}_{x\sim\mathcal{C}_i}\left[\sigma(\langle\vec{v}_j, \vec{f}^{[\ell]}(x)\rangle)\right] \quad (1)$$

$$A_{i,j}(\mathcal{V}) = \left[S_{i,j}(\mathcal{V}) \geq \frac{1}{2}\right] \quad (2)$$

where σ denotes the logistic sigmoid function and $\mathcal{C}_i$ a random variable sampling spectrogram excerpts from tracks of the playlist C_i. Bias is integrated in $\vec{v}_j$ for simplicity. The threshold at $\frac{1}{2}$ for A translates having each playlist centroid on the positive side of the concept hyperplanes. Because $\mathcal{V}$ is learned through logistic regressions that return well-calibrated probabilities, S and A return similarities with well-defined interpretations.

4.2 Hierarchy extraction

Having defined similarities between concepts, we next simplify S and A to a hierarchy that highlights what concepts are similar to many others and what others represent unique and niche ideas.

For our problem and its scale, we propose to adapt the greedy hierarchy construction of Heymann et Garcia-Molina [33] that makes use of the notion of **betweenness graph centrality** [65]. In this method, given an unweighted graph of similarities, a tree is greedily grown by picking each node in decreasing order of centrality in the similarity graph and linking it to the most similar and already-added node in the tree. We denote by $H(S(\mathcal{V}))$ the result of this algorithm on the similarity graph given by the adjacency matrix $A(\mathcal{V})$ and using $S(\mathcal{V})$ as similarity.

Though this algorithm was originally applied to word tags, we argue that the inductive bias of the targeted hierarchy is applicable to our problem. In particular, the use of centrality is justified by the existence of noisy links in the similarity graph, said links are assumed to be more frequent higher up in the hierarchy (*general-general assumption*). For us, this means that general concepts – *e.g. Pop* and *Rock* – should be more likely to be similar than niche concepts – *Bedroom Pop* and *Goth Rock*. This sounds reasonable for music content since we expect niche concepts to relate to a specific musical idea, style, or instrument.

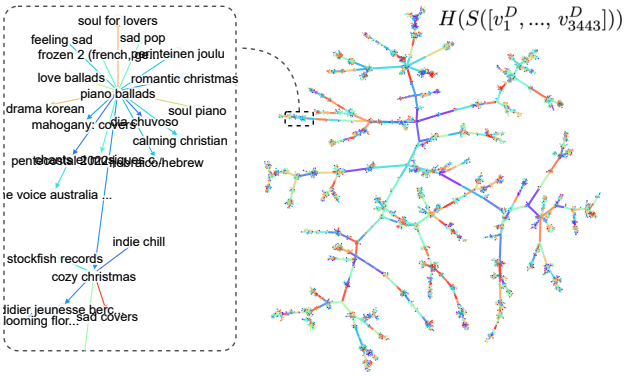

Figure 2. Obtained hierarchy on the Deezer dataset. An interactive plot of this figure, as well as many others, is available at `research.deezer.com/concept_hierarchy/`.

5. EXPERIMENTS

We first detail our experimental setups, then validate that concepts can be reliably learned from audio, and finally show that our proposed structuring method leads to consistent hierarchies for MIR applications.

5.1 Datasets

The set of playlists $\mathcal{C}_D$ we use was exported through the API of the streaming platform Deezer [3]. We have filtered **3635 playlists of mixed types** to be used as concepts: all 1498 editorial playlists available – considered thoughtfully curated but biased by popularity, and 2137 public user playlists with the lower artist popularity – to improve diversity. Playlists have a mean length of 75 tracks and a minimum of 40. This dataset includes the playlist ids, titles, descriptions, and public 30s audio preview for each track. There are 245074 unique tracks from 116497 unique artists: playlists overlap is thus very limited.

In order to compare our computed hierarchy to existing taxonomies, we make use of the APM Music dataset [66]. This is a more traditionally tagged dataset, but its relevance for our task is to include a ground-truth two-level hierarchy of the *music genres* (219) and *moods* (165) tag types. We aggregate sets of positively tagged examples as $\mathcal{C}_{\text{genre}}$ for each genre tags and respectively $\mathcal{C}_{\text{mood}}$ for moods.

5.2 Validating concept learning

We first present experimental evidence related to learning sets of concepts (section 3), to validate goal 1.

5.2.1 Experimental setup

Concept examples are split in a 70% (*train*) / 10% (*validation*) / 20% (*test*) fashion. According to the requirements of our backbone [61], we convert audio inputs to

[3] `https://developers.deezer.com/api`

Source	Audio (↓)	CF (↓)	BERT (↑)	W2V$_1$ (↑)	W2V$_2$ (↑)
$H(S(\mathcal{V}_D))$	**2.449 ± 0.022**	0.845 ± 0.013	0.345 ± 0.007	0.286 ± 0.009	0.542 ± 0.007
$H(S_{\text{CF}})$	**2.413 ± 0.021**	**0.345 ± 0.007**	0.416 ± 0.008	0.336 ± 0.010	0.601 ± 0.008
$H(S_{\text{BERT}})$	2.858 ± 0.028	0.868 ± 0.013	**0.726 ± 0.005**	0.505 ± 0.011	0.652 ± 0.008
$H(S_{\text{W2V-1}})$	2.952 ± 0.028	0.932 ± 0.012	0.523 ± 0.008	**0.804 ± 0.005**	0.721 ± 0.007
$H(S_{\text{W2V-2}})$	2.843 ± 0.026	0.847 ± 0.012	0.531 ± 0.008	0.596 ± 0.009	**0.836 ± 0.004**
Random	3.388 ± 0.027	1.104 ± 0.006	0.239 ± 0.004	0.142 ± 0.006	0.452 ± 0.006

Table 1. Evaluation of the full hierarchy on audio, user-logs and title semantic similarities with 95% confidence. *Audio* and *CF* source are endowed with an **Euclidean distance**, the last three semantic sources use **cosine similarities**.

mel-spectrograms with log-magnitudes. Representations are extracted from the penultimate layer of the backbone, denoted as $f^{[\ell]}$ – which gave us the best performances for concept learning overall. Our complete training code, with further details and exact parameters, is provided for reproducibility at `github.com/deezer/concept_hierarchy`.

5.2.2 *Learning metrics evaluation*

On the Deezer dataset $\mathcal{C}_D$, the mean balanced accuracy of learning concepts is **83.8% ± 0.3**, with a 95% confidence interval. In detail, we display a histogram of test balanced accuracies in Figure 3, showing that a **majority of playlist concepts can be learned reliably from audio**.

As a rationalisation of failure cases, the hypothesis we made in section 3.4 to detect concepts from audio may not always hold. For instance, it fails when playlist concepts rely on factors extraneous to audio (*e.g.* playlist of a movie soundtrack) or when the backbone space is not expressive enough to discriminate concepts. This actually happens in these experiments with concepts similar in all respects but for their singing languages: *e.g.* the model makes no difference between Japanese and British jazz. We filter concepts v_i below a given test accuracy threshold to account for this effect. Fixed at 70%, 192 concepts are filtered out, leading to $K = 3443$ remaining concepts. This threshold was set empirically by checking that those left-out concepts were indeed unclear from audio (*e.g.* OST, new releases, charts). We denote the resulting concept set $\mathcal{V}_D$.

The two smaller APM datasets lead to similar results with a **78.3% ± 0.8** for genres, denoted $\mathcal{V}_{\text{genre}}$, and a **71.3% ± 0.6** accuracy for mood tags, denoted $\mathcal{V}_{\text{mood}}$.

As a wrap-up of this section, goal 1 of detecting concepts from audio seems satisfied in our experiments.

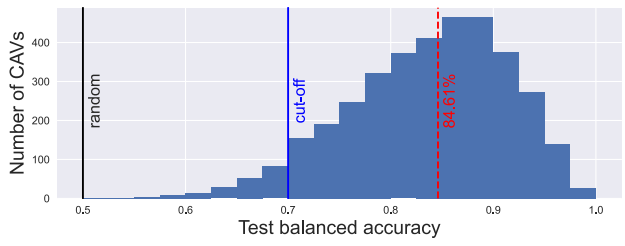

Figure 3. Concept learning performances. The middle line indicates the cut-off at 70% accuracy, the right line is the mean accuracy of the remaining CAVs.

5.3 Hierarchy Mining

We conduct a three-fold evaluation of our proposed hierarchy extraction method (section 4) in order to evaluate goal 3: structure; ground-truth comparison; alignment with other sources of concept similarities.

5.3.1 *Structure priors*

We first provide evidence supporting our choice to extract a hierarchical tree graph over other choices of structures. Though we do not have access to a ground-truth graph of the relations between concepts in $\mathcal{C}_D$, we have some priors on what a satisfying result should be like. For instance, we know that musical concepts are often blended (*e.g.* genres). It is thus safe to assume that a good graph of concepts should be *connected*. Extending this property, isolated nodes should strongly be discouraged. As another prior assumption on our target graph, we know that we can usually find several similar playlists to a given one, but that very strongly connected nodes should be infrequent, *sparsity* should thus also be valued.

With these two priors in mind, we inspect various graph baselines that could straightforwardly be obtained from $\mathcal{V}_D$ without our hierarchy extraction step: the similarity graph $A(\mathcal{V}_D)$ from equation (2); a similarity graph obtained from $S(\mathcal{V}_D)$ with an adjusted threshold to match the sparsity of $H(S(\mathcal{V}_D))$ (*Sparse* A); a top-1 most similar neighbours graph of each node; reference random graphs. Their respective sparsity and connectivity is shown in Table 2. It appears that baseline graphs become disconnected as soon as sparsity drops. We also underline that random baselines provide better-behaved graphs than their counterparts, indicating that similarity links are not evenly distributed among nodes, thus pointing to the existence of communities in the graph that justifies the use of betweenness [67]. Using a hierarchy extraction algorithm helps maintain a low sparsity while connecting every node in the graph.

Graph	#Edges (↓)	#CC (↓)	#IN (↓)
H **(proposed)**	3442 (0.03%)	1	0
$A(\mathcal{V}_D)$	1309163 (11%)	1	0
Sparse A	3443	2766	2735
Top-1	3443	134	0
Random Sparse A	3443	516	430
Random Top-1	3443	7	0

Table 2. Structure evaluation. We count the number of edges in each graph, of connected components (*CC*), and of isolated nodes (*IN*). Lower is better.

This study does not prevent using sparse and connected graphs other than hierarchies. We believe that other relevant structures may exist. Nonetheless, as additional benefits of using hierarchies, we note that tree-like graphs are always planar, which eases their visualisation and navigability by having only one most-relevant parent per node.

5.3.2 Ground-truth evaluation

To validate our generated concept hierarchy, we compare $H(S(\mathcal{V}_{\text{mood}}))$ and $H(S(\mathcal{V}_{\text{genre}}))$ to the expert tag hierarchy provided with the APM dataset – which is unavailable for $\mathcal{V}_D$. As those hierarchies are two-levelled – *i.e.* clustering of tags, we evaluate the accuracy of the mined edges at linking neighbours from the same cluster and compute a silhouette score [68]. Judging from the results given in Table 3, the generation is promising but far from perfect.

The estimated hierarchy of genres is illustrated in Figure 1(c) to help interpret the results. As a typical failure case, the orange cluster ("Electronica") ends up in two separate branches, which can happen because of the greedy construction of our hierarchy. In other cases, however, the ground-truth may be questioned: "Latin influence", "Latin", "Ethnic Dance" and "Calypso" form a link in our hierarchy, but belong to four different clusters in the ground-truth – due to non-musical taxonomic considerations – despite being musically similar. It is not easy to quantify the performance upper-bound we have between our musical concept detection and the practical expert taxonomies we compare to. Nevertheless, seeing that our generated hierarchies roughly align with ground-truth structures is a good sanity check.

Tags	Accuracy (%)	Silhouette
H_{mood}	45.1	-0.09 $\pm$ 0.05
H_{genre}	49.1	-0.17 $\pm$ 0.04

Table 3. Evaluation of our unsupervised hierarchy against ground-truth clustering of moods and genres tags.

5.3.3 Alignment to various sources

Coming back to the difficult setting of $\mathcal{V}_D$, we finally evaluate our hierarchy of concepts with mixed types, illustrated in Figure 2. As we do not have a ground-truth in this general case, we evaluate whether the edges of our hierarchy – built from $S(\mathcal{V})$ – make sense on other sources of similarity. Specifically, since our data is collected from a streaming service, collaborative filtering embeddings [69] based on listening logs are available to estimate playlist similarities (S_{CF}). Playlists similar in concepts could indeed be expected to be co-listened by users, though popularity biases are also at play. We also leverage playlist titles and expect neighbours to be rather close semantically. To that end, we use a large language model [70] that can embed any text prompt (S_{BERT}), and two music-specialised word embedders for which we average representations of in-vocabulary words of each concept names: $S_{\text{W2V-1}}$ [9] and $S_{\text{W2V-2}}$ [71]. For reference, we generate hierarchies from each domain-specific source, include a random hierarchy, and a *Audio* measure based on CAVs weights, following our observations made in section 3.4.

We compute the average similarity on each hierarchy's edges given those several sources of similarities. Results are provided in Table 1. By construction, each hierarchy maximises performance on the source it was built on. We rather inspect how one source of knowledge transfers to other sources. Collaborative filtering being the canonical way of estimating similarities in the streaming industry our dataset is extracted from and in general [45], we underline that our hierarchy – solely based on audio – closely matches its transfer performances, which is a good result [4]. We have thus shown that our hierarchy transfers to other sources of knowledge (goal 3).

5.4 Qualitative discussion

We retrieve many associations that make sense for humans in $H(S(\mathcal{V}_D))$: blues and jazz; rock and pop; motivation, dancing, running, and party are close to one another – which aligns with previous work [72]. More interestingly, we observe that *"LSD Trip"* is the parent of *"Surf"*, *"Summer of love"*, and *"Stoner Rock"*, effectively associating an activity to a sport, an historic phenomenon, and a music genre. Yet, we also find some association that make sense for the model but not for humans: *e.g. "Rock Christmas"* is also a child of *"LSD Trip"*. This phenomenon is hard to avoid with fully unsupervised methods [53, 73]. We can find many more interesting associations, but we have to beware of confirmation biases, as often in XAI [51, 52, 74]. We provide online visualisations of the results [5].

As observable limitations, $\mathcal{V}_D$ is biased by the streaming platform usage towards French, English, and Brazilian content, which could be addressed in future work with importance sampling. Then, some concept titles are misleading, *e.g.* playlists "City sounds: <city>" are confounded by the taste of their curator, resulting in city concepts being close to the 60's genre, despite this not being obvious solely judging from the title. Finally, as already mentioned, the backbone fails to discriminate linguistic information: *e.g. "Queer Pop"* and *"[Current] Pop"* differ by their lyric theme but are neighbours in the hierarchy.

6. CONCLUSION

Spectrograms are hard to interpret. We propose to extend concept learning to learn hierarchies of music concepts from playlists, with greater flexibility than usual music taggers. Our results should be viewed as complementary to expert music ontologies, as a means to witness how music is organically described by users and editors, and thus to capture new or evolving salient aspects of music.

This topic is novel and further steps are necessary in order to overcome cultural biases of our data, and to discover causal relations for our structure. Future work include leveraging the found hierarchy for dynamic music recommendation – e.g. exploring and switching branches.

[4] Why not use CF embeddings then? As a reminder, they are tied to the dataset, and thus fail goal 2. They are only used for comparison.

ABSTRACT

Song embeddings are a key component of most music recommendation engines. In this work, we study the hyper-parameter optimization of behavioral song embeddings based on Word2Vec on a selection of downstream tasks, namely next-song recommendation, false neighbor rejection, and artist and genre clustering. We present new optimization objectives and metrics to monitor the effects of hyper-parameter optimization. We show that single-objective optimization can cause side effects on the non optimized metrics and propose a simple multi-objective optimization to mitigate these effects. We find that next-song recommendation quality of Word2Vec is anti-correlated with song popularity, and we show how song embedding optimization can balance performance across different popularity levels. We then show potential positive downstream effects on the task of play prediction. Finally, we provide useful insights on the effects of training dataset scale by testing hyper-parameter optimization on an industry-scale dataset.

1. INTRODUCTION

Modern Recommendation Systems (RS) rely on embedding vectors to represent the latent user and item factors [1]. They can be employed for several downstream applications, ranging from song recommendation in radio stations or playlists [2–7], search [8, 9], tagging [10], to the generation of artist and genre representations for annotation and recommendation tasks [11–13]. Embeddings are usually generated in the early stages of complex RS pipelines, often through self-supervised methods like Word2Vec [14], which come with default hyper-parameters tuned on non-RS tasks (e.g., NLP).

Practitioners and researchers in the field hence need feasible optimization objectives and reliable metrics to compare against when optimizing embeddings. Recent research shows that hyper-parameter optimization can significantly improve recommendation quality [15,16]. While prior work mainly focuses on recommendation tasks, it is worth considering other tasks like false positive rejection and clustering during optimization.

Additionally, embedding spaces are used as a source of knowledge and interpretation either through visualization tools [17, 18], or by using relationships between items from a statistical standpoint or by leveraging information outside the input data [19–22]. We believe that music-RS practitioners and researchers could benefit from a deeper understanding of the behavior of song embedding optimization in relation to important factors such as song popularity. This could assist them in handling some emerging algorithmic biases like the popularity bias [23–25].

1.1 Contributions

In this work, we provide a strong framework within which it is possible to monitor the performance of embedding models and evaluate the potential of the embedding model to adapt to new tasks. Our work presents a general methodology that can be applied to any embedding system and not only to Word2Vec. The main contributions are:

- We define metrics and optimization objectives for three relevant tasks: next-song recommendation, false neighbor rejection, and genre and artist clustering.
- We demonstrate experimentally that single-objective optimization can have negative side effects on the non optimized metrics and propose a multi-objective optimization approach to combine recommendation and clustering objectives effectively.
- We show that next-song recommendation quality and song popularity are anti-correlated and reveal that song embedding optimization can balance performance across different popularity levels.
- We show the potential positive downstream effects on the task of play prediction revealing that the benefits of song embedding optimization extend beyond the tasks considered during optimization.
- Finally, we study embedding optimization at scale on an internal dataset of billions of listening events and show that increasing training dataset size allows for better configurations at the expense of longer optimization times.

2. METHOD

We consider song embeddings based on Word2Vec. This model was originally created to represent words in an

Mauch, "Multi-objective Hyper-parameter Optimization of Behavioral Song Embeddings", in *Proc. of the 23rd Int. Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

English corpus through a self-supervised shallow neural network trained to learn dense vector representations of the words from sentences based on the surrounding words [14]. The same principle is now commonly used in recommender systems to compute item embeddings from user interaction sequences like site sessions or playlists [25–28].

We study song embedding optimization with respect to four main tasks: next-song prediction, false neighbor rejection, artist clustering, and genre clustering. We define in this section the task and metrics that we used both for embedding optimization and evaluation of its effects on the resulting embedding space.

2.1 Next-Song Prediction

We choose next-song prediction as our primary target task. Next-item prediction is a common recommendation task whose goal is to predict the next item the user will interact with given some context [29]. In music recommenders, this often translates to predicting the next song given the history of songs played by the user [30]. To ensure the contextual relevance of recommendations, the past play history is often limited to the past few played songs or sessions, although more flexible solutions that look beyond a fixed horizon exist [31].

Since our main goal is not to build the most accurate next-song predictor, but rather to measure effects of optimization on the embedding space as directly as possible, we simplified next-song prediction to the extreme case of predicting the next played song based only on the *immediately preceding* song. For each song in the evaluation set (the *target* song henceforth), we consider the song the user played before it as the *query* song. For each (query, target) pair, we simply retrieve the top-100 exact nearest neighbors of the query and compute the average HitRate and Normalized Discounted Cumulative Gain (NDCG) on the top-100 ranked neighbors. HitRate is the fraction of times the target song is contained in the nearest neighbor of the query, while NDCG also accounts for the rank of the correct next-song within the predictions [32].

In order to ensure that improvements are due to true generalisation and not to overfitting, we split the evaluation into in-set and out-of-set. In *in-set evaluation*, we mask the last song in every training sequence and use second-to-last song as the query to compute next-song prediction metrics. In *out-of-set evaluation*, we hold-out the whole play sequences in the validation and test sets, and use every ordered pair of songs therein contained to compute the next-song prediction metrics. We use the average in-set and out-of-set HitRate and NDCG values in our experiments. The precise definition of a sequence varies between our experimental datasets and will be discussed in Section 3.

2.2 False Neighbor Rejection

Since high quality nearest neighbors are essential to providing a good recommendations, we are interested in evaluating the effectiveness of filtering out *spurious* song neighbors, i.e., songs that are in the closest neighborhood of another song merely by chance and not due to real behavioral or metadata similarity.

Query song	Hard Negative Neighbors
Paradise - Coldplay	Snowman - Sia Immigrant Song - Led Zeppelin Basket Case - Green Day
Smells Like Teen Spirit - Nirvana	Power - Kanye West Ob-La-Di, Ob-La-Da - The Beatles Rock Your Body - Justin Timberlake
Carry On Wayward Son - Kansas	Natural - Imagine Dragons Rap God - Eminen It Ain't Me - Kygo & Selena Gomez

Table 1: Examples of hard negative neighbors in Stream.

To this end we define the task of False Neighbor Rejection. We used a chi-squared X^2 test to identify false neighbors in the play sequence dataset [33]. The X^2 test compares the observed co-occurrence frequencies of every pair of songs in the listening sequences against the expected co-occurrence frequencies in case of independence. It is thus suitable to detect pairs of songs that appear in sequence by chance, and not because they are strongly related due to behavioral factors or metadata. In practice, we compute the X^2 coefficient for each unordered bigram of songs in the play sequence dataset. We consider as a *hard negative neighbor* of a song any other song having high co-occurrence but chi-squared statistic below a significance threshold [1] .

One limitation of this approach is that it requires a large number of events to be able to find frequently co-occurring song pairs by chance. We were therefore able to run this analysis only on the Stream dataset, from which we retrieved 5M hard-negative pairs, with an average of 92 hard-negatives per song. Some examples of hard negative neighbors are shown in Table 1. We define the HardNeg metric as the proportion of hard negatives for the top-100 nearest neighbors of every song (the smaller the better). We will use it as a safeguard metric agains undesired side effects of song embedding optimization.

2.3 Artist and Genre Clustering

We are interested in measuring how strongly classes such as artists and genres cluster together in a given embedding space. We introduce here the concept of Local Genre Coherence of the embedding space as the average fraction of songs in nearest neighbors set having the same primary genre as the query song. We similarly define the Local Artist Coherence as the average fraction of nearest neighbors belonging to the same artist as the query song. For example, an embedding space has Local Genre Coherence $= 0.5$ if on average 50% of the nearest neighbors of each song have its same primary genre.

Computing Local Coherence metrics is a costly operation since it requires us to inspect the nearest neighbors of every embedded song. We instead propose to use as *proxy metric* during optimization the much cheaper Caliński-

[1] We empirically chose 10^{-7} times the sum of all song occurrences in the dataset as threshold.

Dataset	Stream	Stream-1%	LFM-1b
Songs	66M	17M	31M
Events	255B	2.6B	1B
Sequences	0.9B	9.3M	120K
Sequence length: mean	277	276	9044
Sequence length: 25th percentile	16	16	1138
Sequence length: median	29	27	3930
Sequence length: 75th percentile	58	57	16155

Table 2: The statistics of the datasets.

Parameter	Default	Range	Description
d	100	$[25, 200]$	Embedding vector dimension
L	5	$[1, 40]$	Sliding window max length
α	0.75	$[-1.0, 1.0]$	Negative sampling exponent
N	5	$[1, 100]$	Number of negative samples
λ	0.025	$[0.001, 0.1]$	Initial learning rate

Table 3: Default Word2Vec hyper-parameters and their respective optimization ranges.

Harabasz index or Variance Ratio Criterion (VRC) [34] over artist and genre clusters in the embedding space. The VRC is the ratio of the sum of between-clusters dispersion and of within-cluster dispersion for all genre clusters, where dispersion is the sum of squared distances. Higher VRC values correspond to better separation among clusters, which is a desirable property because it reduces the chances of uncontrolled, cross-artist and cross-genre pollution in recommendations.

We study the optimization of embedding spaces with respect to clustering metrics and their relation to recommendation quality in Section 4.3 and 4.4.

3. DATASETS

We run our experiments on two datasets. The first is a large-scale proprietary dataset of anonymized streaming listening sequences and playlists. We call this dataset Stream. The second is the LFM-1b dataset which contains 1B time-stamped listening events collected from Last.fm [35].

The main statistics of each dataset are shown in Table 2. The sequence length distribution differs significantly between the two datasets. Stream contains large numbers of both long listening suquences and short playlists (the median length is 58, but mean is 277), while LFM-1b contains mainly long listening sequences (the median length is 3930). This will have an impact on the optimal hyper-parameters discovered for each dataset.

In order to compute artist and genre clustering metrics we need song-level artist and genre annotations. For the Stream dataset, each song in is mapped to the corresponding primary genre and artist through an internal auto-tagging pipeline. LFM-1b already comes with song to artist mappings, however song-level genre annotations are not directly available. We hence mapped each song to the *first* Freebase artist genre from the LFM-1b User Genre Profile dataset [36]. We are aware of the noise introduced by this approximation, yet we believe it provides a useful contribution towards the reproducibility of our experiments.

We partition both datasets by randomly sampling sequences without replacement with proportions 98/1/1 for training, validation and test respectively. However, Stream still contains 7500 times more sequences than LFM-1b, which makes optimization at full-scale impractical. We hence downsample the sequences in the dataset using a 1% rate. We will refer to this subsampled dataset to as Stream-1%. We will investigate how to scale the optimization up to the full dataset in more detail in Section 4.7.

4. EXPERIMENTS

We report here the optimization of song embeddings for the tasks defined in the previous section. We optimize the hyper-parameters of skip-gram Word2Vec by running Bayesian Hyper-Parameter Optimization (HPO) [37], initialized with 10 iterations of Random Search [38] before running Bayesian Search until convergence. Similarly to previous work, we constrained all training times to be approximately equal to the default Word2Vec configuration [16]. This ensures a fair comparison among trials, and prevents the optimizer from discovering configurations that are impractical to train at large scales.

4.1 Background on Word2Vec

Both variants of Word2Vec, Skipgram and the Continuous Bag of Words (CBOW), are self-supervised shallow neural network models trained by minimizing the categorical cross-entropy loss with approximation softmax [14]. Here we consider Skipgram with negative sampling for its superior computational efficiency [39].

The hyper-parameters of Word2Vec, their defaults and optimization ranges are detailed in Table 3. In short, d is the embedding size, L is the maximum window length, α controls the negative sampling (uniform sampling for $\alpha = 0$, popularity sampling $\alpha > 0$, inverse popularity sampling for $\alpha < 0$), N is the number of negative samples used to approximate the softmax and λ is the learning rate.

4.2 Optimizing for Next-Song Recommendation

We first analyze the optimization of next-song recommendation quality by running HPO with the HitRate objective. In line with previous works, we observe significant improvements with respect to the default configurations on both the tested datasets (second line of Table 4). On Stream-1%, HitRate improves by 5% and NDCG by 7%, while HardNeg reduces drastically by 40%. The reduction in HardNeg ensures that the improvement in recommendation accuracy does not comes at the expense of more false positive neighbors. On LFM-1b we similarly observe +19% HitRate and +31% NDCG. The results on this task are in line with previous findings [15, 16].

We are now also able to monitor the effects of optimization on Genre and Artist Clustering metrics. While, $\text{VRC}_{\text{Genre}}$ and $\text{VRC}_{\text{Artist}}$ slightly increase on Stream, they both reduce on LFM-1b. This suggests that recommendation and clustering metrics may be slightly anti-correlated

		Stream-1%					LFM-1b			
Opt. Type	Objective	HitRate	NDCG	HardNeg	$\text{VRC}_{\text{Genre}}$	$\text{VRC}_{\text{Artist}}$	HitRate	NDCG	$\text{VRC}_{\text{Genre}}$	$\text{VRC}_{\text{Artist}}$
N/A	N/A	0.3538	0.1378	0.0180	927	3.373	0.3771	0.1562	520	4.141
Single-obj	HitRate	$0.3725^{\uparrow}$	$0.1482^{\uparrow}$	$0.0108^{\uparrow}$	1033	4.437	$0.4492^{\uparrow}$	$0.2050^{\uparrow}$	382	3.457
	$\text{VRC}_{\text{Genre}}$	0.3000	0.1218	0.0146	2006	5.521	0.3776	0.1609	1293	8.603
	$\text{VRC}_{\text{Artist}}$	0.3402	0.1336	0.0175	1397	**34.347**	0.3532	0.1488	**1444**	**94.476**
Multi-obj	$\lambda_{\text{Genre}}(0.01)$	$\mathbf{0.3772}^{\uparrow}$	$\mathbf{0.1586}^{\Uparrow}$	$0.0084^{\uparrow}$	1495	5.216	$0.4428^{\uparrow}$	$\mathbf{0.2092}^{\uparrow}$	623	5.955
	$\lambda_{\text{Genre}}(0.1)$	$0.3742^{\uparrow}$	$0.1515^{\Uparrow}$	$0.0096^{\uparrow}$	1617	5.771	$0.4067^{\uparrow}$	$0.1698^{\uparrow}$	997	7.298
	$\lambda_{\text{Artist}}(0.01)$	$0.3699^{\uparrow}$	$0.1520^{\Uparrow}$	$\mathbf{0.0057}^{\Uparrow}$	1166	4.580	$0.4458^{\uparrow}$	$0.1883^{\uparrow}$	487	5.469
	$\lambda_{\text{Artist}}(0.1)$	0.3331	0.1332	$0.0093^{\uparrow}$	**2233**	7.422	$\mathbf{0.4537}^{\uparrow}$	$0.1998^{\uparrow}$	619	6.022

Table 4: Results of hyper-parameter optimization on both datasets. The first line reports the metrics for the default configuration. Best results are in **bold**. For HR/NDCG/HardNeg only: $^{\uparrow}$ and $^{\Uparrow}$ denote stat. sig. improvement over the default and the best single-objective configurations respectively (paired t-test at $p < 0.01$ with Bonferroni correction).

for this dataset. We will investigate this effect further in Section 4.3 and 4.4.

4.3 Optimising for Genre and Artist Clustering

We now analyze the optimization of embeddings with respect to the Local Genre and Artist Coherence by using the Variance Ratio Criterion as a proxy objective.

We first show that VRC is a suitable proxy by comparing it against Local Coherence metrics on Stream-1%. We computed Local Genre Coherence on 500 songs with at least 10k plays selected using stratified sampling across the top-10 played genres and using 50 nearest neighbors per song. Figure 1 (left) shows strong positive correlation between average Local Genre Coherence and $\text{VRC}_{\text{Genre}}$ of 5 embedding spaces generated with different hyper-parameters. We similarly computed Local Artist Coherence by sampling 125 artists having at least 25 songs using stratified sampling by artist popularity to account for popularity biases. We then average artist coherence score over 5 songs per artist and 50 nearest neighbors per song. Figure 1 (right) shows positive correlation between Local Artist Coherence and $\text{VRC}_{\text{Artist}}$ of 5 embedding spaces generated with different hyper-parameters.

Table 4 shows that the optimal configuration for genre clustering on Stream-1% doubles the $\text{VRC}_{\text{Genre}}$ score compared to the default hyper-parameters, but with a significant reduction in terms of HitRate and NDCG. The next-song recommendation quality is thus badly affected by the myopic optimization of genre coherence. This effect is slightly less evident for artist clustering optimization, in which we were able to obtain 10 fold greater $\text{VRC}_{\text{Artist}}$ with negligible decrease in HitRate and NDCG. In both cases, HardNeg is not significantly affected.

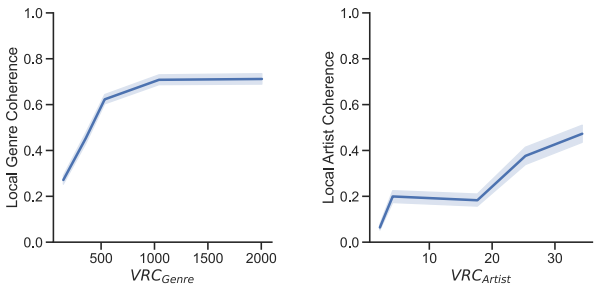

Figure 1: Local Coherence for genres (left) and artists (right) on Stream-1%. Means and 95% Confidence Intervals are shown.

We observe similar effects on LFM-1b, where significant improvements in $\text{VRC}_{\text{Genre}}$ and $\text{VRC}_{\text{Artist}}$ correspond to non significant improvement (genre clustering) or significant deterioration (artist clustering) of next-song recommendation metrics.

For both datasets, the optimal configurations have significantly worse next-song recommendation quality than the optimal one found by single-objective next-song recommendation. This suggests that optimizing embeddings for clustering alone can seriously harm the recommendation quality. In the next section we tackle the problem of optimizing both objectives simultaneously.

4.4 Multi-objective Optimization

High quality next-song recommendation and genre/artist clustering are both desirable properties of the embedding space but, as we have just observed, optimizing for a single objective can harm others. We investigate here the simultaneous optimization of both objectives through Multi-Objective Hyper-parameter Optimization (MOHPO).

The simplest approach to MOHPO is scalarization, which transforms a multi-objective goal into a single-objective one. Examples of scalarization are the weighted sum, Tchebycheff or ϵ-constraint approaches [40]. Advanced MOHPO techniques extend evolutionary algorithms and Bayesian Optimization to explicitly handle different trade-offs between the multiple objectives [40]. The choice of the optimal MOHPO method is beyond the scope of this work, hence we opted for Bayesian Optimization with scalarization since it fits easily into our existing optimization framework.

We focus on the joint optimization of HitRate and $\text{VRC}_{\text{Genre}}$. The same reasoning holds for HitRate and $\text{VRC}_{\text{Artist}}$ and it is omitted for space reasons. Since these metrics have widely different scales, we first define the relative improvement in $\text{VRC}_{\text{Genre}}$ of a new hyper-parameter

configuration t with respect to the default configuration:

$$\text{rVRC}_{\text{Genre}}{}^{(t)} = \frac{\text{VRC}_{\text{Genre}}{}^{(t)} - \text{VRC}_{\text{Genre}}{}^{(def)}}{\text{VRC}_{\text{Genre}}{}^{(def)}} \quad (1)$$

where $\text{VRC}_{\text{Genre}}{}^{(def)}$ is the $\text{VRC}_{\text{Genre}}$ for the default configuration. The new scalarized objective is the simple convex combination of the two objectives:

$$\lambda_{\text{Genre}}(\alpha) = \alpha\text{HitRate}^{(t)} + (1-\alpha)\text{rVRC}_{\text{Genre}}{}^{(t)} \quad (2)$$

where α controls the relative weight of next-song recommendation and genre clustering objectives in the optimization.

We tried values of $\alpha = 0.01$ and 0.1. Results shown in Table 4 highlight the effectiveness of this approach on Stream-1%. While there is not a single solution that performs best on all metrics, the configuration found with objective $\lambda_{\text{Genre}}(0.01)$ *dominates* the best solution discovered by next-song optimization on all metrics, with statistically better NDCG (+7%). The configuration found with objective $\lambda_{\text{Artist}}(0.01)$ also achieves statistically better HardNeg, with a reduction of 68%, at the expense of lower clustering scores. In both cases increasing the value of α to 0.1 we can effectively trade some next-song prediction accuracy for better genre and artist clustering quality. The optimal setup depends on the final application.

Similarly, on LFM-1b we observe that the best next-song recommendation strategies are found through multi-objective optimization, although no solution entirely dominates any single-objective this time. This fact can be partly attributed to the noisy genre annotations we have available for this dataset.

These results highlight the effectiveness of combining recommendation and clustering objectives, which can mutually benefit from each other if combined properly.

4.5 Insights on Song Popularity

The effects of popularity on recommendations are subject of intense research activity within the research community [23–25]. We contribute here by studying the effects of next-song recommendation HPO on (query, target) song pairs belonging to various buckets of popularity.

We first categorize songs into buckets of popularity, each of which comprises 20% of the total listening events in the dataset, being 0 the smallest bucket with most popular songs and 4 the largest bucket containing the least popular ones [2]. We randomly sample 1k songs per bucket pair and the aggregate HitRate based on query *and* target bucket. For the sake of space, we analyze the Stream dataset only here. The results on LFM-1b are available in the Supplementary Material.

Figure 2a shows the values of HitRate by bucket pair for the default configuration of Word2Vec. We first observe that the recommendation quality is localized to the same or nearest popularity bucket to which the query song belongs. As the query and target begin to differ in popularity, HitRate drops. We clearly see that HitRate is anti-correlated with popularity. One possible explanation is that popular songs by definition give less information about the user tastes and hence have larger sets of plausible "next-songs". On the other hand, the less popular songs often belong to taste "niches" and are thus easier to model.

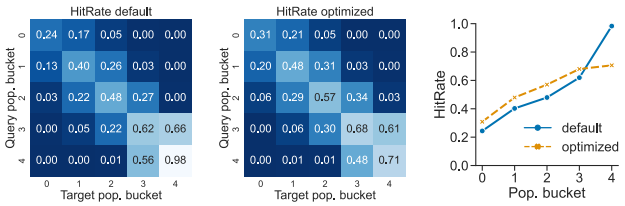

Figure 2: Query-target popularity analysis for Stream: HitRate by popularity bucket for the default configuration (a) and the optimized one (b), and HitRate for song pairs in the same popularity bucket (c). Bucket 0 contains the most popular songs.

Figure 2b shows the values of HitRate by bucket pair for embeddings for the optimal $\lambda_{\text{Genre}}(0.01)$ multi-objective configuration. The behavior of localized performance and anti-correlation observed using the default configuration is still visible. However, we notice a significant difference between the two configurations across the main diagonal. We have highlighted this difference in Figure 2c. We can see that tuning brings significant gains in HitRate at all buckets except for the least popular songs in 4. On both datasets [3] optimization seems to balance recommendation accuracy more across popularity buckets, which is a desirable effect.

4.6 Insights on Play Prediction

As song embeddings are usually used as inputs to other pipelines, we wanted to explore whether embedding optimization had beneficial effects on a different task from the one it was originally run on. For the sake of this experiment, we considered the problem of Play Prediction in seeded radio and autoplay. In seeded radio, the user selects a *seed*, e.g., an artist or a song, and the recommender generates an endless sequence of songs that are related to that seed. Similarly, autoplay generates a stream of music starting from the last played song in an album or a playlist. Seeded radio and autoplay are two prominent product features that allow users to generate streams of songs that are fully machine-learning driven. In both cases, the user organically selects only the seed or the collection from which to start the stream of music, and everything else is left to the recommendation algorithm to decide.

In this context, we study the reaction that users have on the *first* recommended song, since it is where the transition from organic to algorithmic selection happens. A bad listening experience at this point could easily induce users to stop listening entirely. We thus consider the task of pre-

[2] The songs that account for the top-20% of all plays end in bucket 0, the ones for the top-20% to 40% end in bucket 1, etc.

[3] Figures for LFM-1b omitted to fit within space limits.

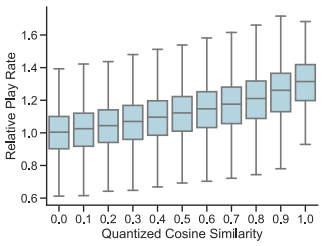

Figure 3: Visualization of the positive correlation between Relative Play Rate and cosine similarity on default embeddings (similarities quantized to the first decimal). Play Rates are scaled relative to cosine similarity $= 0.0$ to preserve business sensitive values.

	Default	Single-obj	Multi-obj
All pairs	0.2055	0.2140	0.2304
Frequent pairs	0.3335	0.3480	0.3717

Table 5: Pearson's correlation between Play Rate and cosine similarity for default and optimized embeddings.

dicting whether the first song generates a play event that lasts at least 30 seconds. We call this task Play Prediction.

Building an accurate predictor is beyond the scope of this paper. We instead measure the correlation between the Play Rate, i.e., the average number of times one organic play is followed by a successful algorithmic play, and the cosine similarity between the embeddings of the recommended and the seed songs. We use Word2Vec embeddings trained on the full Stream dataset. We compare default hyper-parameter configuration to the single-objective and multi-objective configurations having the highest HitRate on this dataset. We compute Play Rates on a proprietary dataset composed of 4.2M song pairs extracted from 184M listening sessions.

Figure 3 shows that there is a strong positive correlation between Play Rate and cosine similarity between embeddings. We observe positive correlation for both the default and optimized embedding spaces (Table 5). The correlation is stronger for the most frequent pairs (≥ 100 occurrences). However, the correlation is stronger for the optimized embeddings than the default ones, $+4\%$ for the best single-objective configuration and $+12\%$ for the best multi-objective configuration. This suggests that embedding optimization can have beneficial effects on tasks different from the one it was initially designed to address. Furthermore, it provides additional evidence on the superiority multi-objective optimization over single-objective one.

4.7 Optimization at Scale

To the best of our knowledge, there exists little literature on hyper-parameter optimization over massive datasets with billions of sequences and events. Previous work on the topic either optimize directly on the full dataset, which is unfeasible at scales like our Stream dataset, or consider a *fixed* subsample rate [16]. However, it is unclear which subsample rate would lead to results that are representative of performance at full-scale.

Sampling	Opt. time	HitRate	NDCG	HardNeg	$\text{VRC}_{\text{Genre}}$	$\text{VRC}_{\text{Artist}}$
N/A	N/A	0.3079	0.1217	0.0126	7229	3.266
1%	28h	0.3432	0.1378	0.0109	7367	3.780
2%	47h	0.3499	0.1421	0.0063	6886	3.374
5%	83h	0.3729	0.1506	0.0167	10410	3.992

Table 6: Results of multiple scale HPO on Stream, with the total optimization time and the best metrics obtained full scale (first line refers to the default configuration). Better performance is obtained at the largest subsample rates at the expense of longer optimization times. All pairwise comparisons on HitRate, NDCG and HardNeg are stat. sig. at $p < 0.01$ using Bonferroni correction, except for HardNeg between default and 1% sampling.

We explore this aspect by running Hyper-Parameter Optimization at increasing training dataset scales. The best hyper-parameters found at each data scale are then used to train the model at full-scale. We limit training time to stay within 25% more the time of training runs with the default hyper-parameters. This allows us to identify the best representative subsample rate while keeping optimization times within reasonable limits.

We split the Stream dataset into 4 overlapping training sets containing 1%, 2%, 5% and 98% of randomly selected sequences respectively, We run Bayesian hyper-parameter search on the first 3 splits and use the best hyper-parameters from each run to train Word2Vec at full 98% scale. For simplicity, we consider just single-objective HitRate optimization. Table 6 shows that there is significant correspondence between the sampling rates used during optimization and the final performance on the full scale dataset. The optimal configuration found at 5% scale is by far the best when evaluated at full-scale on all metrics. However, the total optimization time increases significantly when larger subsamples are used.

5. CONCLUSIONS

In this paper we analyzed the offline optimization of song embeddings through the lens of the tasks they are often employed on downstream. We proposed an effective way to optimize Word2Vec hyper-parameters on recommendation and clustering tasks jointly, with substantial benefits over their respective single-objective optimization variants. We investigated the interactions between next-song recommendation and song popularity. Our results suggest that careful optimization has the desirable property of balancing algorithm performance across popularity buckets. We showed the potential positive effects of optimization on the downstream task of Play Prediction, which provided further evidence on the superiority of multi-objective optimization over single-objective one. Finally, we investigated the effects of optimization at scale, which is particularly relevant for industrial applications.

As future work, we plan to validate these insights with online A/B testing. Our approach can be extended to other tasks, like diversity and fairness, and to the latest findings in Multi-Objective Hyper-parameter Optimization [40,41].

6. AKNOWLEDGEMENTS

We would like to thank Matt Jockers and all the members of the Music Machine Learning team for their help in improving and proofreading this work.

ABSTRACT

Computational models of expressive piano performance rely on attributes like tempo, timing, dynamics and pedalling. Despite some promising models for performance assessment and performance rendering, results are limited by the scale, breadth and uniformity of existing datasets. In this paper, we present ATEPP, a dataset that contains 1000 hours of performances of standard piano repertoire by 49 world-renowned pianists, organized and aligned by compositions and movements for comparative studies. Scores in MusicXML format are also available for around half of the tracks. We first evaluate and verify the use of transcribed MIDI for representing expressive performance with a listening evaluation that involves recent transcription models. Then, the process of sourcing and curating the dataset is outlined, including composition entity resolution and a pipeline for audio matching and solo filtering. Finally, we conduct baseline experiments for performer identification and performance rendering on our dataset, demonstrating its potential in generalizing expressive features of individual performing style.

1. INTRODUCTION

Expressive piano performance has long been explored using data-driven approaches for performance analysis and generation. Recently, more attention has been paid to data-hungry, deep learning techniques, for expressive performance rendering and assessment [1, 2]. Large-scale datasets of expressive piano performances that vary across composition, performers, genres, etc. are demanded by researchers who intend to build comprehensive models and compare different architectures.

Most of the current work that studies expressive piano performances [3–5] uses MIDI rather than audio [6, 7], as MIDI provides easier access to performance attributes including tempo, timing, dynamics, and pedalling. However, datasets that consist of recorded MIDI files from computer-controlled pianos are limited in size and variety. Although promising approaches applied such datasets to train models for rendering human-like piano performances from scores [3,4], researchers were unable to explore performer-specific expressiveness or different schools of playing with deep learning models due to data limitations. Few pay attention to applying deep learning techniques to performer-related tasks such as performer identification [8, 9], style-specific performance rendering [4, 10], and performance style transfer.

Our contribution is three-fold: First, we performed an error analysis for piano performance transcription, comparing state-of-the-art models and verifying the reliability of transcribed performances with listening tests in Section 3. Second, we focus on Western classical piano music and release a dataset with sufficient richness and variety for studying expressiveness and styles across different performers. Our released dataset [1] is a performer-oriented dataset that consists of 11742 virtuoso recordings with 1007 hours of music. Instead of recording MIDI files by computer-controlled piano, we collected our dataset by applying state-of-art piano transcription models such as those by Kong et al. [11] and Hawthorne et al. [12] to transcribe the existing audio recordings of piano performances into MIDI files. More details of our dataset and a reproduction pipeline are presented in Sections 3 and 4. Finally, we demonstrate the application of our dataset to the tasks of performer identification and performance rendering in Section 5. Besides these two tasks, ATEPP can also be utilized in analyzing performance attributes [13–15], comparative study of performances and styles [16], as well as performance visualization [17].

formance idioms, comparative study of performance requires multiple versions of the same piece of music, ideally by multiple performers. In the past, datasets with very limited numbers of pieces were recorded and organized by researchers, such as the Mozart [25, 26], Schumann Träumerei [27] and Schubert [8] datasets. The non-trivial task of Composition Entity Resolution **(CER)**, involving the process of automatically aligning the complex naming schemes of classical music, is the major challenge of obtaining multiple performances of the same music at a larger scale. We will detail our CER process in Section 4.1. Among the existing datasets, only the CHARM Mazurka dataset [2] offers CER.

- **Representation:** While the audio recording most faithfully documents a performance, complex processing is needed to extract the expressive attributes from the waveform [28]. MazurkaBL [20] contains many precalculated features that are provided for the Mazurka dataset. Meanwhile, MIDI can serve as a mid-level, piano-roll like representation of piano performance actions. The SUPRA [18] dataset contains expressive MIDI digitised from pneumatic piano rolls, while SMD [19], Maestro [21] and CrestMusePEDB [22] all contain MIDI recorded from Yamaha Disklaviers.
- **Repertoire and diversity:** Given that piano performance traditions are largely associated with the Western classical music paradigm, SMD [19], Maestro [21] and CrestMusePEDB [22] all include standard repertoire from Baroque to Late-Romantic era, while GiantMidi-Piano [23] includes non-standard pieces that span 1.7k composers. The CHARM Mazurka dataset is a great example allowing for multiple-performance comparison, however its repertoire consists only of 49 mazurkas by Chopin.
- **Symbolic score:** A high-level representation of the composition score is typically needed in tasks such as performance rendering [3]. Expressive deviations can be observed by comparing with the quantized, dead-pan score. MazurkaBL [20] and ASAP [24] contain symbolic scores in MusicXML format.
- **Size:** Large datasets are essential for training deep neural networks. Among existing datasets, only GiantMidi-Piano [23] has more than 200 hours of piano music.

2.2 Automatic Piano Transcription

Empowered by deep learning models, recent automatic piano transcription systems can aid expressive performance research by outputting precise measurements of dynamics, timing and tempo at the note-level. The Onsets and Frames transcription model [29] combined framewise pitch detection with onset detection, to produce a full piano roll with velocity. The High-Resolution model [11] improved precision by regressing the exact timestamp of each note. A recently proposed generic encoder-decoder architecture [12] that exploits language-like modeling achieved model simplicity while retaining performance.

3. TRANSCRIPTION AND POST-PROCESSING FOR EXPRESSIVE PERFORMANCE

3.1 Common Errors Introduced by Transcription

We categorize common transcription errors into the following three rough categories: harmonic error, segmented note, and mis-touched short note. These errors are obtained by transcribing the performances from the Mazurka dataset using the High-Resolution model [11], and then aligning with its symbolic score in MusicXML using the algorithm by Nakamura et al. [30]. This algorithm aligns two signals, reference and performance, using hidden Markov models (HMMs), detects performance errors from the first alignment result, and then employs a merged-output HMM [31] to correct the errors.

1. **HE**: Harmonic errors (fifths and octaves): The most common type of transcription error is falsely detecting or failing to detect notes that are harmonically related to other played or detected notes. Usually these are missing or extra octaves or fifths, and they result from the overlap of the harmonic series of the pitches.
2. **SN**: Segmented notes: One continuous note being transcribed into two segments with a small (<10ms) gap between offset and onset. This error might come from amplitude modulation [32].

Model	HE	SN	MS	Other
High-Resolution [11]	3.2%	1.5%	1.2%	5.6%
OnsetsFrames [29]	4.2%	2.4%	0.1%	6.7%
Seq2Seq [12]	8.1%	2.9%	0.3%	7.9%

Table 2. Transcription note error rate (aligned with symbolic score) on the Mazurka dataset.

3. **MS**: Mis-touched short notes: The spurious, short notes (<16ms) that appear randomly in transcription.

In Table 2, we quantitatively evaluate the presence of these error types on the Mazurka dataset. Given that no performance ground truth exists for this data, we rely on the MusicXML score and the assumption that the performances match the same score version. Among the three most recent deep-learning based transcription models [11, 12, 29], the High-Resolution model [11] makes the fewest errors overall, but generates more short notes compared to the other models.

Besides notewise errors, another factor of concern for transcribed MIDI is the note duration. From the inference output [11], the notes' durations are elongated to achieve a sustain effect that is usually implemented by sustain pedal in reality. Whilst such elongation doesn't make an audible difference in MIDI rendering software, accurate end positions of each note are required in piano performance analysis.

3.2 Joint Note-Pedal Training

With the goal of reconciling the sustain effect from both pedal and keys, as well as achieving more accurate note offsets, we modify the original High-Resolution model [11] with joint note-pedal training. As the first piano transcription model that incorporated the sustain pedal into training, the High-Resolution model trained separate networks for key activity and sustain pedal (with binary velocity), while extending the note offset to match the pedal off timestamp. In joint note-pedal training, 88 keys and 3 pedal channels are combined to output 91 prediction classes with velocity for each channel, and the extension of note offsets is removed. In this case, during training the sustained effect would be conditioned on both key-down duration as well as pedal controls.

As shown in Figure 1, what we model is the key action from the pianist instead of the string damping time of the note (that can either come from the sustain pedal or key action), which deviates from the traditional transcription task. With other training parameters unchanged, the onset F1 score ($tol = 50\,ms$) achieved is 92.1% after 300k iterations, and onsets and offsets evaluation achieved 68.2%. Note that the evaluation results are much lower than the original results, as we are attempting to learn patterns of behaviour that are not present in the audio.

3.3 Score-Alignment and Correction

As described in Section 3.1, a score-performance alignment algorithm [30] is employed to automatically find

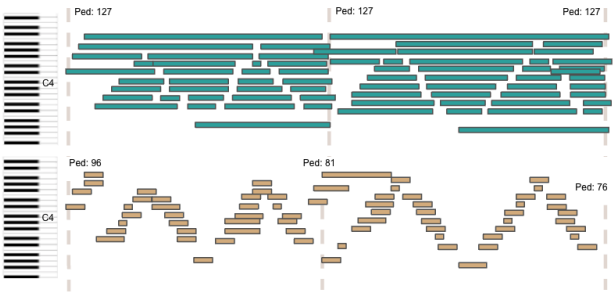

Figure 1. Output pianoroll comparison of the original High-Resolution model (top) and joint note-pedal version (bottom). Dashed lines represent pedal-on messages with velocity.

transcription errors with reference to a score. As a post-processing step, we correct the differences according to the alignment. Extra notes (those in transcription but not in score) are deleted, mismatching notes (aligned with pitch error) are corrected to the pitch given in the score, and missing notes (those in score but not in transcription) are interpolated and written back to MIDI according to the following rule:

$$g(i) = g(i - \Delta_p) + (g(i + \Delta_n) - g(i - \Delta_p))\frac{\Delta_p}{\Delta_p + \Delta_n}, \quad (1)$$

where $g(i)$ is the onset or offset timestamp of the missing note at beat i, and Δ_p, Δ_n represent the beat distances between the missing note and the previous or next existing notes, respectively.

3.4 Listening Evaluation

In order to evaluate the perceptual quality of transcribed piano music, we perform a subjective listening test where participants rate the similarity of reproduced MIDI and the reference recording. In the test, we compare the ground truth with 4 transcribed MIDI renderings: the original High-Resolution transcription system [11] (**C1**), the joint note-pedal model described in Section 3.2 (**C2**), a score-corrected version of C2 as described in Section 3.3 (**C3**), and the language-model transcription system [12] (**C4**). All MIDI performances are rendered using a KAWAI CA49 electric piano and recorded using Zoom H4n Pro Recorder. The recordings are then processed with basic noise-reduction in Audacity.

Participants in the listening test are presented with five *20 s* classical piano excerpts with varying style (Q1-Liszt, Q2-Debussy, Q3-Bach, Q4-Rachmaninov, Q5-Mozart; see appendix for music passages). The test is conducted using the MUSHRA protocol [33], each with 5 recordings (reference plus 4 stimuli). Participants are asked which transcribed stimulus sounded closer to the reference on a 100-point scale. During the test, we explicitly ask participants to ignore the timbral or acoustic differences but make judgements based on the expressive differences between the stimuli such as dynamics and timing.

We collected 1075 ratings from 43 listeners. Half of

	Q1	Q2	Q3	Q4	Q5	Overall
Reference	4.42±0.24	4.17±0.29	4.24±0.31	4.28±0.31	4.46±0.27	4.30±0.12
C1	**4.12±0.38**	3.52±0.37	3.88±0.32	3.60±0.41	3.88±0.4	3.81±0.16

C4	3.88±0.34	2.32±0.47	3.60±0.29	3.84±0.33	3.68±0.37	3.46±0.18

Table 3. Results of listening test. The mean opinion scores (MOS) and 95% confidence intervals are reported.

our listeners reported over 5 years of piano performing experience. Table 3 shows the mean opinion scores (converted to a 5-point scale) from the ratings. According to the Wilcoxon signed-rank test ($p < 0.05$), all stimulus groups differ significantly from the reference. Among the stimuli, C2 is preferred by the listeners, while C3 and C4 have significantly lower ratings compared to the other two groups of stimuli. In free text responses, the score-corrected transcription received negative comments such as *unnatural* and *abrupt*. Consequently, we use the C2, note-pedal jointly trained model for transcribing our dataset. The result also shows a perceptual difference of transcription quality across music styles, demonstrating the bias of transcription models: transcribed fast, arpeggio-heavy passages are rated with lower perceptual quality. But for slow, sparse textures, good transcriptions sound much closer to the reference.

4. DATASET OVERVIEW

4.1 Data Collection and Curation

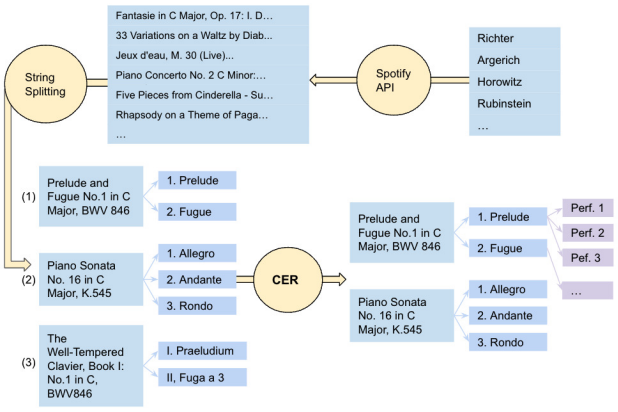

Figure 2. Data curation pipeline.

Our data collection pipeline is presented in Figure 2. Starting with 49 world-renowned pianists, metadata (including composer, performer, album, title and track duration) of their discography was obtained using the Spotify API [3]. After filtering out non-solo keywords such as *concerto* or *trio*, a composition-movement hierarchy was built.

As discussed in Section 2.1, the next challenging step was achieving *Composition Entity Resolution (CER)*, defined as finding out which tracks correspond to the same piece of music, given the variety of naming conventions in classical music. For example, compositions (1) and (3) in Figure 2 actually correspond to the same work, while their title differs so much that a simple string similarity match is not sufficient to resolve them as identical.

We address CER using three steps: **1)** Language-specific mapping. We manually compile a dictionary for interchangeable terms, such as *Prelude* ↔ *Praeludium*. **2)** Unique identifier extraction. Unique information such as key and catalogue number (*Opus*, *BWV*, *K.*, *D.*, etc.) are extracted from the title string. **3)** Fuzzy string matching. For both composition title and movement title, we use normalized Levenshtein distance [34] to compute similarity scores. Note that such string matching is not always reliable, as generic names like *Piano Sonata* are extremely frequent in our discography. Combining the three steps, our composition entity resolution is described in Algorithm 1, where inputs include composition title C and movement title M as well as duration D. Based on the organized metadata, we download each track from a corresponding open source audio at YouTube Music, while the online metadata is again validated by the same CER algorithm.

Algorithm 1 Composition Entity Resolution

```
# UniqueInfo extracts canonical key and composer-specific catalogue number.
for k1, k2 in UniqueInfo(C1, C2) do
    if k1 ≠ k2 then return False
    end if
end for
S_c ← 1 − (Levenshtein(C1, C2))/ max(|C1|, |C2|)
S_m ← 1 − (Levenshtein(M1, M2))/ max(|M1|, |M2|)
S_d ← abs(D1 − D2) / max(D1, D2)
S ← (S_c + S_m)/2 − S_d
return S ≥ 0.6
```

4.2 Audio Matching by Chroma Features

Besides metadata linking using CER, we also match tracks by downloaded audio content to ensure the same piece of music is being performed. Within each group of performances, we apply Chen et al.'s cover song detection algorithm [35] to compare each performance with a reference. We first extract the Harmonic Pitch Class Profile (HPCP) [36] from the reference and the target performance

[3] https://developer.spotify.com/documentation/web-api/

audio. Next, we use the Q_{max} measure, which represents the maximum value of a cumulative matrix computed from the HPCP descriptors of two performances [37]. The similarity between two performances is defined by Eq. 2. We only retain performances whose similarity is larger than 0.9 to build the ATEPP dataset.

$$Sim = 1 - Q_{max}, \quad 0 < Q_{max} < 1 \tag{2}$$

4.3 Applause Filtering with CNN

We also need to filter out any sound that might not be part of a solo piano performance. The most prominent ones are applause and speech from live recordings, which would be transcribed as random pitch. We train a deep learning model based on the Musicnn [38] architecture to filter out any non-solo-piano segment. For each 1 s segment, the probability of non-piano sound is predicted using a binary classifier. In training, a subset of AudioSet [39] with various environmental sounds is used as negative examples, and solo piano recordings are used as positive examples. With a binary tag-gram inferred from the audio, our post-processing step searches for the timestamp of the longest continuous non-solo segment at the beginning and the end to remove from the audio file.

Among the 11742 tracks, 567 of them are detected with starting or ending applause, and were subsequently cleaned. This was followed by a manual verification process by listening to ensure the audio split was accurate.

4.4 MusicXML Score

Given that the musical score is also important for music research, we collect scores in MusicXML format that correspond to our performance data. 228 files are drawn from the ASAP dataset [24], and 90 files from the MuseScore [4] online library, crowd-sourced by the users of MuseScore software. This results in a total of 319 movements, corresponding to 5124 tracks in our dataset (43% of all tracks). The score-performance correspondence is first determined automatically by name matching followed by manual correction.

4.5 Content and Statistics

The ATEPP dataset contains 11742 tracks of 1580 movements. The tracks overlap only 0.2% of the GiantMIDI-Piano dataset [23]. Figure 3 shows a breakdown of the movement-performance distribution. Among 1580 movements, 44% have more than 5 performances, providing us with rich data for studying different interpretations of the same piece of music.

In addition, we show a distribution of the top 25 pianists in our dataset in Figure 4, where Sviatoslav Richter contributes the most data in ATEPP. Composer-wise, solo piano works from 25 Western classical composers are included in our dataset, ranging from the Baroque to the Modern era (a full composer breakdown is given in the appendix).

[4] https://musescore.com/sheetmusic

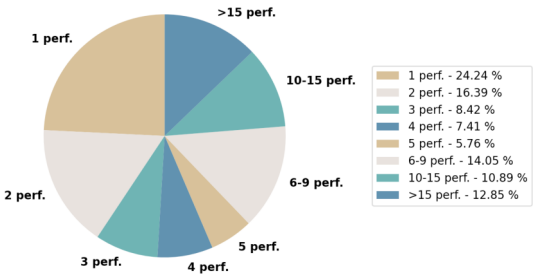

Figure 3. Distribution of movements by number of performances. E.g. 12% of our data have more than 15 performances.

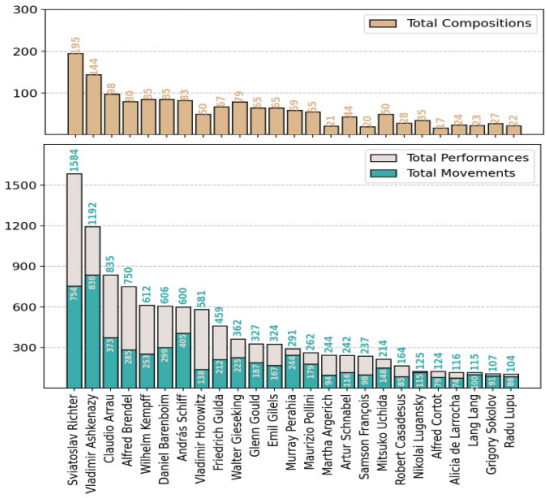

Figure 4. Distribution of the top 25 pianists' performances in the ATEPP dataset.

5. DATASET APPLICATIONS

5.1 Performer Identification

Distinguishing virtuoso performers using computational models has long been studied by researchers who focus on expressive parameters of music performances. Data-driven approaches such as traditional machine learning methods and feature distribution comparison have been applied to this task [8, 9, 40]. However, none of the existing studies have applied deep learning methods to performer identification, due to the lack of large-scale datasets with overlapping performances by different performers.

With the ATEPP dataset, we are now able to train deep neural networks to identify different performers. We choose four subsets from the ATEPP dataset, only considering performers with over 100 performances. For the Mixture subset, we only consider compositions that have more than 15 different performances. We also create three composer-specific subsets (L. Beethoven, F. Chopin, and J. S. Bach) to remove the bias of performer-composer correlation. The train-validate-test split is 8:1:1.

We extracted note-level features including onset and offset time, velocity, and pitch number from the MIDI files without any expression-related preprocessing. We stacked the sequences of those features and input them into a 1D

Subset	Pianists	Size	Acc.	F1-score
Mixture	16	4676	0.47	0.45
Beethoven	12	3078	0.48	0.46
Chopin	5	973	0.55	0.54
Bach	5	1019	0.59	0.55

Table 4. Performer identification results.

convolution neural network (see Appendix for the network details). The model was trained on four subsets at a learning rate of 10^{-4} with a decay weight of 10^{-8}.

With all subsets achieving over 0.45 F1 score in Table 4, our baseline model demonstrates the capability of learning individual performing style if given enough data, as well as generalizing across different compositions.

Moreover, the results from composer-specific datasets show that we can achieve comparable results even when performer-style correlation (e.g. Horowitz's repertoire concentrates on Romantic styles while Gould almost exclusively plays Bach) was removed. Confusion matrices are provided in the appendix as well as precision, recall, and F1-score for each performer.

5.2 Performance Rendering with VirtuosoNet

There has been a growing research interest in quantifying and modelling expressive performance using computational models [1], including understanding of how humans perform [41], automatically generating expressive performances [42], and rendering expressive performances from a score [3]. Again, ATEPP contributes to such tasks by providing expressive performance data on a large scale.

In this study, we show the utility of our dataset using the performance rendering model VirtuosoNet [3]. The model consists of an RNN with a hierarchical attention network to model note, beat and measure level hierarchy of music and a conditional variational autoencoder (CVAE) to model the expressive performance. We selected two pianists' Beethoven performances with over 300 tracks from the ATEPP dataset, and altered the model slightly to render a performance in the style of a particular performer by concatenating a performer label vector to the latent vector. During training, we use the same hyper-parameter setting as the original paper.

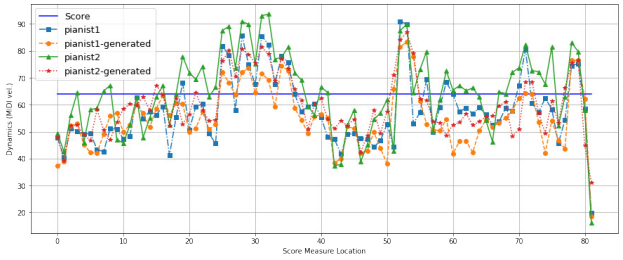

Figure 5. Measure level dynamic variation of Beethoven's Piano sonata No. 3 in C, Op. 2 No. 3, Mvt. II, as performed and generated in the styles of pianists 1 and 2. The flat line depicts the default dynamic level provided in the score file.

The trained model takes a series of note-level score features extracted from MusicXML and a performer name as input, and predicts the corresponding note-level performance features of that performer. Figure 5 shows the real and predicted (pianist1-generated & pianist2-generated) performances of an out-of-sample music, Beethoven's Piano Sonata No. 3 in C Major, Op. 2 No. 3, Mvt. II, by pianist 1 and 2 in terms of dynamics. The flat line represents the default dynamic level of a non-expressive, mechanical rendition of the score.

We can observe that both actual performances and generated performances (in the style of pianist1 and pianist2) tend to deviate from the default interpretation in a similar way; this can be a demonstration of common performance practice. For individual interpretations, we calculated the cross-correlation of the dynamic variation between the actual performance and the generated version using Pearson's correlation coefficient (r). We found that both actual performances from pianist1 and pianist2 are highly correlated ($r > 0.75$) with their generated counterparts, respectively. In addition, we computed the correlation coefficient between the actual performance of pianist1 and the generated performance of pianist2 and vice-versa. Both of them provide a lower correlation coefficient ($r<0.6$). This demonstrates that deep learning architectures are capable of learning some of the expressive techniques of each individual pianist from respective training data.

6. CONCLUSION AND FUTURE WORK

This paper presents ATEPP, a large-scale dataset of 11,742 expressive piano performances by 49 virtuoso pianists. Nearly half of the compositions are provided with scores in MusicXML format. All of the performances were transcribed by a piano transcription model which was trained jointly with pedals and keys. We performed a listening test to evaluate the reliability of the transcription algorithm. To our knowledge, our dataset is the largest dataset of expressive piano performance MIDI with robust metadata of classical music, derived via Composition Entity Resolution (CER). We presented our baseline experiments for performer identification and performer-oriented expressive performance rendering. The results demonstrate that the ATEPP dataset enables us to study expressive features of individual performing styles with deep learning methods.

In the future, we will consider a hierarchical database system that comprehensively links performances with performer, composer, and composition entities through an automatic CER process. A more balanced dataset is planned as well as an extended version with more variety across the skill level of performers.

ABSTRACT

Automatic lyrics transcription (ALT), which can be regarded as automatic speech recognition (ASR) on singing voice, is an interesting and practical topic in academia and industry. ALT has not been well developed mainly due to the dearth of the paired singing voice and lyrics datasets for model training. Considering that there is a large amount of ASR training data, a straightforward method is to leverage ASR data to enhance ALT training. However, the improvement is marginal when training the ALT system directly with ASR data, because of the gap between the singing voice and standard speech data which is rooted in music-specific acoustic characteristics in singing voice. In this paper, we propose PDAugment, a data augmentation method that adjusts pitch and duration of speech at syllable level under the guidance of music scores to help ALT training. Specifically, we adjust the pitch and duration of each syllable in natural speech to those of the corresponding note extracted from music scores, to narrow the gap between natural speech and singing voice. Experiments on DSing30 and Dali corpus show that the ALT system equipped with our PDAugment outperforms previous state-of-the-art systems by 5.9% and 18.1% WERs respectively, demonstrating the effectiveness of PDAugment for ALT.

1. INTRODUCTION

Automatic lyrics transcription (ALT), which recognizes lyrics from singing voice, is useful in many applications, such as lyrics-to-music alignment, query-by-singing, karaoke performance evaluation, keyword spotting, and so on. ALT on singing voice can be regarded as a counterpart of automatic speech recognition (ASR) on natural speech. Although ASR has witnessed rapid progress and brought convenience to people in daily life in recent years [1], there is not an ALT system that has the same level of high accuracy and robustness as the current ASR systems. The main challenge of developing a robust ALT system is the scarcity of available paired singing voice and lyrics datasets that can be used for the ALT model training. Though a straightforward method is to use speech data to enhance the training data of ALT, the performance gain is marginal because there are significant differences between speech and singing voice. For example, the singing voice has some music-specific acoustic characteristics [2,3] – the large variation of syllable duration and highly flexible pitch contours are very common in singing, but rarely seen in speech [4].

Previous works have already made some attempts to artificially generate "song-like" data from speech for model training. Kruspe et al. [5] applied time stretching and pitch shifting to natural speech in a random manner, which enriches the distribution of pitch and duration in "songified" speech data to a certain extent. Nonetheless, the adjustments are random, so there is still a gap between the patterns of "songified" speech data and those of real singing voices. Compared to the work of Kruspe et al. [5], Basak et al. [6] further took advantage of real singing voice data. It transferred natural speech to singing voice domain with the guidance of real opera data. But it only took the pitch contours into account, ignoring duration, another key characteristic. Besides, it directly replaced the pitch contours with those of the real opera data, without considering the alignment of the note and syllable, which may result in the low quality of synthesized audio.

In this paper, we propose PDAugment, a syllable-level data augmentation method by adjusting pitch and duration under the guidance of music scores to generate more consistent training data for ALT training. To narrow the gap between the adjusted speech and singing voice, we adjust the speech at the syllable level to make it more in line with the characteristics of the singing voice. We try to make the speech more closely fit the music score, to achieve the effect of "singing out" the speech content. PDAugment adjusts natural speech data by the following steps: 1) extracts note information from music scores to get the pitch and duration patterns of music; 2) aligns the speech and notes at

Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

syllable level; 3) adjusts the pitch and duration of syllables in natural speech to match those in aligned notes.

Our contributions can be summarized as follows:

- We develop PDAugment, a data augmentation method to enhance the training data for ALT training, by adjusting the pitch and duration of natural speech at syllable level with note information extracted from real music scores.
- We conduct experiments in two singing voice datasets: DSing30 dataset and Dali corpus. The adjusted LibriSpeech corpus is combined with the singing voice corpus for ALT training. The ALT system with PDAugment outperforms the previous state-of-the-art system and Random Aug by 5.9% and 7.8% WERs respectively in DSing30 dataset and 24.9% and 18.1% WERs respectively in Dali corpus. Compared to adding ASR data directly into the training data, our PDAugment has 10.7% and 21.7% WERs reduction in two datasets.
- We analyze the adjusted speech by statistics and visualization and find that PDAugment can significantly compensate the gap between speech and singing voice as well as synthesize relatively high-quality audio.

2. BACKGROUND

2.1 Automatic Lyrics Transcription

The lyrics of a song provide the textual information of singing voice and are important when contributing to the emotional perception of listeners. Automatic lyrics transcription (ALT) aims to recognize lyrics from singing voice, which is of great importance in music information retrieval and analysis. However, ALT is more challenging than ASR – not like speech, in singing voice, the same lyrics with different melodies will have different pitches and durations, which results in the sparsity of training data.

Some works took advantage of the characteristics of music itself: Gupta et al. [7] extended the length of pronounced vowels in output sequences by increasing the probability of a frame with the same phoneme after a certain vowel frame. Kruspe et al. [2] boosted the ALT system by using the newly generated alignment of singing and lyrics. Gupta et al. [8] tried to make use of the background music as extra information to improve recognition accuracy. Ahlback et al. [9] proposed to tag recordings with non-vocal silence and music labels to improve the recognition rate. However, they just designed some hard constraints or added extra information from the music domain, and still did not solve the problem of data scarcity.

Considering the lack of singing voice database, some work aimed at providing a relatively large singing voice dataset: Dabike et al. [10] collected DSing dataset from real-world user information. Demirel et al. [11] built a cascade pipeline with convolutional time-delay neural networks with self-attention based on DSing30 dataset and provided a baseline for ALT task. Some other works leveraged natural speech data for ALT training: they based on pre-trained automatic speech recognition models and then made some adaptations to improve the performance of singing voice: Fujihara et al. [12] built a language model with lyrics but only used the semantic information and ignored the acoustic properties of singing voice. Mesaros et al. [3] used speaker adaptation technique by shifting the GMM components only with global statistics but did not consider the local information.

However, singing voice has some music-specific acoustic characteristics which are not in speech, limiting the performance when training the ALT system directly with natural speech data. Some work tried to synthesize "song-like" data from natural speech to make up for this gap: Kruspe et al. [5] generated "songified" speech data by time stretching, pitch shifting and adding vibrato. However, the degrees of these adjustments are randomly selected within a range, without using the patterns in real music. Basak et al. [6] took use of the F0 contours in real opera data and converted the speech to singing voice through style transfer. Specifically, they decomposed the F0 contours from the real opera data, obtained the spectral envelope and the aperiodic parameter from the natural speech, and then used these parameters to synthesize the singing voice version of the original speech. Nonetheless, in real singing voice, the note and the syllable are often aligned, but they [6] did not perform any alignment of the F0 contours of singing voice with the speech signal. This misalignment may lead to the change of pitch within a consonant phoneme (in normal circumstances, the pitch only changes between two phonemes or in vowels), which further causes distortion of the synthesized audio and limits the performance of ALT system. Besides, they only adjusted the F0 contours, which is not enough to narrow the gap between speech and singing voice.

Some previous works [13, 14] investigated how to convert speech to singing, however, they not only required speech-singing paired data but also a model training process, which made these methods inappropriate for real-time data augmentation.

In this paper, we propose PDAugment, which improves the above adjustment methods by using real music scores and syllable-level alignment to adjust the pitch and duration of natural speech, to solve the problem of insufficient singing voice data.

2.2 Speech vs. Singing Voice

In a sense, singing voice can be considered a special form of speech, but there are still a lot of discrepancies between them [15, 16]. These discrepancies make it inappropriate to transcribe the lyrics from singing voice using a speech recognition model trained on ASR data directly. In order to demonstrate the discrepancies, we randomly select 10K sentences from LibriSpeech [17] for speech corpus and Dali [18] for singing voice dataset, and make some statistics on them. The natural speech and singing voice mainly differ in the following aspects and the analysis results are

listed in Table 1.

2.2.1 Pitch

We extract the pitch contours from singing voice and speech, and compare the range and stability of the pitch. Here we use semitone as the unit of pitch.

Pitch Range Generally speaking, the range of the pitch in singing voice is larger than that in speech. Loscos et al. [15] have pointed out that the frequency range in singing voice can be much larger compared to that in speech. For each sentence, we calculate the pitch range (the maximum pitch value minus the minimum pitch value in this sentence). After averaging the pitch range of the overall 10K sentences in the corpus, the average values are listed in *Pitch Range* in Table 1.

Pitch Stability The pitch of each frame in a certain syllable (when it is corresponding to a note) in singing voice remains almost constant whereas in speech the pitch changes freely along with the audio frames in a syllable. We call the characteristic of maintaining local stability within a syllable as *Pitch Stability*. Specifically, we calculate the pitch difference between every two adjacent frames in a sentence and average it across the entire corpus of 10K sentences. The larger the value of *Pitch Stability*, the more stable the pitch. The results can be seen in *Pitch Stability* of Table 1.

2.2.2 Duration

We also analyze and compare the range and stability of the syllable duration in singing voice and speech. The duration of each syllable varies a lot along with the melody in singing voice. While in speech, it depends on the pronunciation habits of the certain speaker.

Duration Range For each sentence, we calculate the difference between the duration of the longest syllable and the shortest syllable as the duration range. The average values of the duration ranges in the entire corpus are shown as *Duration Range* in Table 1.

Duration Variance We calculate the variance of the duration of syllables in each sentence and average the variances of all sentences in the whole corpus. The results are listed as *Duration Variance* in Table 1 to reflect the flexibility of duration in singing voice.

Property	*Speech*	*Singing Voice*
Pitch Range (semitone)	12.71	14.61
Pitch Stability	0.93	0.84
Duration Range (s)	0.44	2.40
Duration Variance	0.01	0.11

Table 1: The differences of acoustic properties between speech and singing voice.

Besides the differences in the characteristics we mentioned above, sometimes singers may add vibrato in some long vowels or make artistic modifications to the pronunciation of some words to make them sound more melodious, though it will result in a loss of intelligibility. Considering that some characteristics are hard to be quantified, in this work, we start with pitch and duration to build a prototype and propose PDAugment to augment ALT training data by adjusting pitch and duration of speech at syllable level according to music scores.

3. METHOD

3.1 Pipeline Overview

For automatic lyrics transcription, we follow the practice of existing automatic speech recognition systems and choose Conformer encoder [19] and Transformer decoder [20] as our basic model architecture. Different from standard ASR systems, we add a PDAugment module in front of the encoder as shown in Figure 1, to apply syllable-level adjustments to the pitch and duration of the input natural speech according to the information of aligned notes. When the input of ALT system is singing voice, we just do not enable PDAugment module. When the input is speech, PDAugment module takes the note information extracted from music scores as extra input to adjust the pitch and duration of speech, and then adds the adjusted speech into training data to enhance the ALT model. The loss function

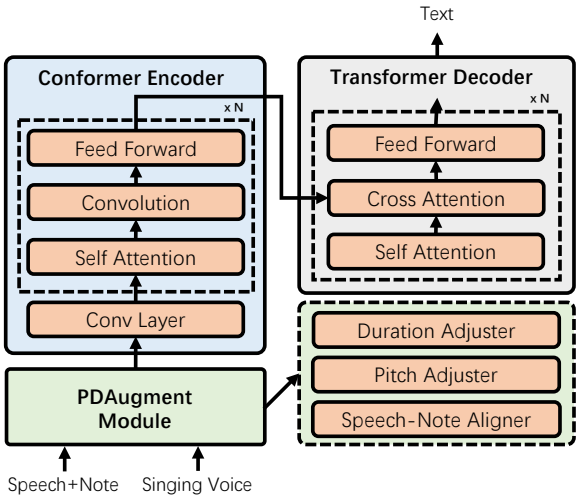

Figure 1: The overall pipeline of the ALT system equipped with PDAugment.

of the ALT model consists of decoder loss $\mathcal{L}_{dec}$, and ctc loss (on top of the encoder) $\mathcal{L}_{ctc}$: $\mathcal{L} = (1-\lambda)\mathcal{L}_{dec}+\lambda\mathcal{L}_{ctc}$, where λ is a hyperparameter to trade off the two loss terms. Considering that lyrics may contain more musical-specific expressions which are rarely seen in natural speech, the probability distributions of lyrics and standard text are quite different. We train the language model with in-domain lyrics data and then fuse it with ALT model in the beam search of the decoding stage.

We try to make the speech fit the patterns of singing voice more naturally as well as to achieve the effect of "singing out" the speech by PDAugment, so we adjust the pitch and duration of speech at syllable level according to those of corresponding notes in music scores instead of applying random adjustments. To do so, we propose PDAugment module, which consists of three key components:

1) speech-note aligner, which generates the syllable-level alignment to decide what the corresponding note of a certain syllable is for subsequent adjusters; 2) pitch adjuster, which adjusts the pitch of each syllable in speech according to that of aligned notes; and 3) duration adjuster, which adjusts the duration of each syllable in speech to be in line with the duration of the corresponding notes. We introduce each part in the following subsections.

3.2 Speech-Note Aligner

According to linguistic and musical knowledge, in singing voice, syllables can be viewed as the smallest textual unit corresponding to notes in the melodies. PDAugment adjusts the pitch and duration of natural speech at syllable level under the guidance of note information obtained from the music scores. In order to apply the syllable-level adjustments, we propose a speech-note aligner, which aims to align the speech and note (in melody) at syllable level.

The textual content can serve as the bridge of aligning notes of melody with the speech. Specifically, our speech-note aligner aligns the speech with notes (in melody) in the following steps:

1) In order to obtain the syllable-level alignment of text and speech, we first convert the text to phoneme using phonemizer [1] and then align the text with speech audio using the Montreal forced aligner (MFA) [21] tool [2] at phoneme level. Next, we group several phonemes into a syllable according to the linguistic rules [22] and get the syllable-level alignment of text and speech.

2) For the syllable-to-note mappings, we set one syllable to correspond to one note by default, because in most cases of singing voice, one syllable is aligned with one note [23]. Only when the time length ratio of the syllable in speech and the note in melody exceeds the predefined thresholds (the lower bound of the ratio is set to 0.5 as the upper bound to 2 from the perspective of preventing severe distortion of the sound), we generate one-to-many or many-to-one mappings to prevent audio distortion after adjustments.

3) We aggregate the syllable-level alignment of text and speech, and the syllable-to-note mappings to generate the syllable-level alignment of speech and note (in melody) as the input of the pitch and duration adjusters.

3.3 Pitch Adjuster

Pitch adjuster adjusts the pitch of input speech at syllable level according to the aligned notes. Specifically, we use WORLD [24], a fast and high-quality vocoder-based speech synthesis system to implement the adjustment. The WORLD system [3] parameterizes speech into three components: fundamental frequency (F0), aperiodicity, and spectral envelope and can reconstruct the speech with only estimated parameters. We use WORLD to estimate the three parameters of natural speech and only adjust the F0 contours according to that of corresponding notes. Then we synthesize speech with adjusted F0 accompanied by original aperiodicity and spectral envelope. Figure 2 shows the F0 contours before and after the pitch adjuster.

Figure 2: The change of F0 contour after pitch adjuster. The content of this example is “opening his door”.

Pitch adjuster calculates the pitch difference between speech and note with syllable-level alignment and adjusts F0 contours of speech accordingly. Some details are as follows: 1) Considering that the quality of synthesized speech will drop sharply when the range of adjustment is too large, we need to keep it within a reasonable threshold. Specifically, we calculate the average pitch of the speech and the corresponding melody respectively. When the average pitch of speech is too different from that of the corresponding melody (e.g., exceeding a threshold, which is 5 semitones in our experiment), we shift the pitch of the entire note sequence to make the difference within the threshold and use the shifted note for adjustment, otherwise, keep the pitch of the original note unchanged; 2) To maintain smooth transitions in synthesized speech and prevent speech from being interrupted, we perform pitch interpolation for the frames between two syllables. 3) When a syllable is mapped to multiple notes, we segment the speech of this syllable in proportion to the duration of notes and adjust the pitch of each segment according to the corresponding note.

3.4 Duration Adjuster

Duration adjuster changes the duration of input speech to align with the duration of the corresponding note. As shown in Figure 3, instead of scaling the whole syllable, we only scale the length of vowels and keep the length of consonants unchanged, because the duration of consonants in singing voice is not significantly longer than that in speech, while long vowels are common in singing voice [5]. There are one-to-many mappings and many-to-one mappings in the syllable-level alignment. For the first case, we calculate the total length of the syllables and adjust the length of all vowels in these syllables in proportion. For the second case, we adjust the length of the vowel, so that the total length of this syllable is equal to the total length of these notes.

4. EXPERIMENTS AND RESULTS

In this section, we first describe the experimental settings, including datasets, model configuration, and the details of training, inference, and evaluation. Then we report the experiment results, visualize the effect of PDAugment, and further conduct more analyses to verify the effectiveness of PDAugment.

4.1 Experimental Settings

4.1.1 Datasets

Singing Voice Datasets We conduct experiments on two singing voice datasets to verify the effectiveness of our PDAugment: DSing30 dataset [10] and Dali corpus (v2.0) [18, 25]. DSing30 dataset consists of about 4K monophonic Karaoke recordings of English pop songs with nearly 80K utterances, performed by 3,205 singers. We use the partition provided by [10] to make a fair comparison with them. Dali corpus is another large dataset of synchronized audio, lyrics, and notes. It consists of 1200 English polyphonic songs (with background music) for a total duration of 70 hours. Following [6], we use the sentence-level annotation of the dataset provided by [18] [4] and divide the dataset into training, development, and test with a proportion of 8:1:1 without any singers overlapping in each partition. We convert all the singing voice waveforms in our experiments into mel-spectrogram following [26] with a frame size of 25 ms and hop size of 10 ms.

Natural Speech Dataset Following the common practice in previous ASR work [19], we choose the widely used LibriSpeech [17] corpus as the natural speech dataset in our experiments and use the official training partition. The LibriSpeech corpus contains 960 hours of speech sampled at 16 kHz with 1129 female speakers and 1210 male speakers. Similar to singing voice, we convert the speech into mel-spectrogram with the same setting [27].

Music Score Dataset In this work, we choose the pop music subset of FreeMidi dataset [5] because almost all of the songs in our singing voice datasets are pop music. The pop music subset of FreeMidi has about 4000 MIDI files, which are used to provide note information for PDAugment module.

[4] https://github.com/gabolsgabs/DALI
[5] https://freemidi.org/genre-pop

Lyrics Corpus In order to construct a language model with more in-domain knowledge, we deliberately collected a large amount of lyrics data to build our lyrics corpus for language model training. Besides the training text of DSing30 dataset and Dali corpus, we collect lyrics of English pop songs from the Web. We crawl about 46M lines of lyrics and obtain nearly 17M sentences after removing duplicates including DSing30 dataset and Dali corpus. We attach a subset of the collected lyrics corpus in the supplementary material.

4.1.2 Model Configuration

We choose Conformer encoder [19] and Transformer decoder [20] as the basic ALT model architecture in our experiments since the effectiveness of the structure has been proved in ASR. Our language model is based on Transformer encoder. More details about the model configuration, training/inference settings, and codes are attached in the supplementary materials.

4.2 Results

In this subsection, we report the experimental results of the ALT system equipped with PDAugment in two singing voice datasets. We compare our results with several basic settings as baselines: 1) *Naive ALT*, the ALT model trained with only singing voice dataset; 2) *ASR Augmented*, the ALT model trained with the combination of singing voice dataset and ASR data directly; 3) *Random Aug* [5], the ALT model trained with the combination of singing voice dataset and randomly adjusted ASR data. The pitch is adjusted ranging from -6 to 6 semitones randomly and the duration ratio of speech before and after adjustment is randomly selected from 0.5 to 1.2. All 1), 2), and 3) are using the same model architecture as *PDAugment*. Besides the above three baselines, we compare our PDAugment with the previous systems which reported the best results in two datasets respectively. We compare our PDAugment with [11] using RNNLM for DSing30 dataset and compare the results with [6] for Dali corpus, All the results are listed in Table 2.

Method	DSing30		Dali	
	Dev	*Test*	*Dev*	*Test*
Naive ALT	28.2	27.4	80.9	86.3
ASR Augmented	20.8	20.5	75.5	75.7
Random Aug [5]	17.9	17.6	69.8	72.1
Previous Work [11]	17.7	15.7	-	-
Previous Work [6]	-	-	75.2	78.9
PDAugment	**10.1**	**9.8**	**53.4**	**54.0**

Table 2: The WERs (%) of DSing30 and Dali dataset. The audios of Dali corpus contain background music.

As can be seen, *Naive ALT* performs not well and gets high WERs in both DSing30 dataset and Dali corpus, which demonstrates the difficulty of the ALT task. After adding ASR data for ALT training, the performances of *ASR Augmented* setting in both of the two datasets have

been improved slightly compared to *Naive ALT*, but still with relatively high WERs, which indicates the limitation of using ASR training data directly.

When applying the adjustments, a question is if we adjust the pitch and duration with random ranges without note information from music scores, how well will the ALT system perform? The results of *Random Aug* can perfectly answer this question. As the results show, *Random Aug* can slightly improve the performance compared with *ASR Augmented*, demonstrating that increasing the volatility of pitch and duration in natural speech helps ALT system training, which is the same as what [5] claimed. *PDAugment* is significantly better than *Random Aug*, which indicates that adjusted speech can better help the ALT training with the guidance of music scores.

Besides, it is obvious that *PDAugment* greatly outperforms the previous work in both datasets. [11] performs worse than *PDAugment* because of not taking advantage of the massive ASR training data. Compared with [6] that replaced F0 contours of speech directly, *PDAugment* can narrow the gap between natural speech and singing voice in a more reasonable manner and achieve the lowest WERs among all the above methods. The results in both datasets show the effectiveness of PDAugment for ALT task and reflect the superiority of adding music-specific acoustic characteristics into natural speech.

4.3 Ablation Studies

We conduct more experimental analyses to deeply explore our PDAugment and verify the necessity of some design details. More ablation studies (different language models) can be found in the supplementary materials. The ablation studies are carried out on DSing30 dataset in this section.

4.3.1 Augmentation Types

In this subsection, we explore the effects of different kinds of augmentations (only adjust pitch, only adjust duration, and adjust pitch & duration) on increasing the performance of ALT system. We generate three types of adjusted speech by enabling different adjusters of PDAugment module and conduct the experiments on DSing30. The results are shown in Table 3.

Setting	*DSing30 Dev*	*DSing30 Test*
PDAugment	**10.1**	**9.8**
Disable Pitch Adjuster	13.6	13.4
Disable Duration Adjuster	13.8	13.8
Disable both Adjusters	20.8	20.5

Table 3: The WERs (%) of different types of augmentation of DSing30 dataset. All of the settings are trained on DSing30 and the original or adjusted LibriSpeech data.

As we can see, when we enable the whole PDAugment module, the ALT system can achieve the best performance, indicating the effectiveness of the pitch and duration adjusters. When we disable the pitch adjuster, the WER on DSing30 is 3.6% higher than *PDAugment*. The same thing happens when we disable the duration adjuster, the WER is 4.0% higher than *PDAugment*. And if both the pitch and duration are not adjusted, which means using the speech data directly for ALT training, the WER is the worst among all settings. The results demonstrate that both pitch and duration adjusters are necessary and can help with improving the recognition accuracy of the ALT system.

4.4 Adjusted Speech Analyses

Following Section 2.2, we analyze the acoustic properties of the original natural speech and the adjusted speech by random and PDAugment, and list the results in Table 4.

Property	*Original*	*Random*	*PDAugment*
Pitch Range (semitone)	12.71	13.87	14.19
Pitch Stability	0.93	0.59	0.69
Duration Range (s)	0.44	0.42	0.59
Duration Variance	0.01	0.01	0.05

Table 4: The differences of acoustic properties between original speech and adjusted speech.

Combining the information of Table 1 and Table 4, we can clearly find that the distribution pattern of acoustic properties (pitch and duration) after PDAugment is closer to singing voice compared with the original speech, which indicates that our PDAugment can change the patterns of pitch and duration in original speech and effectively narrow the gap between natural speech and singing voice. To avoid the distortion of adjusted speech, we limit the adjustment degree within a reasonable range, so the statistics of adjusted speech can not completely match that of singing voice. Nonetheless, adjusted speech is still good enough for ALT model to capture some music-specific characteristics.

In order to visually demonstrate the effect of PDAugment module, we plot the spectrograms of speech to compare the acoustic characteristics before and after different types of adjustments. The visualization of an example adjusted speech is attached in the supplementary materials.

5. CONCLUSION

In this paper, we proposed PDAugment, a data augmentation method by adjusting pitch and duration to make better use of natural speech for ALT training. PDAugment transfers natural speech into singing voice domain by adjusting pitch and duration at syllable level under the instruction of music scores. PDAugment module consists of speech-note aligner to align the speech with notes, and two adjusters to adjust pitch and duration respectively. Experiments on two singing voice datasets show that PDAugment can significantly reduce the WERs of ALT task. We also explore different types of augmentation, and further verify the effectiveness of PDAugment. In the future, we will consider narrowing the gap between natural speech and singing voice from more aspects such as vibrato, and try to add some music-specific constraints in the decoding stage.

6. ACKNOWLEDGEMENT

This work was supported by the Key Project of Natural Science Foundation of Zhejiang Province (No.LZ19F020002), the Key R&D Program of Zhejiang Province (No.2022C03126), and Project of Key Laboratory of Intelligent Processing Technology for Digital Music (Zhejiang Conservatory of Music), Ministry of Culture and Tourism (No.2022DMKLB001). ABSTRACT

Standard evaluation metrics such as the Inception score and Fréchet Audio Distance provide a general audio quality distance metric between the synthesized audio and reference clean audio. However, the sensitivity of these metrics to variations in the statistical parameters that define an audio texture is not well studied. In this work, we provide a systematic study of the sensitivity of some of the existing audio quality evaluation metrics to parameter variations in audio textures. Furthermore, we also study three more potentially parameter-sensitive metrics for audio texture synthesis, (a) a Gram matrix based distance, (b) an Accumulated Gram metric using a summarized version of the Gram matrices, and (c) a cochlear-model based statistical features metric. These metrics use deep features that summarize the statistics of any given audio texture, thus being inherently sensitive to variations in the statistical parameters that define an audio texture. We study and evaluate the sensitivity of existing standard metrics as well as Gram matrix and cochlear-model based metrics in response to control-parameter variations for audio textures across a wide range of texture and parameter types, and validate with subjective evaluation. We find that each of the metrics is sensitive to different sets of texture-parameter types. This is the first step towards investigating objective metrics for assessing parameter sensitivity in audio textures.

1. INTRODUCTION

Audio textures are rich and varied sounds that are produced by a superposition of multiple acoustic events. Unlike the sound of an individual event, such as a footstep, or the complex spectrotemporal structures and sequences of speech or music, an audio texture is defined by properties or parameters that remain constant over time [1] despite statistical variation in the sound over time or between instances. For parametric audio texture synthesis, the goal is to generate novel sounds with descriptive parameters that match those of a target texture. Standard objective evaluation metrics for audio texture synthesis include diversity and quality based measures such as the Inception score [2], and Fréchet Audio Distance (FAD) [3]. However, the existing metrics have not been studied for their sensitivity to systematic variation in the parameter values that define the synthesized audio textures.

Various audio texture synthesis algorithms have been applied to modeling a wide range of natural audio texture types including rhythmic (eg. drums, tapping), pitched (eg. windchimes, churchbells) and other natural sounds (eg. rain, wind), but with different degrees of success. Evaluation of parametric variation textures has typically been through human listening experiments [4, 5].

"Deep features" (activation patterns across layers of neural networks) have been explored for various evaluation tasks such as out-of-distribution detection in audio classification [6], perceptual image similarity evaluation [7], audio distortion assessment [3] and audio texture synthesis [1, 5, 8]. In this work we study several existing objective metrics and also explore deep features and cochlear channel model statistics for potential evaluation metrics sensitive to parameter variations. We make use of a controlled audio texture dataset [9] to study these metrics for a wide range of audio textures - rhythmic, pitched, and non-rhythmic non-pitched under systematic parametric variation. We present a comparative study of the parameter sensitivity of the metrics and validate their reliability through human listening tests.

2. RELATED WORK

2.1 Why is a parameter sensitive metric needed?

McDermott and Simoncelli [1] developed a set of statistics based on a cochlear model to describe the perceptually relevant aspects of a given audio texture. To synthesize a new audio texture, a random input is iteratively perturbed until its statistics match those of a target. This algorithm produces convincing audio for many natural textures such as insect swarms, a stream, or applause. However, human listeners give low scores on realism for resynthesized pitched and rhythmic textures, such as wind chimes, drum break, walking on gravel, and church bells. Besides the audio quality, the statistical parameters associated with these

Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

sounds can fail to be faithfully preserved in the synthesized sounds [4]. Moments derived from the time-averaged scattering coefficients when used for resynthesis of audio textures have also shown similar performance but using fewer coefficients [10, 11]. An objective metric for predicting these human evaluations of texture synthesis failures would be valuable.

Gatys et al. [12] did seminal work on image texture synthesis that replaced hand-crafted statistics with Gram matrix statistics computed as the correlation between hidden feature activations from layers of a trained convolutional neural network (CNN). Iteratively perturbing a random input to match Gram matrices produces compelling and novel image textures. Similarly, Ulyanov et al. [8] improved the quality of synthetic textures based on the dataset from McDermott and Simoncelli [1]. Antognini et al. [5] extended Ulyanov's work by modifying the architecture with 6 parallel single-layered untrained CNNs each with a different convolutional kernel size, and computed autocorrelation and diversity losses in addition to the original Gram matrix loss. They demonstrated some improvements, but found failure modes similar to that of McDermott and Simoncelli [1] using a combination of objective and subjective evaluation. Caracalla and Roebel [13] also relied on human listening tests to show the improvement in sound quality achieved in this kind of iterative texture synthesis using a complex spectrogram audio representation.

The key take-away from these previous studies is that there is a need for evaluating the preservation of statistical parameters in synthesised audio texture but a lack of an objective metric for that purpose.

2.2 The existing audio synthesis evaluation metrics

The evaluation of generative models in terms of perceptual realism is challenging. However, various objective metrics have been formulated for assessing the quality of synthesized audio textures. For example, L2 distance, cosine distance, and signal-to-distortion ratio use a clean reference signal to compare with the modified or enhanced synthetic signal. Such signal-level metrics are agnostic to the type of audio that is being enhanced. However, these metrics may not always correlate with human perception. FAD [3] takes a different approach as a reference-independent metric that, instead of looking at individual clips, computes the distance between the distribution of embedding statistics generated on a large set of clips.

The Inception score [2, 14, 15], passes generated examples through a pre-trained classifier. The mean KL divergence between the conditional output class probabilities and the marginal distribution of the same are then calculated. The Inception score penalizes models whose examples are not easily classified into a single class, as well as models whose examples collectively belong to only a few of the possible classes. However, the Inception score is not the right tool for evaluating a model's sensitivity to parameter differences between sounds within a class.

The goal of most of these audio quality assessment metrics has been to quantify the degradation of an enhanced/modified audio signal. However, to the best of our knowledge, there is a lack of a systematic study of the sensitivity of these metrics to parameter variations in synthesized audio. Such a study is particularly challenging for audio texture synthesis because of the inherent variations that correspond to a particular parametric description.

3. METRICS

We study two standard metrics and three Gram matrix metrics for sensitivity to parametric changes to audio textures.

3.1 Existing Metrics

3.1.1 Fréchet Audio Distance (FAD)

FAD [3] is a reference-independent metric for audio quality assessment that computes the Fréchet distance [16] between the multi-variate Gaussian distributions of the embeddings of train and test set audio data. These 128 dimensional embeddings are extracted from a VGG-ish model [17] pre-trained on clean audio data for classification.

$$FAD = ||\mu_b - \mu_t||^2 + tr(\Sigma_b + \Sigma_t - 2\sqrt{\Sigma_b \cdot \Sigma_t}) \quad (1)$$

where the training and test data embeddings are assumed to have multivariate Gaussian distributions $\mathcal{N}(\mu_b, \Sigma_b)$ and $\mathcal{N}(\mu_t, \Sigma_t)$, respectively. We used the open-source model and FAD computation code [3].

3.1.2 L2 Distance

As another standard metric for our study, we compute the Euclidean distance between the two matrices X_A and X_B, representing the spectrograms of the two input audio signals to be compared, x_A and x_B respectively.

3.2 Gram matrix based Metrics

3.2.1 Gram matrix Metric (GM)

Following Ulyanov and Lebedev [8] and Antognini et al. [5], we use 2D spectrogram representations of audio for iterative updates through the CNNs used to compute a summary statistic in the form of a Gram matrix. Two audio textures sound similar if the computed Gram matrices are similar. Here, we leverage on this property of Gram matrix to develop a metric designed to be sensitive to parameter variations. We define the Gram matrix metric as the mean squared error between the Gram matrices of two textures. We hypothesize that this metric would be sensitive to parametric variations in the statistics of the same texture type such as different rates of flowing water.

Formally, we define the Gram matrix metric GM as,

$$GM = \frac{1}{N}\sum_{n=1}^{N}\frac{1}{D}||G_A^n - G_B^n||_2^2 \quad (2)$$

where, G_A^n and G_B^n are flattened Gram matrices derived from audio clips A and B respectively for the n^{th} CNN in an ensemble of N CNNs, and D is the total number of elements in the Gram matrix. In this work, we adopted the

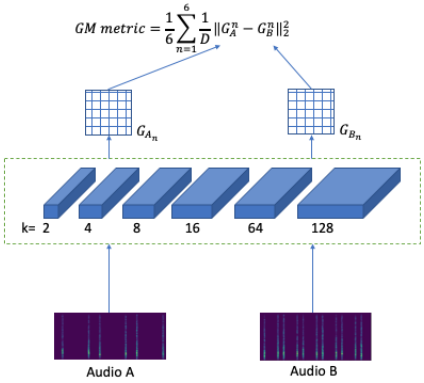

Figure 1. Gram matrix param-sensing metric computation block diagram consisting of an ensemble of six 1 layer 1d-CNNs, with different kernel sizes, k. Each CNN has 512 filters, and the weights are randomly initialized.

architecture used by Antognini et al. [5] for the Gram matrix computation, as shown in Figure 1. It consists of an ensemble of 6 (N=6) single-layered CNNs. We used spectrograms of the audio texture clips as the input to the network computed with 512 FFT bins and hop-size of 128 samples. Unlike images, we consider the spectrograms as one-dimensional input features with the frequency bins as the number of channels. We therefore use a one-dimensional convolution, where each CNN has a convolutional kernel k_n with a different width, in particular 2, 4, 8, 16, 64, 128. The different kernel sizes capture statistics over multiple time scales. We used $F = 512$ filters randomly initialized from a normal distribution (with no training) thus producing six 512×512 dimensional Gram matrices. Details are available in Supplementary Material [1] .

3.2.2 Gram matrix Cos Metric (GMcos)

We compute the cosine distance between the Gram matrices (instead of mean square error) as,

$$GMcos = 1 - \frac{G_A^n \cdot {G_B^n}^T}{||G_A^n||_2 ||G_B^n||_2} \tag{3}$$

where, G_A^n and G_B^n are flattened Gram matrices of audio clips A and B respectively for the n^{th} CNN in an ensemble of N CNNs.

3.2.3 Accumulated-Gram Metric (AGM)

Gram matrices for audio textures are usually sparse (see Supplementary Material (Section 1.) for more info). Neto et al. [18] used a compact version of the Gram matrices to predict the class label of a given sample. Similarly, for a metric that captures the essence of the Gram matrices generated from an audio texture clip, we compute a *Gram vector* corresponding to the clip by accumulating the values from its six Gram matrices, and then aggregating the rows over all the Gram matrices to get a compact one dimensional summarizing vector of length 128. For more details, please refer to Supplementary Material.

[1] https://animatedsound.com/ismir2022/metrics/supplementary/main.html

We define Accumulated-Gram metric (AGM) as the dot product of the difference of the two Gram vectors g_A and g_B corresponding to the two audio clips A and B as

$$AGM = (g_A - g_B) \cdot (g_A - g_B)^T \tag{4}$$

3.3 Cochlear Param-Metric (CPM)

McDermott and Simoncelli [1] use a 3-step texture model to generate a set of statistics of an audio texture as synthesis parameters. A filterbank with a set of cochlear filters is first applied on the incoming sound to decompose the sound to many sub-bands. Then, sub-band envelopes are computed and compressed. And finally a filterbank with a set of modulation filters is applied on each compressed subband envelope. They use seven sets of time-average statistics of nonlinear functions of either the envelopes or the modulation bands as a representation of textures, which includes marginal statistics, variance, and correlations. During synthesis, a white noise signal is iteratively modified to minimize the distance between the synthesised and target sound statistics. Our experiments are based on McWalter's implementation [4] of the [1] algorithm. An overview of the method, implementation details, and statistical parameters are summarized in Supplementary Material (Section 2.).

We use the statistical parameters calculated by this algorithm as a representation for the Cochlear Param-Metric (CPM). For each sound x, we calculate the seven sets of statistics S^i where $i = [1...7]$, and compute CPM as

$$CPM = \sum_{i=1}^{7} D(S_A^i, S_B^i) \tag{5}$$

where S_A^i is a flattened vector of the i^{th} statistics set of sound clip A, and $D(x1, x2)$ calculates the cosine distance between two vectors.

4. EXPERIMENTAL SETUP

4.1 Dataset

We use a subset of audio textures from [9] as summarized in Table 1. There are 13 texture types, each of which has a collection of examples that are determined by a set of variable control parameters. For example, various *windchimes* sounds are determined by parameters *chimesize* and *strength*. For our experiments only one control parameter varies at a time. For example, for the set of audio textures *windchimes-strength*, we generate 11 audio files with a varying strength parameter, with the first file having the lowest strength parameter value and the 11th file having the highest strength value. We generate 10 files for each these 11 setting, where all the 10 versions have the same parameter settings but are different instances. All the audio files being used are between 1.5 and 2 seconds long.

The *pitched* sound group consists of the frequency modulation, windchimes, chimes (without the wind sound), and feedback noise (FB noise). FB noise has the parameter 'pitchedness' that changes the texture from a noisy

Group	Texture Type	Parameters
Pitched	FM	modulation frequency (FM-mf) carrier frequency (FM-cf) modulation index (FM-mi)
	Windchimes	chimesize (windchimes-size) strength (windchimes-strength)
	Chimes	chimesize (chimes-size) strength (chimes-strength)
	FB Noise	pitchedness (fbnoise-pitchedness)
	Nsynth brass	pitch (nsynth-pitch)
Rhythmic	Pops	rate (pops-rate) center freq (pops-cf) irregularity (pops-irreg)
	Chirps	rate (chirps-rate) center freq (chirps-cf) irregularity (chirps-irreg)
	Tapping	rate (tapping-rate) relative phase (tapping-relphase)
	Drum break	tempo (drum-tempo) reverb (drum-rev)
Others	Wind	gustiness (wind-gust) howliness (wind-howl) strength (wind-strength)
	Waterfill	fill-level (water-fill)
	Bees	center frequency (bees-cf) busy-body (bees-busy)
	Applause	rate (applause-rate) no. of clappers (applause-clappers)

Table 1. Dataset overview

signal to a pitched sound. Under the *rhythmic* group are pops, chirps, tapping, and drum-break. The tapping sound is similar to the "tapping 1-2" sound in the collection of sounds in [1], and the drum break sound set is recorded and then processed with varying tempo and reverb parameters. The *others* group includes wind, water filling a container, buzzing bees, and applause. Most sounds are synthesized [2], except the waterfill, Nsynth brass, and drum-break textures, which are recorded or are manipulated versions of a real recording.

4.2 Subjective Evaluation

Listening tests were conducted to quantify listeners' sensitivity to control parameter changes based on their ability to identify the order and proximity of audio samples w.r.t two selected reference samples as well as each other. This evaluation was done to provide a perceptual baseline for our objective metrics comparison. Each audio trial consisted of 7 audio samples - 2 references and 5 test samples. The 2 references were selected for each texture with the control parameters (as in the Parameters column in table 1) set to 0 (left endpoint) and 1 (right endpoint). The 5 test samples are from the same texture selected with parameters between 0 and 1. A total of 9 such texture-trials were created, each with a different combination of control parameter settings for the 5 test audio samples. This was done to ensure that all the 9 control parameters values between 0 and 1 are included and are uniformly distributed across trials. The references, test samples, and the sequence of the individual texture-trials were randomized while conducting the test.

An interface was developed specifically for this test with the goal to intuitively convey the task details to the listeners. First they listened to the two references and then to the individual samples in the test. Then they were asked to create an arrangement by positioning thumbs on a slider corresponding to each test sample depending on how they perceived the order and distance of each sample w.r.t. the two references. Adjustments could be made by listening to their arrangement until they were satisfied. The listening test interface can be viewed on our webpage [3]. Amazon Mechanical Turk (AMT) was used to collect 30 responses per trial from a total of 348 unique participants.

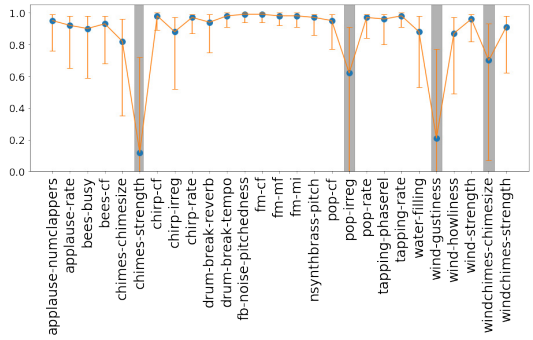

Figure 2. Correlation of perceptual distances with control parameters used to generate the textures. Grey bars indicate textures with no significant correlation.

5. EXPERIMENTS AND RESULTS

In this study, we experimentally address two main questions: 1) Are the objective metrics consistent for texture instances generated with the same parameters (Section 5.2)? 2) Are the objective metrics sensitive to parameter variations (Section 5.3)? We evaluate each metric by comparing them with the subjective responses.

5.1 Subjective tests

Figure 2 shows the correlation coefficients for the subjective perceptual distance captured w.r.t the synthesis control parameters. Parametric variations for chimes-strength, pop-irreg, wind-gustiness and windchimes-chimesize did not result in significant correlations primarily due to wide variance in human ratings, and are excluded from further comparison with objective metrics. Based on the distance measures, we derive rank ordering for the audio samples along the parametric dimension to compare with metrics. See the Supplementary Material for summary rank-order plots obtained from the listening tests for all textures under consideration in this paper. A selection of sounds used in our listening tests can be auditioned on our webpage.

5.2 Metric Consistency

Metric consistency means that the distance between two texture instances with the same parameter settings is small. We analyse consistency in terms of relative mean for three texture types - FM, pops, and water filling. The metric values are computed over one hundred comparisons between two parametrically identical textures. Relative mean is the single parameter mean with respect to the maximum average mean value of comparisons across different parameter settings for the texture as computed in Section 5.3.

Text-Param	L2	FAD	CPM	GM	GMcos	AGM
FM-cf	54.04	5.69	8.05	**0.07**	**0.02**	0.12
pops-rate	21.36	5.27	**3.44**	6.81	**2.46**	4.28
water-fill	61.09	40.60	23.09	16.19	**7.83**	**12.17**

Table 2. Metric Consistency in terms of relative mean in % for three texture types - FM, pops, and water filling. Lower is better. The best two in every row are highlighted in bold.

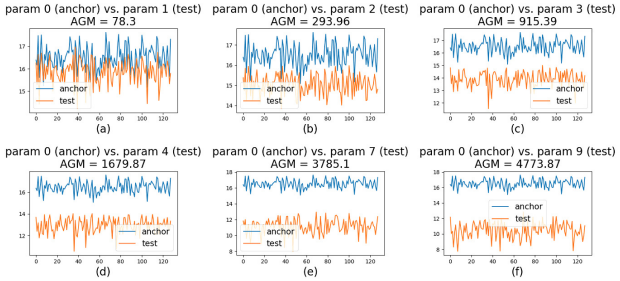

Figure 3. Gram vectors and AGM values of anchor for applause sounds with an increasing number of clappers from (a) to (f) compared to the anchor sound of a single clapper.

The results are shown in Table 2. The L2 metric shows a high relative mean value for all three texture types which confirms the understanding that a spectrogram-based distance measurements does not capture the statistics that define a texture. It is too sensitive to the "irrelevant" variations between similarly parameterized textures.

Although the relative mean of FAD is not as high as that of L2, it is higher than the Gram matrix based metrics, because the embeddings extracted from VGGish provide a holistic representation of the audio including both the overall statistics and temporal structure. The effect of the exact temporal structure of the sound on the metric is reduced but still present. The statistical metrics (CPM and GM-based) exhibit low relative mean values (good consistency), especially GMcos. The waterfill texture shows higher relative mean values across all metrics. This is at least in part because for real recordings, even for short durations, the fill-level is never constant while filling a container.

5.3 Metric Sensitivity to Parameter Variation

To further investigate the sensitivity of the objective metrics to parameter variations, we fix one texture example to a low parameter value (0), called the *anchor*, and compare it with nine *test* clips of the same texture-type but increasing parameter values (1-9). We compute this over 10 versions of the same anchor and test parameter settings, and average over them for the metrics L2, CPM, GM, GMcos, and AGM. However, to calculate FAD, we compute Fréchet distance between normal distributions of embeddings of the 10 versions, instead of between the embeddings of individual audio files (Eq. 1). An example of the sensitivity of the 1×128 dimensional AGM Gram vector to parameter variations is shown in Figure 3. The Gram vectors of a reference (anchor) applause audio texture clip that has the number of clappers parameter set to 1, is compared with six test audio clips of applause textures with increasing number of clappers. The divergence between the Gram vectors of the anchor and test sounds grows as the number of clappers is increased.

Texture-Param	L2	FAD	CPM	GM	GMcos	AGM
Pitched						
FM-mf	**0.99**	0.94	**0.99**	**1.00**	**0.99**	0.64

applause-clappers	**0.97**	0.94	0.93	**0.99**	**0.99**	**0.99**

Table 3. Pearson's Correlation between the avg human rank orders and the distance from the anchor computed by the objective metrics. The best two values in every row are in bold. Correlation values >=0.5 are green, <0.5 orange.

Figure 4 shows the plots of all the metric values for three textures compared with human responses in terms of average rank order. The Pearson's correlation between the objective metrics and the subjective responses are presented for all textures in Table 3, and their corresponding plots are available in the Supplementary Material.

5.3.1 Metric Performances

The L2 metric is again a poor performer. This is particularly clear for drumbreak-tempo textures as can be observed in the L2 column in Figure 4(b). FAD performs better than Gram matrix based measures for chimes-size, but shows worse performance for FM-cf, FM-mi, FBnoise-pitchedness, and waterfill (Table 3). FAD performs well for most of the rhythmic textures except pop-rate, drum-tempo, and drum-rev. Since FAD preserves some information about exact spectro-temporal structure, the result is variable sensitivity to parameters (Figure 4, FAD row).

The statistics designed by [1] are known to synthesize good quality sounds for natural textures such as bees and wind which is clearly reflected in our results. However, these statistics are also known for low realism scores for synthesized pitched sounds such as windchimes, and rhythmic sounds such as drum break. Compared to the Gram matrix based metrics, CPM performs well except for windchimes-strength, pop-rate, drum-rev, and water-fill.

When an event rate varies, the features captured by the Gram matrix may reflect some individual events, especially for shorter kernel sizes. In such cases, AGM captures the summary of those statistics instead of individual events, thereby showing a higher parameter sensitivity than metrics based on the entire matrix. This trend can be seen

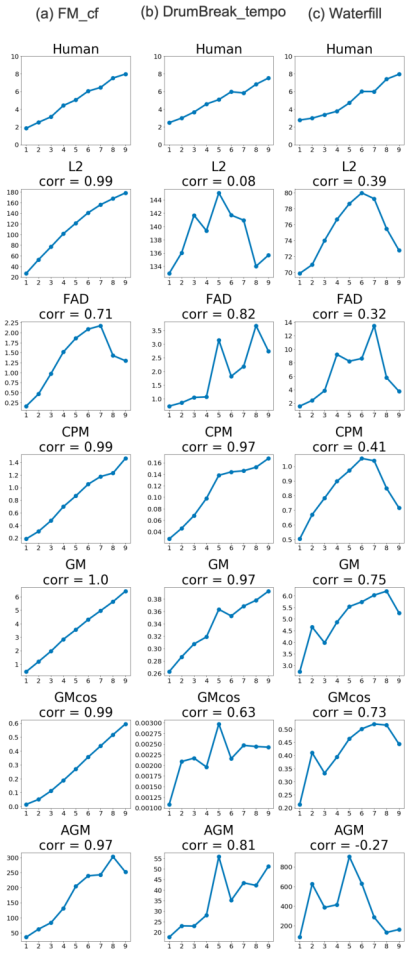

Figure 4. Trends of human responses and objective metrics to parameter variations for three texture-param combinations, (a) FM with carrier frequency variable parameter, (b) Drum-break with tempo a variable parameter, and (c) Waterfill with fill-level parameter, along with the Pearson's correlation between the objective metric values and the subjective responses.

in applause-rate, pop-rate, tapping-rate, chirp-rate, as well as bees-busy (increase in busy body parameter sounds like increase in the rate of buzzing vibrations), where AGM outperforms GM.

The cases where GM outperforms AGM are FM-mf, bees-cf, windchimes-strength, waterfill, and wind-strength, where the parameter variation occurs in the frequency domain, i.e. the center frequency in bees-cf, wind and windchimes-strength, modulation frequency in FM-mf, and resonant frequencies in water-fill. AGM summarization loses information about the statistics in the frequency domain, and this suggests a future study where methods such as eigenvalue decomposition might be better for extracting key information from the Gram matrix.

5.3.2 Some curious cases

Water-fill shows an interesting trend in most of the metrics, where there's a gradual increase, and then a decrease in the metric values (Figure 4(c)), possibly because the resonances of the container wrt changing water and air column heights cause the audio textures of an almost full container to have some statistical similarities with that of an almost empty container. That is, the high-level fill-level parameter has a non-linear affect on the resonant frequencies of the system. For a sound such as water-fill where multiple perceptual dimensions are varying, GM and GMcos show higher correlation with humans than others.

Nsynth-pitch is a curious example where none of the metrics perform well except CPM. The sustained portion of musical tones are atypical as textures because of the lack of temporal variation. Each spectrogram frame is almost exactly the same. Also, as the pitch of the brass instrument increases, the harmonics also change. The Gram matrix summarizes the temporal statistics through the 1D audio representations, but not the frequency statistics, thereby showing a noisy performance.

6. DISCUSSION

We explore a variety of metrics for use with audio textures for their sensitivity to controlled parametric variation. However, in a realistic situation, there may effectively be multiple simultaneous dynamic parameters. One such example in our dataset was the waterfill texture-type, where the fill parameter maps to both rising and falling resonant frequencies. We saw that most of the metrics were responding to a combination of fill parameter and resonances. Further investigation is required to understand how metrics behave in such complex realistic situations.

The systematic parameter variation we used creates textures perceptually close to each other. Further study is required to understand the behavior of these metrics for cross texture-type comparisons, for example, bees compared to water. Such a study would help in mapping audio textures to a perceptual space, the way musical instrument space has been mapped in previous work [19, 20].

Our perceptual study involved placing textures within a 1D space between two reference textures, but there is an inherent lack of an absolute perceptual frame of reference for the meaning of control parameter variation. A systematic study is needed to understand perceptual "just noticeable differences" in parameter variations for complex sounds. Different parametric variations could then be compared on a unified scale.

7. CONCLUSIONS

We present a comprehensive study on the parameter change sensing property of various existing audio evaluation metrics as well as three potential audio statistical and deep-feature based metrics [4]. CPM and FAD emerge as the best metrics, while GM based metrics show promising results. This shows the potential of these deep-features for the purpose of evaluation of audio textures. This study is a fruitful first step towards understanding audio textures, metric design for audio textures, building better synthesis models of this rich and complex class of sounds, and generally toward mapping the space of audio textures.

ABSTRACT

Multi-modal music classification creates supervised models trained on features from different sources (modalities): the audio signal, the score, lyrics, album covers, expert tags, etc. A concept of "multi-group feature importance" not only helps to measure the individual relevance of features of a feature type under investigation (such as the instruments present in a piece), but also serves to quantify the potential for further improving classification by adding features from other feature types or extracted from different kinds of sources, based on a multi-objective analysis of feature sets after evolutionary feature selection. In this study, we investigate the stability of feature group importance when different classification methods and different measures of classification quality are applied. Since musical scores are particularly helpful in deriving semantically meaningful, robust genre characteristics, we focus on the feature groups analyzed by the jSymbolic feature extraction software, which describe properties associated with instrumentation, basic pitch statistics, melody, chords, tempo, and other rhythmic aspects. These symbolic features are analyzed in the context of musical information drawn from five other modalities, and experiments are conducted involving two datasets, one small and one large. The results show that, although some feature groups can remain similarly important compared to others, differences can also be evident in various applications, and can depend on the particular classifier and evaluation measure being used. Insights drawn from this type of analysis can potentially be helpful in effectively matching specific features or feature groups to particular classifiers and evaluation measures in future feature-based MIR research.

1. INTRODUCTION AND RELATED WORK

There are music research scenarios where manually designed features can have value, and where gaining understanding of which features are particularly effective for various classification tasks can be of central importance. Researchers seeking to gain domain knowledge can be interested in more than just optimizing performance. Those working on composer attribution or genre classification, for example, might be interested in learning about the specific qualities that delineate musical style, so comparing the performance of different musically meaningful features can provide important insight. There can also be situations where only very limited training data are available, such as when there is only so much extant music by a given composer, and where data augmentation techniques can only improve matters so much. In such situations, deep learning that self-learns features can be less useful, and handmade features become valuable, as do approaches for selecting more promising features when many are available.

Multi-modal features drawn from a variety of data sources can be of particular interest. Although there can be redundancy across types of musical data (e.g., both audio and symbolic data specify pitch), such information is not always equally accessible (e.g., pitch is harder to extract from dense polyphonic audio), and there are other times when different source types contain complementary information (e.g., album art can provide cultural information that is inaccessible from audio or scores). Multi-modal research often plays an essential role in musicology, and involving sources as diverse as concert programs, manuscript illuminations, critical accounts, contemporary visual portrayals, and scores themselves. MIR research can and has similarly taken advantage of multi-modal information, both for improving performance in an engineering sense and in learning more about the connections between different types of musical data in a scientific or musicological sense. There is a rich MIR literature involving two modalities, but relatively few studies have considered more [1–6], and relatively few multi-modal public datasets are available (standouts are described in [5, 7–10]). There are also several papers that provide useful summaries of multi-modal MIR research [11–14].

Of course, with more types of data come more features, and the curse of dimensionality becomes a concern. Although handmade features can help, since they tend to represent information more concisely than raw data, too many can still present problems when training data are limited. Although there is substantial literature on dimensionality reduction (e.g., [15]), and important related MIR studies [4, 16–23], some approaches sacrifice feature independence (e.g., PCA), which compromises interpretability,

Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

and feature selection approaches can be sensitive to particular classifier and evaluation methodologies.

So, it can be of value to get a sense of how consistently features perform across different classification and evaluation methodologies, in order to gain a deeper musical understanding of which features and groups of features are most important in delineating classes of interest. This paper is concerned with exactly this: attempting to measure the stability in importance of various features for a given music classification task, which can ultimately help to avoid overfitting the choice of features (or modalities), and can provide insights into underlying musical meaning.

We focus here on symbolic features, as they tend to be particularly interpretable, especially when collaborating with musicologists or theorists. This research maintains a fundamentally multi-modal character, as it also uses information from five other source types to ground feature stability measurements in a broader context: we used the same audio, album cover image, playlist co-occurrence, semantic tag, and lyric text feature data as [10]. These data are particularly useful because they include both a small but clean dataset and a large but noisy dataset, permitting stability to be measured in both scenarios. All symbolic features were extracted with jSymbolic [24], which provides access to many features usefully grouped into feature types whose relative stability can be compared.

We selected genre classification as the test domain for this research, but there is nothing about the techniques we propose that is specific to genre. Furthermore, the same techniques could just as easily be refocused on modalities other than symbolic music. It is also important to note that there are fundamental concerns related to the evaluation of musical classification [25–28]; although there is insufficient space to detail these here, this is essential reading for MIR researchers working in classification.

2. MULTI-GROUP FEATURE IMPORTANCE

We have proposed the concept of *multi-group feature importance* in [10], as an extension of earlier work [29–31]. A feature selection scenario based on two objectives was constructed, with the goal of simultaneously minimizing balanced relative error m_{BRE} (defined as a mean of relative errors for positive and negative instances) and maximizing the share of features g_i belonging to a given group i under investigation, such as rhythmic descriptors. This approach makes it possible to answer not only the questions "what is the lowest error rate achieved by rhythmic features in predicting a musical category?" and "which are the best rhythmic features for the current prediction task?", but also "how can performance be improved when features of other groups, domains, or modalities are also introduced?"

While the formal details of "importance" and the mathematical backing of multi-objective optimization are left to [10], we will briefly illustrate the core ideas here with the help of Figure 1. The connected circles in Subfigure (a) show a *non-dominated front* after feature selection, which simultaneously maximizes the share of rhythmic features g_{RHYTHM} and minimizes m_{BRE}, when features from all six modalities are considered (i.e. not just other symbolic features). Each circle corresponds to a feature set that is not *dominated* by any other feature set. This means that no other feature sets have been identified after feature selection that are "better" than the one under consideration, in combined terms of the two measures being optimized (i.e., using *a greater share* of rhythmic descriptors and achieving *smaller* classification error at the same time). For instance, the feature set in the upper right corner contains only rhythmic descriptors ($g_{RHYTHM} = 1.0$), but $m_{BRE} = 0.4236$ is rather high. No other feature sets that contain only rhythmic descriptors have lower errors, meaning that they are dominated by the upper right corner set, and are not shown in the plot. The feature set in the bottom left corner has the smallest $m_{BRE} = 0.0139$, but has only 37.86% rhythmic descriptors. Other circled feature sets between these corner solutions consist of various trade-offs between the two measures, and are also not dominated by any other found feature sets. The non-dominated fronts in the figures are constructed after ten feature selection repetitions and an independent evaluation on the reserved test set created with music tracks used neither for training the models nor for evaluating the selected feature sets.

Subfigure (a) indicates that rhythmic descriptors do not perform well for Traditional Blues music. This is not only because the error is high in general (this can occur, for example, if a category is too hard to predict or is badly defined), but also because the error is substantially reduced if other features (e.g., audio features) are allowed to contribute to the feature sets used to train the classification models. So, the overall *multi-group feature importance* of rhythmic descriptors is low, which is indicated graphically by the large area shaded grey on the graph. As the number of all possible non-empty feature sets is typically very high ($2^N - 1$ for N features), an evolutionary algorithm is proposed in [10] to explore many different combinations of features in a non-deterministic way, guided by a process inspired by natural evolution, where feature sets can be randomly changed by *mutation* that switches feature dimensions on or off. Only fitter feature sets survive after an exit condition is fulfilled, such as a cap on the overall number of mutations.

In [10], we have also investigated the importances of different modalities and proposed the complementary concept of *multi-group feature redundancy*. However, despite a large number of experiments, the results should be treated with caution because of two limitations of the study: only random forest classifiers were used and balanced relative error was the only measure of classification quality. It was therefore unclear whether estimated importances would remain similar if other classification methods were applied or other evaluation measures used. The present study addresses both of these gaps, by investigating how stable multi-group feature performance is when classification method or evaluation measure are varied.

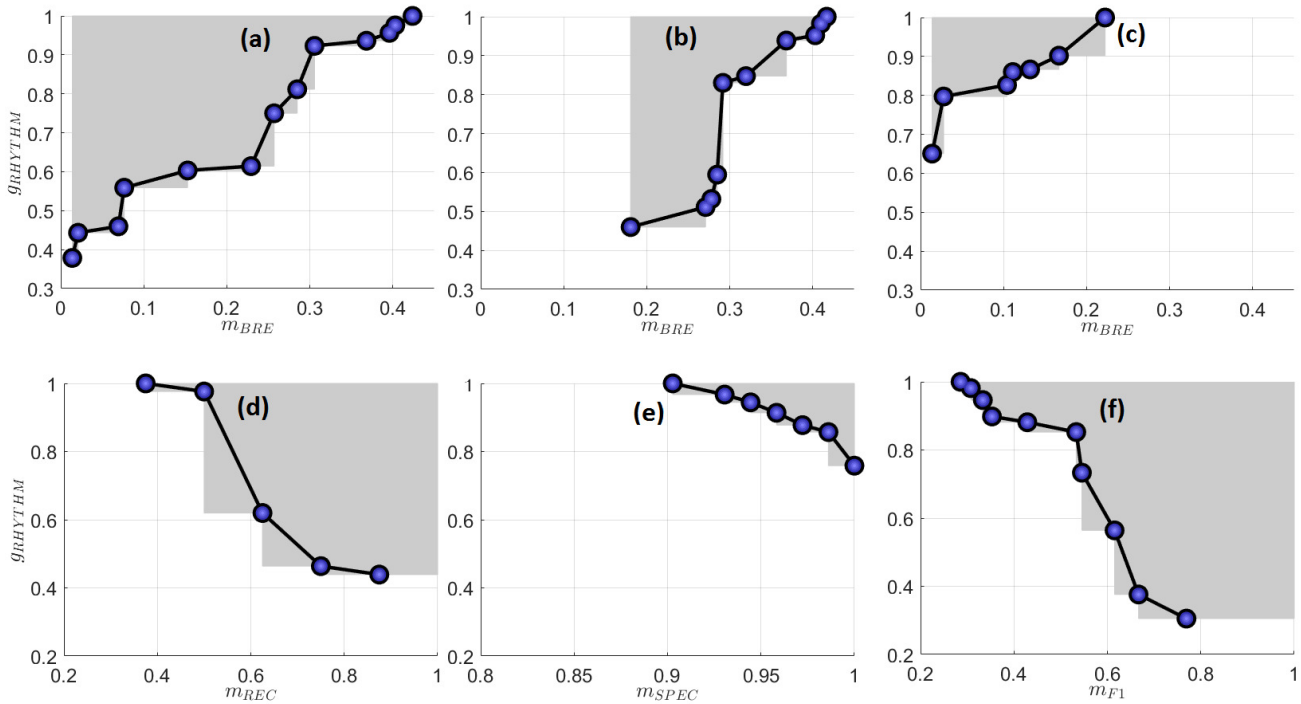

Figure 1. Non-dominated fronts after multi-objective feature selection for the identification of Traditional Blues in the SLAC dataset [2], with rhythmic descriptors the feature group being focused on. Top row: the share of rhythmic descriptors g_{RHYTHM} is maximized and the balanced relative error m_{BRE} is minimized using random forest (a), k-nearest neighbors (b), or support vector machine (c) classifiers. Bottom row: random forest classifiers are used to maximize both g_{RHYTHM} and recall m_{REC} (d), specificity m_{SPEC} (e), or F1-measure m_{F1} (f).

3. DESIGN OF EXPERIMENTS

We conducted our experiments on two pre-existing datasets, namely LMD-aligned [32] and SLAC [2], involving a total of 20 genres and sub-genres. While LMD-aligned is a larger dataset, it has problems with noisiness and structure (e.g., it is unbalanced, with an overly large representation of Pop/Rock songs). SLAC is smaller but carefully designed with, for example, an equal number of pieces belonging to each genre, each of which can be broken into two equally represented sub-genres. We made use of multi-modal features extracted from 1,575 Lakh and 250 SLAC tracks, which have been made publicly available. [1]

Table 1 shows sample jSymbolic features, divided into feature groups; the full list of symbolic (and other) features is available online. [2] We excluded the dynamics features used in [10], as dynamics are often inconsistently encoded.

In the first part of this study we measure the importance of eight groups of symbolic features (relative to features from all six modalities considered) not only with the random forests (RF) classifiers used in [10], but also with k-nearest neighbor (kNN) and support vector machine (SVM) classifiers. As can be observed in Figure 1, subfigures (a)-(c), notable differences in importance can be evident when the classification method is changed. Of course, a limitation of this study is that all classifiers are applied with default hyperparameters in the AMUSE framework [33]: 100 trees for RF, $k = 1$ for kNN and a linear kernel for SVM. In practice, varying hyperparameters may well also introduce meaningful variance in measured feature importances.

We chose to omit deep neural networks from our experiments, despite their popularity in MIR, for two reasons. First, they typically learn their own features, which can make it difficult to analyze the relative relevance of interpretable semantic descriptors for a given musical category. Second, the typically very large number of parameters they involve can lead to overfitting in situations with limited available data, such as when a musical category is defined by a small number of "positive" and "negative" tracks, as in real-world situations where a listener may wish to provide only a few labeled examples to train a supervised classification model.

In the second part of this study we vary the evaluation measures used in the two-objective feature selection. Although m_{BRE} is generally a good choice for binary classification tasks, as it can help to measure performance with unbalanced test sets [34, p.344], it is not often used in MIR classification studies. We have therefore extended the setup from [10] with three additional evaluation criteria. Recall and specificity measure classification errors associated with, respectively, instances annotated in the ground truth as belonging or not belonging to a category [34, p.342]. F1-measure is a weighted combination of precision and recall that, like m_{BRE}, can be useful for less

[1] https://zenodo.org/record/5651429
[2] https://doi.org/10.5334/tismir.67.s1

Group	Feature Examples
Pitch	First pitch, last pitch, major or minor, pitch class histogram, pitch variability, range
Melodic	Amount of arpeggiation, direction of melodic motion, melodic intervals, repeated notes
Chords	Chord type histogram, dominant seventh chords, variability of number of simultaneous pitches
Rhythm	Initial time signature, metrical diversity, note density per quarter note, prevalence of dotted notes
Tempo	Initial tempo, mean tempo, minimum and maximum note duration, note density and its variation
Instrument presence	Note prevalences of pitched and unpitched instruments, pitched instruments present
Instrument prevalence	Prevalences of individual instruments/instrument groups: acoustic guitar, string ensemble, etc.
Texture	Average number of independent voices, parallel fifths and octaves, voice overlap

Table 1. Sample jSymbolic [24] features grouped into eight semantically meaningful groups.

balanced datasets [34, p.344]. The potential for differences in measured importances based on recall, specificity, and F1 is demonstrated in subfigures (d), (e), and (f).

We conducted 24,000 feature selection experiments involving 20 genres and sub-genres $\times$ 3 cross-validation folds $\times$ 8 feature groups $\times$ 5 new combinations of classifiers and measures $\times$ 10 statistical repetitions, with runtimes between about 2 and 50 hours per experiment.

4. DISCUSSION OF RESULTS

Tables 2 and 3 show multi-group feature importances for all 20 classes, with each value indicating results aggregated over three folds. In each row, the importance values across the eight feature groups are shown with color: the group with the highest importance (compared to the other feature groups in the same row) is marked in deep red, and the group with the lowest importance in deep blue. The four "more important" feature groups are shown in shades of red, and four "less important" groups in shades of blue.

The instrument presence feature group seems to be the most important group in most of the experiments, with the instrument prevalence group being the most important in a few others. Features measuring pitch statistics are the most important in five experiments (e.g., RnB prediction using kNN and m_{BRE}). Interestingly, instrument prevalence is the least important group for almost all LMD-aligned genres (even when instrument presence is the most important group). Another intriguing result is that melodic features seem to be particularly unimportant for the Classical SLAC genre and its ClassBaroq and ClassRomant sub-genres.

As anticipated in Figure 1, these results reveal differences between importances when the classifier is varied. Such difference may be particularly meaningful when a cell's color changes from red to blue or vice versa: for example, chords are among the four more important groups for predicting Country using RF and SVM, but are among the less important groups when kNN is used. On the other hand, for this same genre tempo-based features become more important using kNN, not only relatively (the cell goes from blue to red), but also with respect to mean importance values (0.861 instead of 0.656 and 0.651, respectively). This supports our preliminary suspicion that the choice of classifier can have a strong impact, even for "robust" features groups (e.g., symbolic characteristics arguably describe musical properties in concise and clearly understood ways compared to audio descriptors). However, this is certainly not always the case: for 480 combinations of 20 classes, 8 feature groups, and 3 classifiers, in 62 cases (12.92%) the cell shade remains the same when the classifier is changed for a fixed genre and feature group.

When the evaluation measures are varied for a fixed classifier (note that here results were restricted to RF), the changes seem to be slightly less impactful: for 640 related combinations (20 classes, 8 feature groups, 4 measures), the shade changed in only 53 cases (8.28%).

A randomly chosen decision will assign a feature group to be either "more" or "less" relatively important with an expected probability of 25% for three classifiers (1 case with all more important values, 1 case with all less important values, and 6 remaining cases), and with 12.5% for the four measures. Although this interpretation is not perfect, as the change of a light red shade to a light blue shade will indicate a switch between "more" and "less" important, our main inference from the complete study is that it is not enough to claim that some feature group is "generally" more or less important for a particular musical category. Our results suggest that it is indeed necessary to accompany feature group evaluations with specification of the classifier and evaluation measure used. More general claims about the suitability of particular feature groups should be substantiated with broader experiments involving multiple classifiers and evaluation measures (and, perhaps, classifier hyper-parameters).

5. CONCLUSIONS

This paper studied the stability of multi-group feature importance when classifiers and evaluation measures are varied. Eight symbolic feature groups were focused on within a multi-modal classification context involving features extracted from six modalities (symbolic and five others). Various combinations of features and classification approaches were used to predict genres and sub-genres for two datasets with publicly available pre-extracted feature values. The results show that, although in most cases the relative importance of individual feature groups is not affected by the choice of classification method or evaluation measure, either or both of these do nonetheless have an influence in a non-negligible number of cases. Multiple parameters of the feature importance estimation chain can impact determination of which musical properties are more or less relevant for a particular musical category.

In the future, we plan to continue our experiments by

Table 3. Multi-group symbolic feature importances for ten SLAC sub-genres, aggregated over 3 folds. F1: F1-measure; Rec: recall; Spec: specificity. The first three rows of each sub-genre block were evaluated with balanced relative error m_{BRE}.

pects like extraction times, statistical properties, and suitability for data augmentation. We will also run further trials in order to be able to apply more developed statistical significance testing.

6. ACKNOWLEDGMENTS

The experiments were carried out on the Linux HPC cluster at TU Dortmund (LiDO3), which was partially funded by the Large-Scale Equipment Initiative by the German Research Foundation (DFG) grant 271512359. The second author's work was funded by the Fonds de recherche du Québec – Société et culture, under grants 2021-CHZ-282456 and 2022-CHZ-309882.

ABSTRACT

The performance of machine learning (ML) models is known to be affected by discrepancies between training (source) and real-world (target) data distributions. This problem is referred to as domain shift and is commonly approached using domain adaptation (DA) methods. As one relevant scenario, automatic piano transcription algorithms in music learning applications potentially suffer from domain shift since pianos are recorded in different acoustic conditions using various devices. Yet, most currently available datasets for piano transcription only cover ideal recording situations with high-quality microphones. Consequently, a transcription model trained on these datasets will face a mismatch between source and target data in real-world scenarios. To address this issue, we employ a recently proposed dataset which includes annotated piano recordings covering typical real-life recording settings for a piano learning application on mobile devices. We first quantify the influence of the domain shift on the performance of a deep learning-based piano multi-pitch estimation (MPE) algorithm. Then, we employ and evaluate four unsupervised DA methods to reduce domain shift. Our results show that the studied MPE model is surprisingly robust to domain shift in microphone mismatch scenarios and the DA methods do not notably improve the transcription performance.

1. INTRODUCTION

Recent advances in Automatic Music Transcription (AMT) enable its practical application in musical education applications where students can record themselves while playing a musical instrument and retrieve a performance feedback in near real-time. The underlying algorithms are driven by deep learning and commonly trained on audio data (source domain), which was gathered in specific and ideal recording setups such as music studios with high-quality microphones [1–3]. In real-life scenarios however, the recording setups may vary from user to user due to different recording devices, room acoustics, and music instrument timbres (target domain). Due to the resulting distribution discrepancy between both domains (domain shift), AMT algorithms might exhibit performance degradation. To overcome this issue, one approach would be to fine-tune pre-trained transcription models using labeled data recorded in real-world settings [4]. This comes with two main drawbacks. First, this procedure would have to be repeated for each user. Second, it requires a lot of effort to obtain perfectly aligned score annotations by manually transcribing audio recordings. For this reason, domain adaptation (DA) methods are used to bridge the gap between different data domains and ensure a good model performance even on previously unseen data. These methods can align the target data distribution to the source data distribution (or vice-versa) [5].

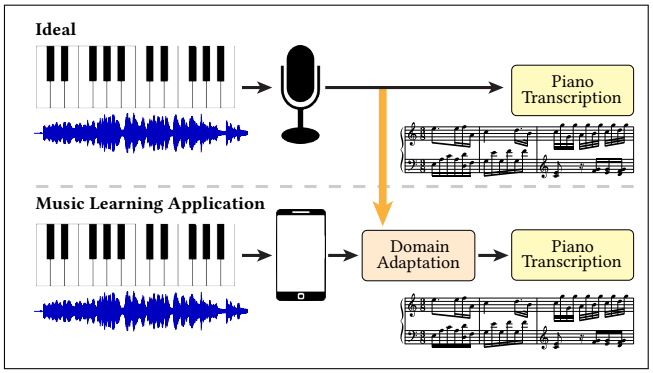

Figure 1. Illustration of the piano transcription process including domain adaptation. Piano music is captured with different recording devices (high-quality microphone, mobile devices), adapted to the source domain, and transcribed by an MPE model.

The contributions of the paper are as follows: We study the task of piano multi-pitch estimation (MPE), i. e., the estimation of simultaneously sounding note pitches, from audio recordings captured with different mobile devices. We first analyze and quantify the mismatch of recording devices by comparing their frequency responses. Then, we study the effectiveness of four different DA methods as a pre-processing step to improve MPE algorithms. We do this by investigating to what extent the microphone mismatch impacts the performance of a deep learning-based

Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

MPE model with and without DA. We use the representation shift metric to assess whether the domain shift was reduced by DA.

2. DOMAIN ADAPTATION

2.1 Application in Audio Domain

DA was successfully applied for various tasks in different audio domains. Several acoustic scene classification (ASC) algorithms were proposed during the Detection and Classification of Acoustic Scenes and Events (DCASE) challenge [6,7] to compensate domain shift caused by mismatched recording devices. Furthermore, Yang et al. [8] proposed a two-stage domain adaptation approach to improve the robustness of sound event detection (SED) models by aligning synthetic and real audio data distributions in feature space during training. DA was also applied in Music Information Retrieval (MIR) tasks, such as expressivity analysis in piano recordings [9], representation learning for music processing [10], and instrument activity detection [11], and in automatic speech recognition, DA methods are employed to avoid overfitting of a model which was trained on limited data by transferring knowledge from a source model [12].

2.2 Selected Methods

2.2.1 Zero-mean Unit Variance (ZMUV) Normalization

A common pre-processing step for machine learning (ML) models is the standardization of input features to zero mean and a standard deviation of one. We implemented four variants of the zero-mean unit variance (ZMUV) standardization process from [4] as unsupervised DA methods, which do not require data annotations. The statistics used to standardize the target domain data (mean and standard deviation coefficients) are computed either from the source dataset (*global* variants) or from the target dataset (*adaptive* variants). As a consequence, global variants require access to the source domain data whereas adaptive variants only need fractions of the target domain data.The statistics can be computed either over all available files of the selected domain or individually per file. Furthermore, it is possible to have a finer resolution when computing frequency-wise, i. e., by averaging over all time frames and obtaining coefficients per frequency bin, or patch-wise statistics, i. e., by averaging all frequencies within a patch of 16 time frames. These methods are summarized in Table 1. Finally, in addition to standardizing the target domain features, the source domain data will also be standardized before training the model.

2.2.2 Band-wise Statistics Matching (BWSM)

Band-Wise Statistics Matching (BWSM) is an unsupervised DA method, which involves a band-wise alignment of the first and second statistical moments of the target domain data to the ones of the source domain data [13]. Similarly to standardization, the method is applied on the data level and avoids a re-training of a ML model. First, the sample mean and standard deviation values are computed over source and target domain data per frequency bands. Then, a band-wise standardization is applied to the target domain in a similar way as in the adaptive ZMUV normalization per frequency as discussed in the previous section. At the final stage, the adapted features in the target domain $\mathbf{X}_\mathrm{T}$ are aligned to the source domain $\mathbf{X}_\mathrm{S}$, sharing the same means and standard deviations. In contrast to other assessed DA methods, source domain data remains unchanged and the originally trained ML models can be re-used.

Type	Data Scope	Resolution
Global	Domain (all)	Frequency
Adaptive	Domain (all)	Frequency
Adaptive	File	Frequency
Adaptive	File	Patch

Table 1. Overview of the implemented standardization methods w.r.t. their type (global or adaptive), data scope (whole domain or per file), and resolution (subdivision by frequency bins or patches).

2.2.3 Correlation Alignment (CORAL)

Sun et al. [14] proposed CORrelation ALignment (CORAL) as an unsupervised DA method to align the statistical moments of source and target data. After whitening the source domain data (i. e., removing correlation among features), the covariance matrix of the target domain data distribution $\mathbf{C}_\mathrm{T}$ is transferred to the source distribution (re-coloring). Then, a new model needs to be trained on the adapted source domain data.

Given that the distribution of target domain data varies with each mobile device, room, and piano type in our given scenario, it is not feasible to train a new MPE model each time one of these parameters changes. In contrast to the original publication, we implemented CORAL such that the target domain data is adapted using the statistics obtained from the source domain data. We follow [14] and use a regularization parameter $\lambda = 1$ for traditional whitening without a singular value decomposition (SVD). The target domain data $\mathbf{D}_\mathrm{T}$ is whitened as in [14] and then re-colored with the source domain covariance matrix $\mathbf{C}_\mathrm{S}$ as $\mathbf{D}_\mathrm{T} \leftarrow \mathbf{D}_\mathrm{T} * \mathbf{C}_\mathrm{T}^{-\frac{1}{2}} * \mathbf{C}_\mathrm{S}^{\frac{1}{2}}$. This way, the source domain data remains unchanged and the same classifier can be used for all target domains. However, Sun et al. [14] observed a lower performance with this approach and supposed that a model trained on adapted source domain data may benefit from the knowledge inherited by the target data distribution. This is not possible if only the target domain data is modified by DA, as the model is trained on the original source domain data independent of the target domain data.

2.2.4 Feature Projection-Based Unsupervised Domain Adaptation (FPDA)

Mezza et al. [15] proposed Feature Projection-based Unsupervised Domain Adaptation (FPDA) to address the mismatch between the distributions of training and test data acquired under different recording conditions. FPDA is based on the projection of both source and target domain features onto a common subspace using a subset of the eigenvectors of the sample covariance matrix of the source domain data. After standardizing the spectrograms extracted from the source domain in a band-wise fashion, the sample covariance matrix $\mathbf{V}_{\mathrm{s}}$ of the source domain data matrix and the respective eigenvectors and eigenvalues are calculated. The eigenvectors corresponding to the L largest eigenvalues are retained as matrix $\mathbf{V}_{\mathrm{s}}^{(L)}$ and using this matrix source domain and target domain data are projected onto a common subspace as $\mathbf{X}_{\mathrm{S}} = \bar{\mathbf{S}}_{\mathrm{2D}}\mathbf{V}_{\mathrm{s}}^{(L)}$ and $\mathbf{X}_{\mathrm{T}} = \bar{\mathbf{T}}_{\mathrm{2D}}\mathbf{V}_{\mathrm{s}}^{(L)}$.

There are several differences between the application of FPDA in Acoustic Scene Classification (ASC) [15] and our application scenario for real-time piano transcription. Firstly, in [15], source and target domain data contain the same audio signal recorded simultaneously on different recording devices with a constant length of ten seconds, whereas the files contained in our source domain data have entirely different musical content as compared to the target domain data. Moreover, the number of samples varies greatly throughout both the source and target domain dataset in our case. For this reason and for FPDA to be applicable w.r.t. a real-time piano transcription scenario, we chose $L = 16$, so that the DA can be applied in a block-wise fashion, 16 frames at a time. To use the domain-adapted features as input for the piano transcription model, we project the features back to the original feature space as $\hat{\mathbf{S}}_{\mathrm{2D}} = \mathbf{X_S}\mathbf{V}_{\mathrm{s}}^{(L)^T}$ as $\hat{\mathbf{T}}_{\mathrm{2D}} = \mathbf{X_T}\mathbf{V}_{s}^{(L)^T}$. Then, the MPE model is trained on the resulting modified source domain data.

3. MULTI-PITCH ESTIMATION

3.1 Recent Approaches

While traditional MPE methods mostly relied on spectral decomposition techniques such as non-negative matrix factorization (NMF) [16], modern methods are based on different neural network (NN) architectures [17]. Hawthorne et al. [18] propose a general purposed piano transcription model that combines two branches of convolutional recurrent neural networks (CRNNs), which jointly predict the pitches and onset times of played piano notes. Kong et al. [19] proposed a high-resolution AMT system consisting of several CRNNs acoustic models dedicated to different tasks such as velocity, onset and offset regression. More recently, generic encoder-decoder architectures such as transformer networks have been used to remove the need of custom NN design, as done by Hawthorne et al. [20].

3.2 Model Architecture

Following recent advances in the field of computer vision, the U-net architecture is employed for different MIR tasks. In particular, it was used for different AMT tasks such as bass transcription [21], melody transcription [22, 23], as well as polyphonic piano transcription [24]. The structure of a U-net resembles an autoencoder, but is extended by skip connections between encoder and decoder blocks. Input features are first processed by an encoder that sequentially reduces the time-frequency resolution. The intermediate features are then handed over to the decoder part at the so-called bottleneck, where the compression is strongest. In the decoder, the time-frequency resolution is gradually restored by upsampling and interpolation. The main goal is to train the U-net such that it learns a mapping function from a spectrogram-like audio representation to a piano roll representation. In this study, we consider MPE as binary classification task, where each pitch can be either active or inactive at a given time frame. The encoder of our U-net model comprises three layers with alternating blocks of convolutional filter blocks and max pooling. In the decoder, bilinear interpolation operations are used for upsampling. Intermediate activations at similar levels in the encoder and decoder are connected by skip connections. The model output lies in the same feature space as the input features, but with a reduced frequency resolution of 72 bins instead of 216 bins.

The model was trained for 300 epochs with the Adam optimizer at an initial learning rate of $5 \cdot 10^{-4}$, early stopping patience of 20, and the binary crossentropy loss function.

3.3 Audio Representation

The MPE model expects input features as an harmonic Constant-Q transform (HCQT) [25] $H_{h,f,t}$ indexed by harmonic ratio h, frequency f, and time t. For any harmonic $h > 0$, we compute a standard Constant-Q transform (CQT), where the minimum frequency is scaled by the harmonic ratio h. For this MPE task, the HCQTs are computed for the harmonic ratios $h \in \{0.5, 1, 2, 3, 4, 5\}$, that is, one sub-harmonic below the fundamental frequency ($h = 0.5$), the fundamental frequency ($h = 1$) and four harmonics above ($h = [2, 3, 4, 5]$). As the fundamental frequency and the first harmonic often contain similar harmonic patterns [25], one sub-harmonic below the fundamental is included to distinguish between the two.

Features are extracted with the *librosa* Python library [26] with a hopsize of 512 samples, a sampling rate $f_{\mathrm{s}} = 22.05\,\mathrm{kHz}$, a frequency resolution of 36 bins per octave (bpo), and a minimum frequency for the CQT of $f_{\mathrm{min}} = 32.7\,\mathrm{Hz}$. This results in input features of dimension $\mathbf{X} \in \mathbb{R}^{M \times K \times C}$, with the number of time frames $M = 16$ for patch-wise processing, number of frequency bins $K = 216$, and amount of channels $C = 6$.

4. DATASET

4.1 Source Dataset

The U-net MPE model was trained and tested on subsets of the MIDI Aligned Piano Sounds (MAPS) dataset [1]. We used the dataset split labelled "Configuration 2" by Sigtia et al. [27], which divides MAPS into 210 synthesized audio files for training and 60 real-world audio recordings for test data. The audio and aligned MIDI data used for training were generated using synthesis software based on high-quality sample libraries, whereas the test set contains piano recordings from a MIDI-controlled Disklavier which was recorded on two omnidirectional Schoeps microphones in a studio setting. We refer to the training data as `MAPS-train` and test data as `MAPS-test`.

4.2 Target Dataset

To assess the selected DA methods, we require a dataset of multiple transcribed piano recordings which cover different mobile devices as recording devices, recording locations with different acoustical properties, and various acoustic piano models (upright and grand piano). Because no openly available dataset fulfilled all our requirements, we created a new dataset called `IDMT-PIANO-MM` [28].

`IDMT-PIANO-MM` contains a total of 432 audio files (about 4 h 7 min) and 72 MIDI files corresponding to 72 unique piano performances recorded simultaneously on five recording devices (3 smartphones, 2 tablets) and a high-quality stereo microphone. The 72 MIDI files were generated and aligned manually to match the actual piano performance. The recording environments range from small rooms to large lecture halls. Three grand pianos, four upright pianos, and one electronic stage piano of various age, brand and price segments were recorded. In each room we recorded a human piano performance of a self-composed swing pattern, chord progression, a chromatic scale, as well as sections (between 24 s and 54 s) out of five classical music pieces and one ragtime piece.

5. ANALYZING DOMAIN SHIFT

5.1 Investigation of Microphone Mismatch

To validate the microphone mismatch, we compute the spectrum correction coefficients as described in [29] to compare the acoustic characteristics of different recording devices. We choose the high-quality stereo microphone as reference device r. The frequency response of each mobile device d is compared per frequency bin with the reference to obtain a vector of multiplicative correction coefficients, which allows to make the frequency response of the device d equal to the one of the reference device r. Figure 2 illustrates the band-wise coefficients obtained for each mobile device. The correction coefficients show that there are considerable differences among the recordings associated to the different devices and their microphones. This confirms the microphone mismatch condition and suggests there is a domain shift between the training data from MAPS and the test data recorded with different mobile devices.

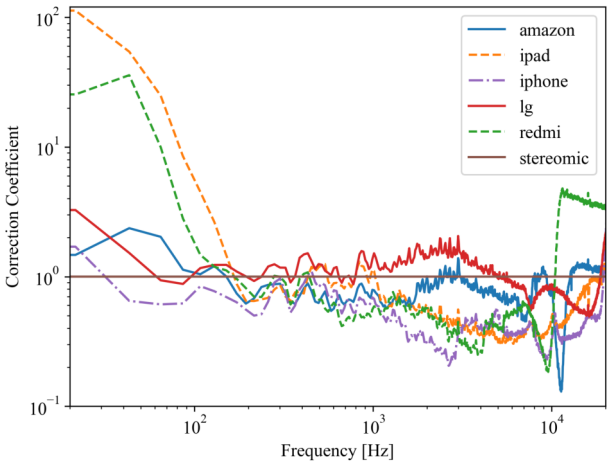

Figure 2. Frequency-dependence of the spectrum correction coefficients for all devices in respect to the `stereomic` microphone.

5.2 Quantifying Domain Shift

Due to the observed differences in the acoustic characteristics of the recording devices, we expect a measurable domain shift, which we quantify using the representation shift metric proposed by Stacke et al. [30]. The main idea is to compute an abstract representation of source and target domain features from a latent representation within a deep neural network and compare the data distributions between both domains in this latent feature space. In our experiments, we computed the activations after the last convolutional layer of the encoder in the U-net MPE model to measure domain shift, as we expect the highest degree of abstraction here.

In [30], the layer activations at layer l and filter f are averaged across the two spatial dimensions of a feature map. Since we deal with audio instead of images, these dimensions correspond to time frames and frequency bins. As the convolutional neural network (CNN) structure used in [30] is not directly comparable with the U-net architecture, we assumed that the U-net only has one filter operation per layer for simplicity. The mean value of a layer activation $\phi_l(x)$ at layer l is denoted as

$$c_l(x) = \frac{1}{N}\frac{1}{K}\sum_{i=1}^{N}\sum_{j=1}^{K}\phi_l(x)_{i,j} \qquad (1)$$

with the number of time frames N, number of frequency bands K, and i and j as time and frequency index of the feature map, respectively. The mean values of layer activations are aggregated over all input features of a domain. The probability density function (PDF) of all mean values is approximated by computing a probability density histogram with 500 bins for each HCQT channel. The resulting PDFs are averaged over all HCQT channels. Finally, we compute the representation shift r as the mean distance between the distributions of the source and target domain. We employ the Wasserstein distance, which is a symmetric distance measure that can be seen as the least amount of

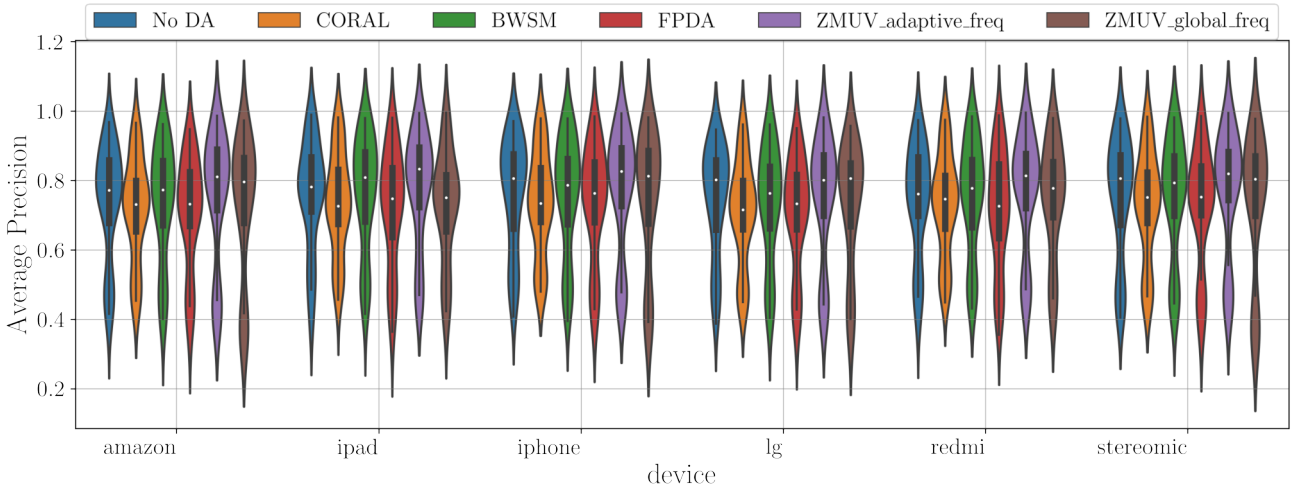

Figure 3. Performance of the MPE model on `IDMT-PIANO-MM`. The average precision score is presented for different DA methods grouped by recording devices.

Domain Pairs	r
`MAPS-train` vs. `IDMT-PIANO-MM`	0.035
`MAPS-train` vs. `IDMT-PIANO-MM-BWSM`	0.029
`MAPS-train` vs. `MAPS-test`	0.029

Table 2. Representation shift r based on the Wasserstein distance between source training data and source test data (`MAPS-train` vs. `MAPS-test`), source training data and target data (`MAPS-train` vs. `IDMT-PIANO-MM`), source training data and with BWSM domain-adapted target data (`MAPS-train` vs. `IDMT-PIANO-MM-BWSM`).

effort required to align two distributions w.r.t. the amount of data and the distance that has to be moved [30]. The representation shift between the used datasets is given in Table 2. The DA method BWSM was chosen as, in contrast to other DA methods, source domain data is not modified, which enables to directly compare the implementation with and without DA with identical MPE models.

6. IMPACT OF DOMAIN SHIFT ON PERFORMANCE

The performance of the MPE model is tested by comparing the estimated pitches with MIDI data as ground truth per frame. We chose mean Average Precision (mAP), i. e., the area under the precision-recall curve [31], as an evaluation metric, which is denoted as Average Precision (AP) in the following. Unlike other popular ML evaluation metrics like F-score or accuracy, AP does not depend on a particular binarization threshold for the pitch activity predictions.

6.1 Effect of Domain Adaptation

Figure 3 shows the AP scores of the U-net MPE model on the benchmark dataset separated by recording device. It shows that the microphone mismatch has no significant effect on the performance of the MPE model. Presumably as a direct consequence, we observe only little variation in transcription performance caused by DA. `ZMUV adaptive` performs consistently best, `ZMUV global` and `BWSM` report a similar performance as using no DA, and with `FPDA` and `CORAL` the AP scores are lowest amongst all DA methods, including not applying any DA.

6.2 Impact of Musical Content and Acoustic Context

We also assessed the impact of other parameters on the MPE performance, such as room acoustics and musical pieces. Our results showed no significant influence of the room and instrument characteristics towards the MPE performance. In contrast, the musical content shows the greatest impact on transcription performance. Figure 4 displays the influence of music content on the AP score when no DA or different DA methods are applied. Due to missing annotations of offsets, we assume that the MPE performance is lower for `beethoven1` and `beethoven2` as these pieces involve the use of the sustain pedal. While some of the DA methods vary in effectiveness for different music content, like FPDA and CORAL, overall the results of DA seem to be quite consistent and do not improve performance significantly regardless of the musical content.

7. DISCUSSION

Although the examined DA methods reduced the domain shift between `MAPS-train` and our test dataset `IDMT-PIANO-MM` (see Table 2), the MPE performance could not be improved significantly by DA. We see several possible explanations for this.

First, it should be noted that the applied method to quantify domain shift assumes that each convolutional layer of the MPE model contains only one filter, which is not given with the U-net MPE model. Further research must investigate how this discrepancy leads to a biased measurement. Yet, we expect that the computed domain shift values can

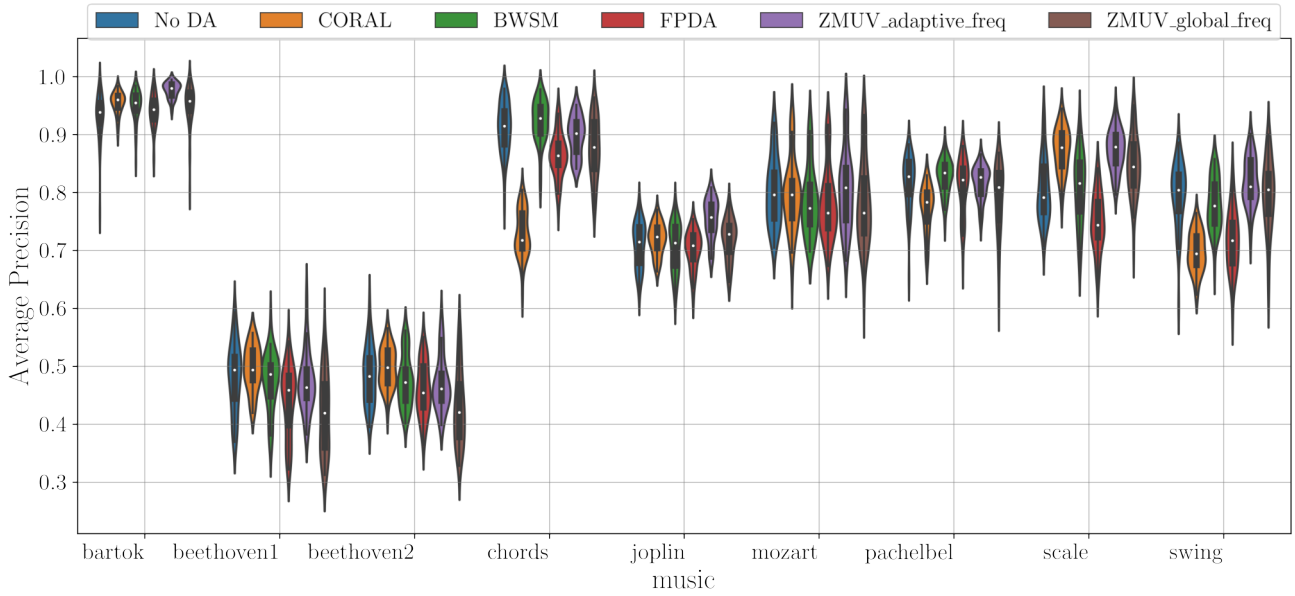

Figure 4. Performance of the MPE model on `IDMT-PIANO-MM`. The average precision score is presented for different DA methods grouped by music pieces.

still provide a general tendency.

Second, the employed MPE model might already generalize well enough to the given task. In fact, the U-net model itself can be considered as a reconstruction-based deep DA implementation as defined in [5]. The encoding procedure ensures that domain-specific features are disregarded, while the decoding part enables to attribute a feature within a domain. Therefore, it would be interesting to examine the presented DA methods for MPE models with other network architectures.

Third, the benchmark dataset `IDMT-PIANO-MM` does not provide precise offset annotations, which can introduce label noise to the frame-wise MPE evaluation.

Finally, there are further restrictions for particular DA methods. Our implementation of FPDA involves cutting the features after 16 time frames (about 0.372 s), whereas the original approach [15] keeps 10 s of data for the transformation matrix. As we reduced the size of the transformation matrix extremely, our implementation could be inaccurate. Moreover, unlike in the original paper [15] it was not possible to use recordings with identical content (denoted as "parallel data" in [13]). This requires audio data to be simultaneously captured using source and target domain devices, which is not applicable in this study. Besides, CORAL is implemented as time-independent DA since frequency patterns are only compared within one time frame. The domain-specific knowledge of time is disregarded due to buffer memory limits. As there is no reference implementation for CORAL in the audio domain to our knowledge, we cannot compare this approach to other findings. The effectiveness of adaptive ZMUV normalization is restricted by the sole dependency on recorded target data. Unlike in global ZMUV normalization, no source domain data is used to modify target data. Hence, if the amount of cached target data is too small, the DA may fail.

8. CONCLUSION

In this paper, we studied the influence of domain shift to piano MPE under microphone mismatch conditions. As our first contribution, we created and published a novel benchmark dataset of piano recordings captured with various mobile devices. In our initial experiments, we verified differences in the used recording devices using the spectrum correction coefficient method. As a second step, we quantified the domain shift between the source domain (`MAPS-train`) and different target domains of a novel benchmark dataset (`IDMT-PIANO-MM`) using the representation shift based on the Wasserstein distance between distributions of intermediate activation map values of the MPE model. We investigated in particular the performance of an MPE model based on the U-net architecture. As expected, the domain shift was greater between source and target data than between two subsets of the MAPS dataset (0.035 vs. 0.029 respectively), possibly due to different types of recording settings.

As a third step, we investigated the influence of domain shift on the MPE performance and found that the U-net model is surprisingly robust to domain shift conditions. We assume the main reason for this is that spectral peaks contain the main information for the MPE. Domain shift, however, mainly causes deviations in the overall spectral envelope of the signal, which are mostly irrelevant for the given task. Finally, we evaluated four different unsupervised DA methods in order to reduce the domain shift. The DA method BWSM was able to reduce the measured domain shift from the initial 0.035 to 0.029.

In future research, we aim to evaluate additional MPE models based on other neural network architectures, such as CRNNs or transformer models, to assess the influence of the network architecture on the robustness against domain shift.

MELODY TRANSCRIPTION VIA GENERATIVE PRE-TRAINING

ABSTRACT

Despite the central role that melody plays in music perception, it remains an open challenge in MIR to reliably detect the notes of the melody present in an arbitrary music recording. A key challenge in *melody transcription* is building methods which can handle broad audio containing any number of instrument ensembles and musical styles—existing strategies work well for *some* melody instruments or styles but not all. To confront this challenge, we leverage representations from Jukebox [1], a generative model of broad music audio, thereby improving performance on melody transcription by 20% relative to conventional spectrogram features. Another obstacle in melody transcription is a lack of training data—we derive a new dataset containing 50 hours of melody transcriptions from crowdsourced annotations of broad music. The combination of generative pre-training and a new dataset for this task results in 77% stronger performance on melody transcription relative to the strongest available baseline. [1] By pairing our new melody transcription approach with solutions for beat detection, key estimation, and chord recognition, we build Sheet Sage, a system capable of transcribing human-readable lead sheets directly from music audio.

1. INTRODUCTION

In the Western music canon, *melody* is a defining characteristic of musical composition, and can even constitute the very identity of a piece of music within the collective consciousness. Because of the significance of melody to our music perception, the ability to automatically transcribe the melody notes present in an arbitrary recording could enable numerous applications in interaction [2], education [3], informatics [4], retrieval [5], source separation [6], and generation [7]. Despite the potential benefits, reliable melody transcription remains an open challenge.

A closely-related problem that has received considerable attention from the MIR community is *melody extraction* [8–11], where the goal is to estimate the time-varying, continuous F0 trajectory of the melody in an audio mixture. In contrast, the goal of melody transcription is to output the *notes* of the melody, where a note is defined by an onset time, a pitch, and an offset time. While F0 trajectories are useful for several downstream tasks (e.g., query by humming) and more inclusive of music which does not use equal-tempered pitches, unlike notes, trajectories cannot be readily converted into formats like MIDI or scores which are more convenient for musicians.

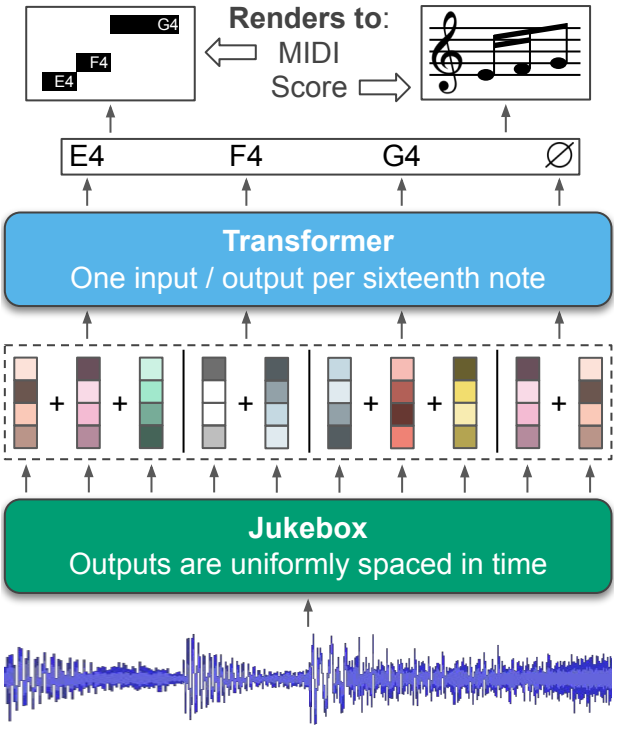

Figure 1. Our melody transcription approach involves (1) extracting audio representations from Jukebox [1], a generative model of music, (2) averaging these representations across time to their nearest sixteenth note (dashed outline—uses `madmom` [12, 13] for beat detection), and (3) training a Transformer [14] to detect note onsets (or absence thereof) per sixteenth note. Outputs can be rendered to MIDI (by mapping beats back to time) or a score.

The relative lack of progress on melody transcription is perhaps counterintuitive when compared to the considerable progress on seemingly more difficult tasks like piano transcription [15, 16]. This circumstance stems from two primary factors. First, unlike in piano transcription, melody transcription involves operating on *broad* audio mixtures from arbitrary instrument ensembles and musical styles. Second, there is a deficit of training data for melody transcription, which particularly impedes the deep learning approaches central to recent improvements on other transcription tasks. Moreover, collecting data for melody tran-

scription is difficult compared to collecting data for tasks like piano transcription, where a Disklavier can be used to create aligned training data in real time.

To overcome the challenge of transcribing broad audio, in this work we leverage representations from Jukebox [1], a large-scale generative model of music audio pre-trained on 1M songs. In [17], Castellon et al. demonstrate that representations from Jukebox are useful for improving performance on a wide variety of MIR tasks. Here we show that, when used as input features to a Transformer model [14], representations from Jukebox yield 27% stronger performance on melody transcription (as measured by note-wise F1) relative to handcrafted spectrogram features conventionally used for transcription. To our knowledge, this is the first evidence that representations learned via generative modeling are useful for time-varying MIR tasks like transcription, as opposed to the song-level tasks (e.g. tagging, genre detection) examined in [17].

To address the data deficit for melody transcription, we release a new dataset containing 50 hours of melody annotations for broad audio which we derive from HookTheory. [2] The user-specified alignments between the audio and melody annotations in HookTheory are crude—we refine these alignments using beat detection. To overcome remaining alignment jitter, we resample features to be uniformly spaced in beats (rather than time) and pass these *beat-wise resampled* features as input to melody transcription models. This procedure has a secondary benefit of enabling simple conversion from raw model outputs to human-readable scores (Figure 1).

By training Transformer models on this new dataset using representations from Jukebox as input, we are able to improve overall performance on melody transcription by 70% relative to the strongest available baseline. A summary of our primary **contributions** follows:

- We show that representations from generative models can improve melody transcription (Section 6).
- We collect, align, and release a new dataset with 50 hours of melody and chord annotations (Section 4).
- We propose a method for training transcription models on data with imprecise alignment (Section 5.3).
- As a bonus application of our melody transcription approach, we build a system which can transcribe music audio into lead sheets (Section 7).

2. RELATED WORK

Melody transcription is closely related to but distinct from the task of melody extraction, originally referred to as predominant fundamental frequency (F0) estimation [8, 9]. Melody extraction has received significant interest from the MIR community over the last two decades (see [10, 11] for comprehensive reviews), and is the subject of an annual MIREX competition [18]. Melody extraction may be a component of a melody transcription pipeline in combination with a strategy to segment F0 into notes [19–21]—we directly compare to such a pipeline in Section 6.2.

Compared to melody extraction, melody transcription has received considerably less attention. Earlier efforts use sophisticated DSP-based pipelines [22–25]—unfortunately none of these methods provide code, though [24] provides example transcriptions which we use to facilitate direct comparison. A more recent effort uses ground truth chord labels as extra information to improve melody transcription [26]—in contrast, our method does not require extra information. Another line of work seeks to transcribe solo vocal performances into notes [27–30]. As singing voice often carries the melody in popular music, we directly compare to a baseline which firsts isolates the vocals (using Spleeter [31]) and then transcribes them.

Polyphonic music transcription is another related task which involves transcribing *all* of the notes present in a recording (not just the melody). This task has its own MIREX contest (Multiple Fundamental F0 Estimation) alongside a growing collection of supervised training data resources [7, 32–34]. The similarity of the polyphonic and melody transcription problems motivates us to experiment with representations learned by a polyphonic system—specifically, MT3 [35]—for melody transcription.

3. TASK DEFINITION

In this work, melody transcription refers to the task of converting a music recording into a *monophonic* (non-overlapping) sequence of *notes* which constitute its dominant melody. [3] More precisely, given a music waveform $\boldsymbol{a}$ of length T seconds, our task is to uncover the sequence of N notes $\boldsymbol{y} = [\boldsymbol{y}_1, \ldots, \boldsymbol{y}_N]$ that represent the melody of $\boldsymbol{a}$. For many MIR tasks, including transcription, it can be convenient to work with *features* of audio $\boldsymbol{X} = \texttt{Featurize}(\boldsymbol{a})$, rather than waveforms. Hence, a melody transcription algorithm is a procedure that maps featurized audio to notes, i.e. $\boldsymbol{y} = \texttt{Transcribe}(\boldsymbol{X})$.

Canonically, a musical note consists of an onset time, a musical pitch, and an offset time. However, in this work we disregard offsets and define a note to be a pair $\boldsymbol{y}_i = (t_i, n_i)$ consisting of an onset time $t_i \in [0, T)$ and discrete musical pitch $n_i \in \mathbb{V} = \{\text{A0}, \ldots, \text{C8}\}$. We ignore offsets for two reasons. First, accurate offsets have been found to be considerably less important for human perception of transcription quality compared to accurate onsets [36]. Second, in our dataset, a heuristically-determined offset is identical to the user-annotated offset for 89% of notes. [4]

Formally, a musical audio recording of length T seconds sampled at rate f_s is a vector $\boldsymbol{a} \in \mathbb{R}^{Tf_s}$. A featurization of audio $\boldsymbol{X} \in \mathbb{R}^{Tf_k \times d}$ is a matrix of d-dimensional features of audio, sampled uniformly at some rate $f_k \ll f_s$ (for example, $\boldsymbol{X}$ could be a spectrogram). Intuitively, the function $\texttt{Featurize} : \mathbb{R}^{Tf_s} \to \mathbb{R}^{Tf_k \times d}$ defined by

[2] https://www.hooktheory.com/theorytab

[3] Melody is difficult to precisely define—here we adopt an implicit definition based on a dataset of crowdsourced melody annotations.

[4] The specific heuristic that we use sets the offset of one note equal to the onset of the next, i.e., it assumes the melody is legato.

$\boldsymbol{a} \mapsto \boldsymbol{X}$ maps raw audio to a feature representation more conducive to learning. A melody of length N is a sequence of notes $\boldsymbol{y} = [\boldsymbol{y}_1, \ldots, \boldsymbol{y}_N] \in \mathbb{Y}^N$ consisting of onset-pitch pairs $\boldsymbol{y}_i = (t_i, n_i) \in \mathbb{Y} = \mathbb{R}^+ \times \mathbb{V}$ where $t_i < t_j$ if $i < j$. Given a featurization $\boldsymbol{X}$, the melody transcription task is to construct a transcription algorithm $\texttt{Transcribe} : \mathbb{R}^{Tf_k \times d} \to \mathbb{Y}^N$ such that $\boldsymbol{X} \mapsto \boldsymbol{y}$.

3.1 Evaluation

To evaluate a melody transcription method `Transcribe`, we adopt a standard metric commonly used for evaluation in polyphonic music transcription tasks, namely, "onset-only note-wise F-measure" [36]. This metric scores an estimated transcript $\texttt{Transcribe}(\boldsymbol{X})$ by first matching its note onsets to those in the reference $\boldsymbol{y}$ with 50ms of tolerance (default in [37]), and then computes a standard `F1` score where an estimated note is treated as correct if it is the same pitch as its matched reference note. This "note-wise" metric represents a departure from the "frame-based" metrics typically used to evaluate melody extraction algorithms—Ycart et al. demonstrate in [36] that this particular note-wise metric correlates more strongly with human perception of transcription quality than any other common metric, including frame-based ones.

We make a slight modification to this note-wise metric specific to the melody transcription setting: an estimate $\texttt{Transcribe}(\boldsymbol{X})$ may receive full credit if it is off by a fixed octave shift but otherwise identical to the reference. In downstream settings, melody transcriptions are likely to be used in an octave-invariant fashion, e.g., they may be shifted to read more comfortably in treble clef, or performed by singers with different vocal ranges. Hence, we modify the evaluation criteria by simply taking the highest score over octave shifted versions of the estimate:

$$\max_{\sigma \in \mathbb{Z}} \texttt{F1}(\texttt{OctaveShift}(\texttt{Transcribe}(\boldsymbol{X}), \sigma), \mathbf{y}).$$

Henceforth, we refer to this octave-invariant metric as `F1`.

4. DATASET OVERVIEW

A major obstacle to progress on melody transcription is the lack of a large volume of data for training. To the best of our knowledge, there are only two datasets available with annotations suitable for melody transcription: the RWC Music Database [38–40] (RWC-MDB), and a dataset labeled by Laaksonen [26]. The former is larger but the annotations are inconsistent—Ryynänen and Klapuri note that only 8.7 hours (130 songs) are usable for melody transcription [24], while the latter only contains 1.5 hours.

We derive a suitably large dataset for melody transcription using crowdsourced annotations from HookTheory.[5] HookTheory is a platform where users can easily create and share musical analyses of particular recordings hosted on YouTube, with Wikipedia-style editing. The dataset contains annotations for 22k segments of 13k unique recordings totaling 50 hours of labeled audio. The audio content covers a wide range of genres—there is a skew towards pop and rock but many other genres are represented including EDM, jazz, and even classical. We create an artist-stratified 8:1:1 split of the dataset for training, validation, and testing. The dataset also includes chord annotations which may facilitate chord recognition research.

While HookTheory data has been used previously for MIR tasks like harmonization [41, 42], chord recognition [43], and representation learning [44], making use of this platform for MIR is currently cumbersome. One obstacle is that the annotations are created via a "functional" interface, i.e., one which uses scale degrees and roman numerals relative to a key signature instead of absolute notes and chord names. In contrast, most MIR research favors absolute labels. Hence, we convert annotations from this functional format to a simple (JSON-based) absolute format. One caveat is that the HookTheory annotation interface uses a relative octave system, so there is no way to reliably map annotations to a ground truth octave. Thus, melodies in our dataset also contain only relative octave information, consistent with the octave-invariant evaluation proposed in Section 3.1.

5. METHODS

Similar to state-of-the-art methodology used for polyphonic transcription [45], our approach to melody transcription involves training Transformer models [14] to predict notes from audio features. However, to address the unique challenges of melody transcription, our approach differs in two distinct ways. First, because melody transcription involves operating on broad audio, we leverage representations from pre-trained models as drop-in replacements for the handcrafted spectrogram features used as inputs to other transcription systems. Secondly, because alignments in our dataset are approximate, we propose a new strategy for training transcription models under such conditions.

5.1 Pre-trained representations

We explore representations from two different pre-trained models for use as input features to transcription models. In [17], Castellon et al. demonstrate that representations from Jukebox [1]—a generative model of music audio pre-trained on 1M songs—constitute effective features for many MIR tasks, though notably they do not experiment on transcription. We adopt their approach to extract features from Jukebox ($f_k \approx 345$ Hz, $d = 4800$), though we use a deeper layer (53) than their default (36) which improved transcription performance in our initial experiments.

We also explore features from MT3 [35], an encoder-decoder transcription model pre-trained on a multitude of different transcription tasks (though not melody transcription). For this model, we use the encoder's outputs as features ($f_k = 125$ Hz, $d = 512$). The two models have different trade-offs with respect to our setting: Jukebox was pre-trained on audio similar to that found in our dataset but in a generative fashion, whereas MT3 is pre-trained on transcription but for different audio domains.

[5] HookTheory annotations are published under a CC BY-NC-SA 3.0 license, which our dataset inherits.

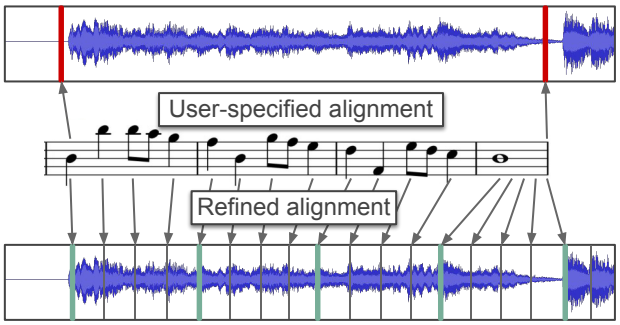

Figure 2. We refine the crude user-specified alignments from HookTheory by using beat and downbeat tracking. The first segment beat is mapped to the detected downbeat nearest to the user-specified starting timestamp, and remaining beats are mapped to subsequent detected beats.

5.2 Refined Alignments

The alignments between audio and HookTheory annotations are crude—users provide only an approximate starting and ending timestamp of their annotated segment within the audio. Because transcription methodology generally depends on precise alignments, we make an effort to refine the user-specified ones. To this end, we make use of the beat and downbeat detection algorithm from `madmom` [12, 13]. Specifically, our approach aligns the first beat of the segment to the detected downbeat which is nearest to the user-specified starting timestamp. Then, we align the remaining beats to the subsequent detected beats (see Figure 2 for an example). This provides a beat-level alignment for the entire segment, which we linearly interpolate to fractional subdivisions of the beat. Formally, we construct an alignment function $\texttt{Align} : [0, B) \to [0, T)$ that assigns each of B beats in the metrical structure to a time $t \in [0, T)$ in the audio. In an informal listening test, this produced an improved alignment for 95 of 100 segments, where the primary failure mode in the remaining 5 segments occurred when `madmom` detected the wrong beat as the downbeat. We use these refined alignments for training and evaluation and release them alongside the dataset.

5.3 Beat-wise resampling

Here we outline our approach for training transcription models in the presence of imprecise alignments. Existing transcription methods were largely designed for domains where perfect alignments are readily available, e.g., piano transcription data captured by a Disklavier. Despite our best efforts, the refined HookTheory alignments are still imprecise when compared to alignments in the datasets used to develop existing methods. Consequently, in initial experiments, we found that naively adopting existing methods (specifically, [16, 45]) resulted in poor performance on our dataset and task. Additionally, initial experiments on training models with an alignment-free approach [46] also resulted in poor performance.

Accordingly, to sidestep small alignment deviations, we perform a beat-wise resampling of audio features $\boldsymbol{X} \in \mathbb{R}^{Tf_k \times d}$ to yield features that are uniformly spaced in subdivisions of the beat (using `Align`—see Section 5.2) rather than in time. For an audio recording with B beats, we sample features $\tilde{\boldsymbol{X}} \in \mathbb{R}^{4B \times d}$ at sixteenth-note intervals. The value $\tilde{\boldsymbol{X}}_i$ is constructed by averaging all feature vectors in $\boldsymbol{X}$ that are nearest to the i'th sixteenth note into a single vector which acts as a proxy feature. For example, if a recording has a tempo of 120 BPM, a sixteenth note represents 125 ms of time, which would entail averaging across 43 feature vectors from Jukebox ($f_k \approx 345$ Hz). The intuition is that, while our alignments may not be precise enough to identify which of those 43 frames contains an onset, we can be reasonably confident that it occurs *somewhere* within them, and thus the relevant frame will be incorporated into the proxy. A similar approach was previously explored for song structure analysis in [47].

5.4 Modeling

Together with the beat-wise resampling $\tilde{\boldsymbol{X}} \in \mathbb{R}^{4B \times d}$, we convert the sparse task labels $\boldsymbol{y} \in (\mathbb{R}^+ \times \mathbb{V})^N$ into a dense sequence $\tilde{\boldsymbol{y}} \in \{\{\varnothing\} \cup \mathbb{V}\}^{4B}$, which indicates whether or not an onset occurs at each sixteenth note.[6] Formally,

$$\tilde{\boldsymbol{y}}_i = \begin{cases} n_j & \text{if } \texttt{Align}(\frac{i}{4}) = t_j \text{ for some note } \boldsymbol{y}_j, \\ \varnothing & \text{otherwise.} \end{cases}$$

We formulate melody transcription as an aligned sequence-to-sequence modeling problem and attempt to predict the sequence $\tilde{\boldsymbol{y}}$ given $\tilde{\boldsymbol{X}}$. Specifically, we train models of the form $f_\theta : \mathbb{R}^{4B \times d} \to \mathbb{R}^{4B \times (|\mathbb{V}|+1)}$, which parameterize probability distributions $p_\theta(\tilde{\boldsymbol{y}}_i | \tilde{\boldsymbol{X}}) = \texttt{SoftMax}(f_\theta(\tilde{\boldsymbol{X}})_i)$ over elements of the sequence $\tilde{\boldsymbol{y}}$. One unique aspect of our dataset is that absolute octave information is absent (see Section 4). Hence, we construct an octave-tolerant cross-entropy loss by identifying the octave shift amount that minimizes the standard cross-entropy loss (denoted `CE`) when applied to the labels:

$$\min_{\sigma \in \mathbb{Z}} \sum_{i=0}^{4B-1} \texttt{CE}(p_\theta(\tilde{\boldsymbol{y}}_i | \tilde{\boldsymbol{X}}), \texttt{OctaveShift}(\tilde{\boldsymbol{y}}_i, \sigma)).$$

We require a thresholding scheme to convert the dense sequence of soft probability estimates $p_\theta(\tilde{\boldsymbol{y}}_i | \tilde{\boldsymbol{X}})$ into a sparse sequence of notes required by our task (see Section 3). Given a threshold $\tau \in \mathbb{R}$ (in practice, tuned on validation data), we define a sorted *onset list*

$$\mathcal{I} = \texttt{Sort}(\{i \in \{0, \ldots, 4B-1\} : p_\theta(\tilde{\boldsymbol{y}}_i = \varnothing | \tilde{\boldsymbol{X}}) < \tau\}).$$

This should be interpreted as a list of N metrical positions where an onset likely occurs. The timings of these onsets are given by the alignment, and we will predict the note-value with the highest probability. The sparse melody transcription is thus defined for $j = 1, \ldots, N$ by

$$\texttt{Transcribe}(\tilde{\boldsymbol{X}})_j = (t_j, n_j), \text{ where}$$
$$t_j = \texttt{Align}\left(\frac{\mathcal{I}_j}{4}\right),$$
$$n_j = \arg\max_{v \in \mathbb{V}} p_\theta(\tilde{\boldsymbol{y}}_{\mathcal{I}_j} = v | \tilde{\boldsymbol{X}}).$$

[6] This requires quantizing labels to the nearest sixteenth note. In practice, less than 1% of notes in our dataset are affected by this quantization.

Features	d	F1
Mel	229	0.514
MT3	512	0.550
Jukebox	4800	**0.615**
Mel, MT3	741	0.548
Mel, Jukebox	5029	0.617
MT3, Jukebox	5312	0.622
Mel, MT3, Jukebox	5541	**0.623**

Table 1. HookTheory test set performance for Transformers trained with different features (top) and combinations (bottom). Features are complementary—combining all three yields highest performance—but marginally so compared to Jukebox alone.

Approach	F1 (All)	F1 (Vocal)
MT3 Zero-shot [35]	0.133	0.085
Melodia [48] + Segmentation	0.201	0.268
Spleeter [31] + Tony [28]	0.341	**0.462**
DSP + HMM [24]	**0.420**	0.381
Mel + Transformer	0.631	0.621
MT3 + Transformer	0.701	0.659
Jukebox + Transformer	**0.744**	**0.786**

Table 2. Performance of different approaches on a subset of RWC-MDB [38–40]. The bottom three approaches were trained on the HookTheory dataset. For fair comparison to vocal transcription baselines, we also separately report performance on the vocal portions of this dataset.

6. EXPERIMENTS

Here we describe our experimental protocol for training melody transcription models on the HookTheory dataset. The purpose of these experiments is two-fold. First, we compare representations from different pre-trained models to handcrafted spectrogram features to determine if pre-training is helpful for the task of melody transcription (Section 6.1). Second, we compare our trained models holistically to other melody transcription baselines (Section 6.2).

All transcription models are encoder-only Transformers with the default hyperparameters from [14], except that we reduce the number of layers from 6 to 4 to allow models to be trained on GPUs with 12GB of memory. During training, we select random slices from the annotated segments of up to 96 beats or 24 seconds in length (whichever is shorter). We train using our proposed loss function from Section 5.4 and perform early stopping based on max F1 score across thresholds τ on the validation set, using the best validation τ for testing. All models converge within 15k steps or about a day on a single K40 GPU.

6.1 Comparing input features

We compare representations from Jukebox [1] and MT3 [35] (see Section 5.1) to handcrafted spectrogram features, which are commonly used by existing transcription methods. Specifically, we compare to log-amplitude Mel spectrograms using the formulation from [16] ($f_k \approx 31$, $d = 229$). Because features may contain complementary information, we also experiment with all combinations of these three features. Note that our beat-wise resampling strategy allows for trivial combination of these features (by concatenation) despite their differing rates. In Table 1, we report F1 (as described in Section 3.1) on the HookTheory test set for all input features.

Overall, using representations from Jukebox as input features results in stronger melody transcription performance than using either representations from MT3 or conventional handcrafted features. Representations from both MT3 and Jukebox outperform conventional handcrafted features, implying that both pre-training strategies are helpful for melody transcription. Note that these two pre-training approaches are compared holistically—these models differ on several axes (number of parameters, pre-training data semantics, pre-training task), and thus it is impossible to disentangle the individual contributions of these different factors without retraining the models.

Qualitatively speaking, there is a noticeable difference in performance across the three different input features which correlates with quantitative performance (see footnote 1 for sound examples). Using representations from Jukebox tends to result in fewer wrong notes than the other features, and substantially reduces the number of egregiously wrong notes (e.g., notes outside of the key signature). Representations from Jukebox also appear to aid in the detection of more nuanced rhythmic patterns. Moreover, using handcrafted features will often result in several repeated onsets during a longer sustained melody note—in contrast, using representations from Jukebox appears to mitigate this failure mode.

Different features also appear to complement one another to a degree. The strongest performance overall is obtained by combining all three features, though the improvement over Jukebox alone is marginal. The practical downsides of combining all features outweigh the marginal benefits—running both pre-trained models effectively doubles the overall runtime, and the models have incompatible software dependencies. Hence, in the remainder of this paper we focus on models trained on individual features.

6.2 Comparison to melody transcription baselines

We compare overall performance of our proposed melody transcription approach to several baselines. We evaluate all methods on a small subset of 10 songs from RWC-MDB [38–40], another dataset which includes melody transcription labels. We chose this specific subset in an effort to compare to early DSP-based work on melody transcription—none of the early approaches [22–25] shared code, however [24] shared melody transcriptions for this 10-song subset.

In addition to [24], we also compare to a baseline which applies a note segmentation heuristic [19] to a melody extraction algorithm [48]. We additionally compare to MT3 in a zero-shot fashion—this model was not trained on melody transcription but was trained on some tasks which incorporate vocal transcription. Finally, because the vo-

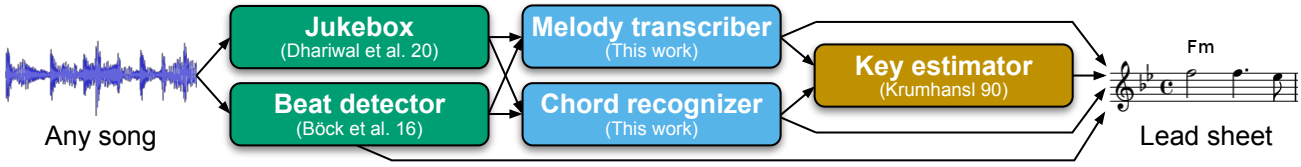

Figure 3. Inference procedure for Sheet Sage, our proposed system which transcribes any Western music audio into lead sheets (scores which depict melody as notes and harmony as chord names). The green, blue, and yellow boxes respectively take audio, features, and symbolic music data as input. Green boxes are modules that we built as part of this work—both are Transformers [14] trained on their respective tasks using audio features from Jukebox [1] and data from HookTheory [49].

cals often carry the melody in popular music, we compare to a baseline of running the Tony [28] monophonic transcription software on source-separated vocals isolated with Spleeter [31]. Because this approach will only work for vocals, we also separately report performance on a subset of our evaluation set where the vocals represent the melody. Scores for all methods and baselines appear in Table 2.

Overall, our approach to training Transformers with features from Jukebox significantly outperforms the strongest baseline in both the vocals-only and unrestricted settings ($p < 0.01$ using a two-sided t-test for paired samples). Qualitatively speaking, the stronger baselines produce transcriptions where a reasonable proportion of the notes are the correct pitches, but they have poor rhythmic consistency with respect to the ground truth. In contrast, our best model produces the correct pitches more often and with a higher degree of rhythmic consistency.

7. SHEET SAGE

As a bonus demo, here we describe Sheet Sage, a system we built to automatically convert music audio into lead sheets (see footnote on first page for examples), powered by our Jukebox-based melody transcription model. In Western music, a piece can often be characterized by its melody and harmony. When engraved as a lead sheet—a musical score containing the melody as notes on a staff and the harmony as chord names—melody and harmony can be readily interpreted by musicians, enabling recognizable performances of existing pieces. Hence, for some music, a lead sheet represents the essence of its underlying composition. Existing services like Chordify [50] can already detect a subset of the information needed to produce lead sheets (specifically, chords, beats, and keys) for broad music audio. However, despite past research efforts [24, 25], no user-facing service yet exists which can convert broad music audio into lead sheets, presumably due to the poor performance of existing melody transcription systems.

To build Sheet Sage, we also train a Jukebox-based chord recognition model on the HookTheory data, using the same methodology that we propose for melody transcription (we simply replace the target vocabulary of onset pitches with one containing chord labels). Passing audio through our Jukebox-based melody transcription and chord recognition models results in a score like format containing raw note names and chord labels per sixteenth note. Engraving this information as a lead sheet requires additional information: the key signature and the time signature. We estimate the former using the Krumhansl-Schmuckler algorithm [51, 52], which takes the symbolic melody and chord information as input. For the latter, we use `madmom` [12, 13]. Finally, we engrave a lead sheet using Lilypond [53]. See Figure 3 for a full schematic.

Subjectively speaking, Sheet Sage often produces high-quality lead sheets, especially for the chorus and verse segments of pop music which have more prominent melodies. Performance is fairly robust across styles and instruments, even those which are less represented in the training data—one user reported particularly strong success on Bollywood music. However, the system occasionally struggles, especially with quieter vocals, layered harmonies, unusual time signatures, or poor intonation. Sheet Sage is also limited to fixed time and key signatures due to limitations of its downbeat detection and key estimation modules.

8. CONCLUSION

We present a new method and dataset which together improve melody transcription on broad music audio. Our method benefits from the rich representations learned by generative models pre-trained on broad audio. This suggests that further improvement in melody transcription may be possible without additional data, i.e., by scaling up or otherwise improving the pre-training procedure. By open sourcing our models and dataset, we hope to spark renewed interest for melody transcription in the MIR community, which may in turn reduce the gap between human perception and machine recognition of a fundamental aspect of music.

9. ETHICAL CONSIDERATIONS

Our definition of melody transcription incorporates equal temperament, a Western-centric tuning system. This could lead to disparate treatment of non equal-tempered music, e.g., if a streaming service were to use melody transcriptions for recommendation. We therefore advocate for the deployment of transcription only in contexts where users are self-selecting music to listen or play along to. Transcription may also be used to create training data for generation—as with any work on generation, there are risks of plagiarism and labor displacement. We recommend that any work on generation involve careful auditing and mitigation of plagiarism. Due to the incomplete nature of a melody, we argue that melody generation tools are more likely to be *incorporated* into co-creation workflows (see [54]) rather than used to displace musicians.

10. ACKNOWLEDGEMENTS

Thanks to Annie Hui-Hsin Hsieh, John Hewitt, Maggie Henderson, Megha Srivastava, Nelson Liu, Pang Wei Koh, Rodrigo Castellon, Sam Ainsworth, and Zachary C. Lipton for helpful discussions, support, and advice. We thank all reviewers for their helpful comments.

SOURCE SEPARATION OF PIANO CONCERTOS WITH TEST-TIME ADAPTATION

Yigitcan Özer **Meinard Müller**
International Audio Laboratories Erlangen, Germany
{yigitcan.oezer, meinard.mueller}@audiolabs-erlangen.de

ABSTRACT

Music source separation (MSS) aims at decomposing a music recording into its constituent sources, such as a lead instrument and the accompaniment. Despite the difficulties in MSS due to the high correlation of musical sources in time and frequency, deep neural networks (DNNs) have led to substantial improvements to accomplish this task. For training supervised machine learning models such as DNNs, isolated sources are required. In the case of popular music, one can exploit open-source datasets which involve multitrack recordings of vocals, bass, and drums. For western classical music, however, isolated sources are generally not available. In this article, we consider the case of piano concertos, which is a genre composed for a pianist typically accompanied by an orchestra. The lack of multitrack recordings makes training supervised machine learning models for the separation of piano and orchestra challenging. To overcome this problem, we generate artificial training material by randomly mixing sections of the solo piano repertoire (e.g., piano sonatas) and orchestral pieces without piano (e.g., symphonies) to train state-of-the-art DNN models for MSS. As our main contribution, we propose a test-time adaptation (TTA) procedure, which exploits random mixtures of the piano-only and orchestra-only parts in the test data to further improve the separation quality.

1. INTRODUCTION

Music source separation (MSS) is a central task in music information retrieval, which seeks to recover individual musical sources in audio recordings. In general, a musical source can refer to singing, an instrument, or an entire group of instruments providing an accompaniment. Since musical signals often exhibit non-stationary spectro–temporal properties and may be highly correlated in time and frequency, MSS proves to be a challenging task in music processing [1]. In the last years, deep neural networks (DNNs) have led to substantial improvements in separating musical sources [2–11]. Despite their effectiveness, one disadvantage of data-driven deep models is their need for a large training dataset, which in the case of MSS consists of multitrack recordings with (isolated) individual sources or stems. Most of the open-source datasets with isolated stems are limited to popular music, e.g., MUSDB18 [12]. However, for western classical music, professionally produced multitrack recordings are quite rare [13, 14].

In this article, we consider the separation of piano concertos, which are a genre of central importance in western classical music. From the Baroque era onward, numerous composers have written piano concertos, which are compositions highlighting the virtuosity of pianists. As an example, Figure 1 shows an excerpt from the first movement of Piano Concerto in D minor (KV 466) by Wolfgang Amadeus Mozart. In addition to the large number of compositions, there also are many prominent historical recordings of piano concertos in classical music archives. In this context, separation of piano and orchestra can enable applications such as editing and upmixing historical and modern piano concerto recordings.

As the piano is the lead instrument and the orchestra takes over the accompaniment, separation of piano concertos can be regarded as a lead instrument and accompaniment separation task [15–17]. The piano has distinct timbral characteristics, e.g., clear onsets, which intuitively may help a separation model in distinguishing it from orchestral instruments such as strings, woodwinds, and brass. Nevertheless, the high spectro–temporal correlations between the piano and orchestral parts in concertos constitute a challenging problem.

In this paper, we adapt the spectral-based Spleeter model [5] to address the separation of piano and orchestra in piano concertos. Spleeter has achieved impressive results for the separation of four stems (vocals, drums, base, and others) in the SiSEC challenge [18]. Building upon its standard architecture, which is an encoder–decoder convolutional neural network (CNN), we train our baseline model using a proprietary dataset.

When training deep MSS models, generating random mixes of solo instrument recordings may improve the separation quality [4, 19]. Random mixing for data generation and augmentation has opened up new paths for separating instrument mixtures, for which multitrack recordings are not available. For example, Chiu et al. [20] created their own synthetic dataset comprising classical violin and pop piano solo recordings, which serve as training material of an MSS model for the separation of piano and violin duos. Inspired by the recent advances in deep learning and data

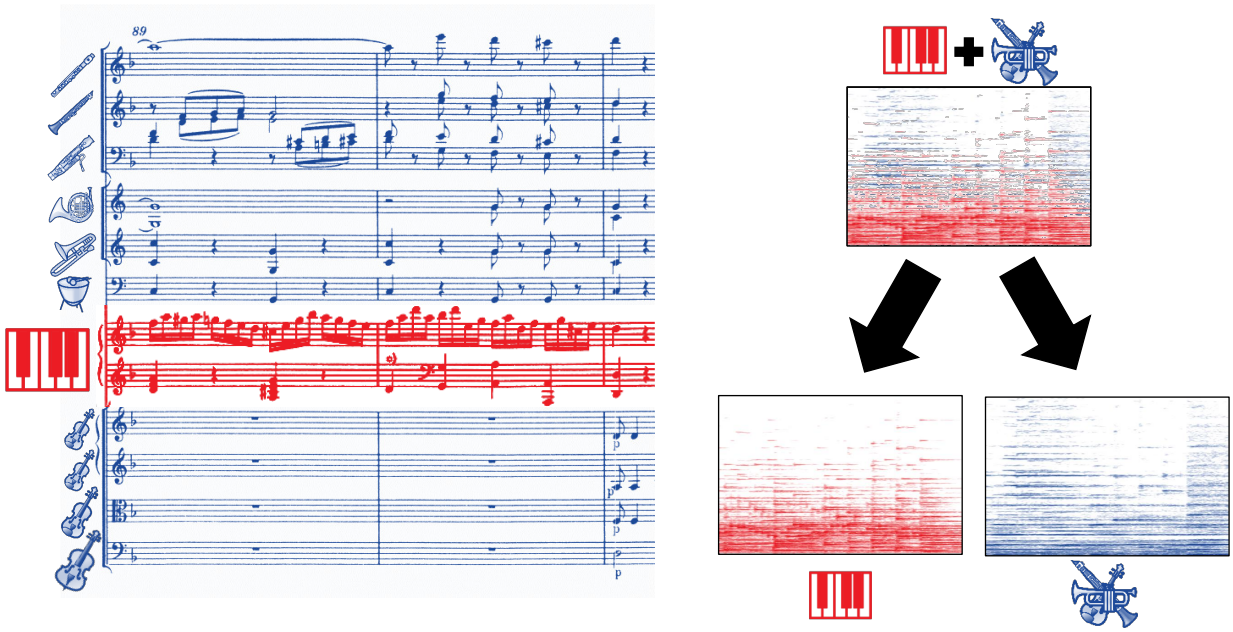

Figure 1: An excerpt from the first movement of the Piano Concerto in D minor (KV466) by Wolfgang Amadeus Mozart. Our goal is to estimate the magnitude spectrograms of the piano part (red) and orchestral part (blue).

augmentation, we generate in our setting an artificial training dataset through randomly mixing samples from the solo piano repertoire (e.g., piano sonatas, mazurkas, etc.) and orchestral pieces without piano (e.g., symphonies) to simulate piano concertos.

Whereas one can improve the performance of data-based models using artificially generated data, a supervised machine learning model necessitates a representative training set to ensure its robustness during the testing phase. In the case of MSS, many recordings have specific acoustic properties (e.g., historical recordings) that are not reflected in training datasets, thus leading to a poor separation performance. To overcome this issue, one can exploit the occurence of repeating patterns in the same recording [21], use bootstrapping to improve separation results [22, 23], or adapt a pre-trained model to one specific target mixture [24, 25]. In this work, our approach is based on the latter strategy. To this end, we first train on our artificial dataset and then finetune the model at the testing stage. As our main contribution, we propose a test-time adaptation (TTA) method similar to [26], where we exploit that a piano concerto typically has relatively long piano-only and orchestra-only passages. Generating random mixes of these sections, we adapt the separation model at the test time individually for each piano concerto in our test dataset. Our systematic experiments highlight the benefits of TTA trained with the spectrogram-domain MSS model Spleeter [5]. To evaluate the performance of our models, we use the widely-used Signal to Distortion Ratio (SDR) [27], and the *2f-model* [28], which is an objective quality measure. Furthermore, we conduct Multiple Stimulus with Hidden Reference and Anchors (MUSHRA) listening tests [29] to assess the perceptual separation quality.

The remainder of the paper is organized as follows. In Section 2, we describe our MSS approach, explore the recent state-of-the-art spectrogram-domain DNN model Spleeter to address the MSS task and describe our experimental setting. In Section 3, we introduce the TTA procedure to improve the separation quality of piano concertos and present our dataset. In Section 4, we report on the quantitative empirical results, including a subjective evaluation. Finally, we conclude in Section 5 with prospects on future work.

2. MUSIC SOURCE SEPARATION APPROACH

Recent DNN approaches for MSS can be divided into two categories: waveform-domain architectures [6, 7] and spectrogram-domain approaches [2–5]. In this paper, our focus is the latter type of models, which learn to approximate the magnitude spectrogram of a target source. To reconstruct the separated audio signals, spectrogram-based models typically use binary masking, soft masking or multichannel Wiener filtering [30].

In particular, we adapt the Spleeter model [5] for separating piano concertos. Its default setting is based on a *U-Net* [31], which has recently been a widely-used architecture in the MIR community to address the MSS task [2, 6, 25, 32, 33]. Following this trend of research, we adapt a U-Net model to predict the magnitude spectrograms of the constituent piano and orchestral parts in a piano concerto. In the following, we revisit the U-Net architecture in Section 2.1 and present our experimental setting in Section 2.2.

2.1 U-Net Model

The U-Net model is composed of a convolutional encoder-decoder architecture with skip connections, which account for the resurrection of fine-grained details in the reconstructed representation. Following the default setting of the U-Net model in [2], we use a 12-layer network (6 layers for the encoder and 6 for the decoder). Each encoder layer uses a strided 2D convolution with a kernel size of 5×5 and a stride size of 2, preceded by a leaky rectified linear unit (ReLU) activation function, and batch normalization. The decoder is composed of strided deconvolution layers with a kernel size of 5×5 and a stride size of 2, as in the encoder. The decoder uses ReLU as the activation function, different from the encoder. To avoid overfitting, we use here dropout with a probability of 0.5 in the first three layers of the decoder. The final layer of the network is a sigmoid activation function, yielding a soft mask for each target source, which contains values between 0 and 1. As the loss function, we use ℓ^1-norm between masked input mixture and target spectrograms. For further details about network architecture, we refer to [2, 5].

2.2 Experimental Setting

In our experiments, we use mono recordings, which are sampled at 22.05 kHz. We generate the magnitude spectrograms using a Hann window size of 2048 and hop size of 512. In a first step, we train our models using an artificial dataset which contains 20-second random chunks from the mixtures of solo piano recordings (e.g., piano sonatas) and orchestral pieces without piano (e.g., symphonies) by 16 different composers from different periods. The total duration of our randomly generated proprietary dataset is circa 45 hours. We regard this model as our pre-trained model, which we denote as `PT`.

We train all our models on a single NVIDIA GeForce 1080 Ti GPU, using a batch size of 8, and a learning rate of $1\mathrm{e}{-4}$ with ADAM optimizer. To improve the separation quality of real piano concerto recordings, we finetune the model with TTA, which we describe in the next section.

3. TEST-TIME ADAPTATION

Supervised deep learning models addressing the MSS task typically require a large dataset that consists of isolated recordings. As a data augmentation method, one can use random mixes to provide training material for an MSS model in the case isolated stems are missing [19, 20]. While this approach cannot simulate the harmonic and rhythmic relationships between various instruments in a real recording, it helps the model to distinguish timbral characteristics of the concurrent musical sources. However, the acoustic properties of recordings (including reverberation, and background noise) play an essential role when upmixing and separating different musical tracks. For instance, in the case of poor recording conditions, (e.g., historical recordings) the properties of the test data may not be reflected well in the training set, thus resulting in a poor separation quality. Finetuning a pre-trained MSS model in the testing phase using a few samples drawn from the test data (also called *test-time adaptation (TTA)* [26]) can improve the separation quality by capturing the specific acoustic features found in a music recording.

From this perspective, separation of piano concertos is a particularly suitable scenario for applying TTA thanks to their compositional form. Depending on the period in which the work was composed, these compositions often comprise long piano-only (e.g., in the cadenza) and orchestra-only parts (e.g., in the exposition, also called *opening riternello*). Using these sections, one can create artificial mixes which come from the audio material of the given test item. As a result, the mixes share the same recording conditions as the test data.

To investigate this approach, we consider seven piano concerto recordings (see Figure 2a). The selected movements of these piano concertos have a long cadenza, which contains only the piano (see Figure 2b). Note that, with the exception of `BrahOp015`, these musical pieces also comprise a long exposition in which only the orchestra plays. For our experiments, we annotate the piano-only and orchestra-only sections, which are publicly available. [1] Exploiting the structural characteristics of piano concertos, we create random mixes of piano-only and orchestra-only sections, which serve as further training data for model adaptation for each piano concerto individually. In the next section, we investigate the improvement of qualitative and subjective separation quality via TTA.

4. EVALUATION

In this section, we report on the separation results acquired by our pre-trained model `PT` and the finetuned models `TTA`. In Section 4.1 we describe our test dataset. We discuss the quantitative empirical results in Section 4.2 and present the subjective evaluation in Section 4.3.

4.1 Test Dataset

For the evaluation of our models, we generate 30-second random mixes of piano-only and orchestra-only parts sampled from the annotated piano concertos (see Figure 2b). These are different from the artificial training set, which we use for the pre-trained model, as they share harmonic and acoustic properties originating from the same recording. Note that we ensure that the samples used for training do not overlap with the test mixtures which we use for the evaluation purposes.

4.2 Quantitative Evaluation

To get a first impression of the performance of the models `PT` and `TTA`, we use the SDR [27] as our quantitative evaluation metric for the separation. Table 1 provides a comparison of the resulting SDR values between a baseline for the SDR values (denoted as `BL`), which we compute using the test mixture as the target signal and ground-truth sources as the reference, pre-trained `PT`, and finetuned `TTA`

To finetune the pre-trained model with the test-time adaptation (TTA) approach, we generate random mixtures of the piano-only (e.g., in the *Cadenza*, denoted as **C**) and orchestra-only (e.g. in the *Exposition*, denoted as **E**) sections.

Figure 2: Overview of the piano concertos in our test dataset.

after 100 iterations. One can observe that PT leads to a substantial improvement in SDR values compared to BL over the whole dataset, both for the piano and orchestra. It is interesting to observe that PT improves the SDR value of BeetOp015 for the separation of piano from 4.48 to 4.60, which is a relatively low improvement compared to other piano concertos in the dataset. Note that BeetOp015 is a historical recording (see Figure 2a for the recording year of the piano concertos), whose inadequate recording conditions may not be well represented in the random mixes used for the training of the PT, thus leading to a relatively poor separation performance.

Now, we focus on the comparison between PT and TTA. In general, the SDR-based results demonstrate that TTA enhances the separation of PT across all the piano concertos, for both the piano and the orchestra. For example, in the case of BeetOp015, PT yields an SDR value of 4.60 for the separated piano. After finetuning with TTA for 100 iterations, this improves to 8.95. For the separated orchestra of BeetOp015, TTA also improves the SDR from 0.09 to 3.67. In the case of better quantitative separation results by PT, e.g., MozKV595, we observe that the improvement via TTA is relatively lower. Here, the SDR values improve from 12.74 to 13.00 for the piano and from 5.25 to 5.58 for the orchestra. Furthermore, our analysis reveals that the SDR value for the separated orchestra is generally lower than piano for both PT and TTA over the whole test dataset, except for MozKV467. An informal inspection states that the TTA leads to a significant improvement in the separation performance for historical recordings, which are not well-reflected in the training dataset of the pre-trained model PT.

In our next experiment, we investigate the performance of the finetuned models TTA per iteration. Figure 3 illustrates the evolution of the SDR values for each piano concerto in our test dataset. The overall convergence behavior exhibits a general trend of improvement of SDR values through TTA over PT for the separation of the piano and the orchestra. In particular, the SDR values for the separation of BeetOp015 depict a rapid improvement within

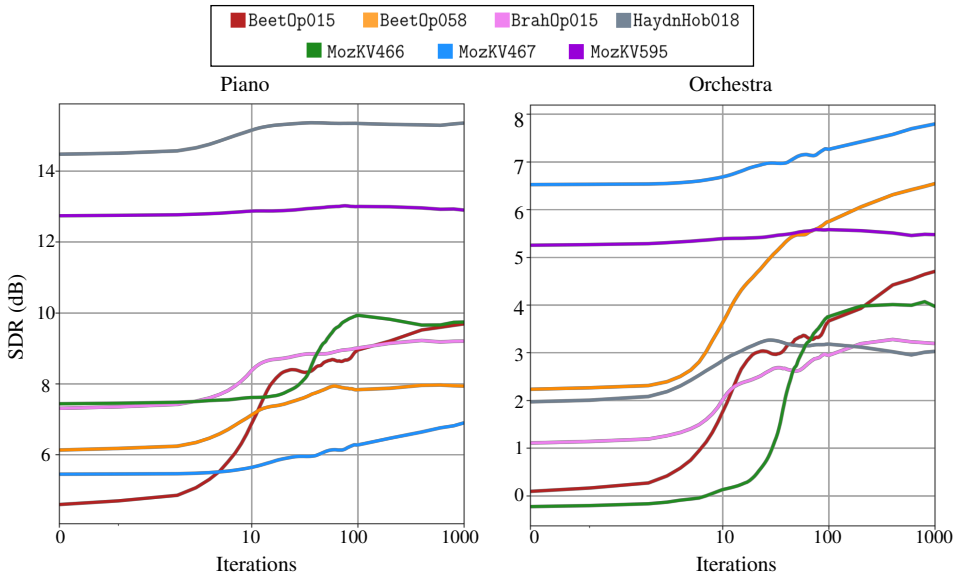

Figure 3: Evolution of SDR values based on our test dataset, applying TTA on the pre-trained model PT.

the first 10 iterations. For the other piano concertos, the improvement of SDR values generally accelerates after the 10th iteration. After the 100th iteration, the separation performance remains steady for most of the piano concertos. Furthermore, after the 100th iteration, the SDR values constantly increase in the case of BeetOp015 and MozKV467 for both piano and orchestra.

Although SDR is widely used as a quantitative evaluation metric for MSS, it is well known that it may not be suitable for determining the perceptual sound quality of separated musical sources [34]. The work by Torcoli et al. [35] provides a comparison of objective quality measures in the source separation domain. Their analysis indicates that a quantitative evaluation using the metric called *2f-model* exhibits the best correlation with ground-truth data based on the subjective ratings from MUSHRA listening tests. For a detailed account of the 2f-model, we refer to [28]. Note that the 2f-model values range from 0 to 100 following MUSHRA rating scores (see Section 4.3). Table 2 provides the resulting 2f-model values for the separated sources by PT and TTA using 100 iterations. In general, one can observe here a similar trend as for the SDR. PT mostly reveals better 2f-model scores than the baseline BL, except for the piano separation of BeetOp015, which presumably suffers from its poor recording conditions that are not well-represented in the artificial training set.

As for the SDR-based results, 2f-model values increase via TTA after 100 iterations for both the piano and the orchestra. For example, in the case of BeetOp015, PT yields a 2f-model value of 21.50 for the separated piano, improving to 28.39 after applying TTA. Interestingly, the separation of the orchestral part yields better results than the piano according to 2f-model values. This is opposed to the evaluation based on the SDR, where the separation results are significantly better in the case of piano separation (see Table 1).

4.3 Subjective Evaluation

In this section, we describe the experimental setting for our subjective evaluation to assess the perceived separation quality. We carried out two listening tests using the MUSHRA methodology following the ITU-R BS.1534-3 recommendation [36]. It is a double-blind multi-stimulus test method with a hidden reference and an additional lower anchor signal. The rating scores range from 0 to

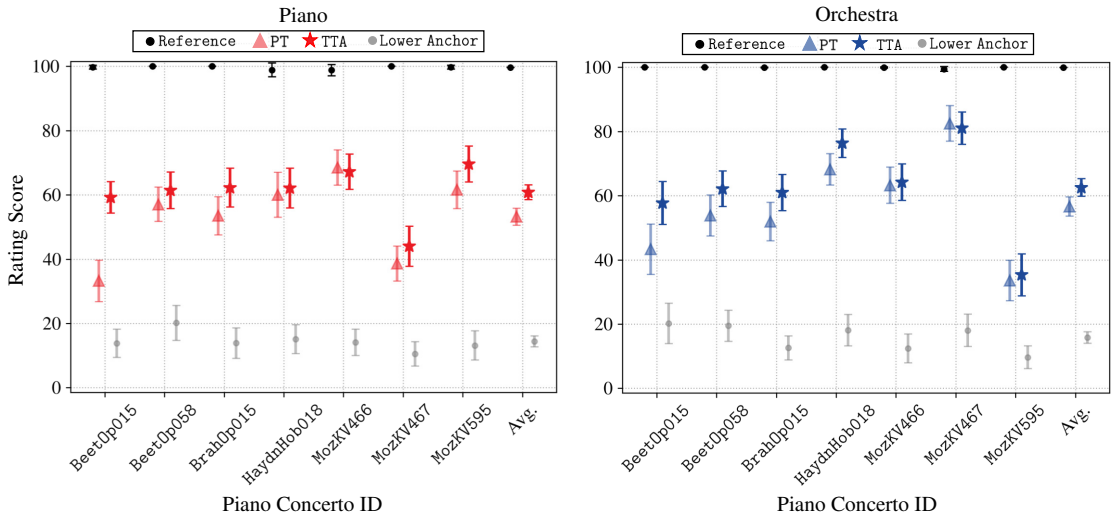

Figure 4: Results of our subjective evaluation based on MUSHRA listening tests for the piano (left) and orchestra (right). The colored markers indicate the average rating scores enclosed by 95% confidence intervals (indicated by the vertical lines).

100, involving five categories: Bad (0-20), Poor (20-40), Fair (40-60), Good (60-80), and Excellent (80-100).

In total, 34 participants were involved in our listening tests (31 experienced listeners and 3 inexperienced listeners). The MUSHRA methodology suggests a post-screening of the participants stating that participants should be excluded from the listening test if they give the hidden reference a score lower than 90 for more than 15% of the test items. Concerning our tests, one of the participants was excluded after post-screening.

Each of the two listening tests contains seven test items. For each test item, we generated four different signals with a duration of 12 seconds (maximum allowed signal duration for MUSHRA listening tests), which are excerpts from the test mixtures that we use for our quantitative evaluation. In our first listening test, we asked the participants to rate the overall audio quality for each of the four signals (also called *conditions*) with respect to a reference signal, which is a clean piano-only section. Similar to [37], we created the lower anchor signals by low-pass filtering the test mixtures to a 3.5 kHz cut-off frequency and by adding musical noise, i.e., randomly setting 20% of the remaining time/frequency coefficients to zero. The other two signals involve separated piano parts by `PT` and `TTA`. Similarly, our second listening test evaluates the overall quality of the separated orchestral parts following the same procedure as the first listening test.

Figure 4 summarizes the results from our listening tests. First, one can observe that the participants rated the reference signal with an average MUSHRA rating score of 99 and the lower anchor is significantly below the conditions `PT` and `TTA`. Remarkably, the general trend of the performances by `PT` and `TTA` support our quantitative analyses, inferring that the TTA procedure generally improves the separation of both the piano and orchestra. When observing the rating score of the piano concertos individually, one can observe that the rating of the historical recording `BeetOp015` is significantly lower than other items for `PT`. Intuitively, this is due to its poor recording conditions. After applying TTA, the average rating score of `BeetOp015` improves from 33 to 59 for the piano and from 43 to 58 for the orchestra. Furthermore, the orchestra separation led to a lower MUSHRA score in the case of `MozKV595`, both for `PT` and `TTA`. One reason may be the audible clipping artifacts in the reference signal and hidden separated orchestra, which a subset of the participants noted during the listening test.

As a final remark, the subjective results demonstrate that the average separation quality of the orchestra is better than for the piano, which is in favor of the results based on the 2f-model (see Table 2). This again illustrates that quantitative and subjective evaluations need to be carefully interpreted.

5. CONCLUSION

In this paper, we investigated the separation of piano and orchestra in piano concertos. We trained our model using a U-Net architecture based on the Spleeter implementation with random mixes of solo piano and orchestral recordings, which we regarded as our baseline pre-trained model. As the main contribution, we proposed a TTA procedure to enhance the separation quality using the random mixes created from the samples found in the test data. We showed that TTA substantially improved the quantitative and subjective evaluation results, both for the piano and orchestra. For the future, we aim to explore musically plausible data augmentation methods that simulate more realistic mixtures. To further improve the separation quality, avenues of research may be to integrate a transcription model as proposed by [38] or to incorporate phase information into the network by using, e.g., a complex U-Net [39]. Moreover, we intend to further investigate objective evaluation measures for the source separation of piano concertos.

ABSTRACT

In this paper, we present a music information retrieval (MIR) pipeline to aid musicologists in making editions of mensural music sources. We designed this pipeline by improving existing MIR tools and allowing for their interoperability rather than implementing a new monolithic tool. These MIR tools include technologies such as optical music recognition (OMR), automatic voice alignment for mensural notation, editorial correction software, and computational counterpoint error detection. To ease the editorial correction process necessary to obtain correctly lined-up scores, we evaluate whether the use of counterpoint error-detection tools makes the correction process more efficient. While this idea has been discussed before, this paper presents the first attempt at implementing it. The results confirm that marking illegal dissonances in the score following the rules of Renaissance counterpoint makes the process of editorial correction of scribal errors in Renaissance music more efficient by reducing the time taken and improving the accuracy of such corrections. Moreover, it also allowed us to catch OMR errors that had passed through undetected at a previous step of the pipeline. This paper is part of a larger project to preserve and increase access to a set of Guatemalan polyphonic choirbooks through digital images and symbolic scores.

1. INTRODUCTION

This paper discusses part of a larger project to preserve and increase access to a set of six Guatemalan Cathedral choirbooks (the *GuatC* collection). [1] These choirbooks, written in mensural notation, contain mostly sixteenth-century polyphonic music that was copied in the seventeenth and eighteenth centuries [1]. They document a continuous performance tradition of sacred choral music from the Renaissance until the beginning of the nineteenth century and are valuable sources for studying the transmission of music from Europe to Latin America.

[1] *GuatC*: Guatemala. Guatemala City. Catedral, Archivo Capitular. Other sigla include GCA-Gc.

Fujinaga, "Counterpoint Error-Detection Tools for Optical Music Recognition of Renaissance Polyphonic Music", in *Proc. of the 23rd Int. Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

Given the limited access to these manuscript sources, it is of utmost importance to digitize and encode this corpus which otherwise might be lost, damaged, or forgotten. We used a set of digitization and music information retrieval (MIR) technologies to obtain digital images and symbolic files encoding scores with editorial corrections for each of the pieces of the first choirbook of the collection, *GuatC 1* (see Figure 1). In the process, we tested the following three-step pipeline: (i) digitization, (ii) optical music recognition, and (iii) automatic voice alignment & editorial correction. The digitization step, conducted with a do-it-yourself scanner, was discussed in a previous publication [2]. In this paper, we focus on the encoding part of the pipeline, the last two steps.

1. **Optical music recognition (OMR) & correction of the results.** We perform OMR on the images to retrieve a symbolic file (a Mensural MEI file) encoding the music of the manuscript. We used the *Music Recognition Encoding and Transcription* (*MuRET*) OMR framework for this step (see Section 2.2).

2. **Automatic voice alignment & editorial corrections.** Since we are dealing with mensural notation, OMR is not enough to encode the full rhythmic information of the pieces and obtain a score with the voices properly lined up (see Section 2.1). Two additional steps are needed: (1) *automatic voice alignment*, which provides the actual duration of each note and returns a preliminary score; and (2) *editorial correction*, which allows for corrections of scribal errors, some of which can affect the alignment of the voices into a score. We used the *Measuring Polyphony* (*MP*) *Editor* for this (see Section 2.3).

This process generates symbolic scores with editorial corrections in a semi-automatic way through OMR and automatic voice alignment. The user manually corrects the output of each step, correcting the results of the OMR—the recognized symbols and their pitches—in MuRET and correcting the results of the voice alignment in the MP Editor. The latter normally implies the correction of scribal errors in the form of editorial corrections and occasional OMR errors that went undetected in the previous step of the pipeline. We evaluate whether the use of a tool that identifies illegal dissonances in Renaissance counterpoint (see Section 2.4) helps in the correction of this last step of the pipeline. The goal of this MIR pipeline is to aid musicologists in making editions of mensural music sources,

with the last step aimed to reduce the challenge of aligning (possibly error-ridden) polyphonic parts by automatically scoring up the voices and by flagging areas of special attention to the human editor—given how time-consuming it can be to find scribal errors. While the idea of using counterpoint rules to detect errors in the original mensural sources has been mentioned before [3], it has not been implemented yet. This paper provides the first attempt at its implementation and evaluation by conducting a small experiment to test our hypothesis.

Figure 1: Example of a piece in GuatC 1. The voices are written in choirbook layout, where each voice is in a different area of the book opening.

2. BACKGROUND

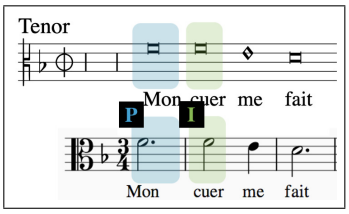
The GuatC collection consists of a set of six manuscript choirbooks written in mensural notation. The first three books have been inventoried [4–6], and the fourth one has been fully transcribed [6]. An overview of the whole collection was presented in [1] and a full inventory is expected [7]. Microfilm images for the first three books were created in the 1980s [8, pp. 3–4]; however, these images are of low quality, with cropped areas and missing folios.

We decided to test the MIR pipeline presented in Section 1 with the first choirbook (GuatC 1, one of the best-preserved manuscripts). The GuatC 1 is a book of masses. It contains twelve masses and fifteen short polyphonic pieces. Eight of the masses are from sixteenth-century composers, one mass is by a seventeenth-century composer, another by an eighteenth-century one, and two by composers whose period of activity remains unknown. On the other hand, most of the short polyphonic pieces are anonymous. Modern transcriptions of ten of the masses and four of the short pieces can be found in the *Choral Public Domain Library* (*CPDL*) wiki, although the provenance of the materials on which the transcriptions were based is shrouded in contradictory accounts. [2]

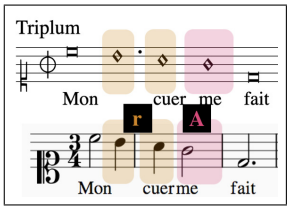
[2] The account found at the *Música Colonial Archive* page (https://www.cpdl.org/wiki/index.php/Música_Colonial_Archive) cannot be corroborated by the Centro de Investigaciones Regionales de Mesoamérica (CIRMA), the institution that holds the original microfilms, as indicated by the director of CIRMA's historical archive (Thelma Porres, personal communication, November 2018).

2.1 Mensural Notation and the Voice-Alignment Issue

Mensural notation was used for polyphonic music in Europe from the thirteenth to the seventeenth centuries. In triple meter, the duration of the notes in mensural notation depends on the context (i.e., the notes preceding or following), as shown in Figure 2. In Figure 2a, the same note shape has two different durational values, a ternary value, which is called *perfect*, and a binary value, which is called *imperfect*. In Figure 2b, another note shape represents two different durations, a regular one and an *altered* one where the note has twice the duration of its regular value. These three durational values of notes, perfect, imperfect, and altered, are common in fourteenth- to sixteenth-century mensural notation.



(a) Same note shape with a perfect (P; triple) and imperfect (I; duple) value.



(b) Same note shape with a regular (one beat) and altered (A; two beats) value.

Figure 2: Example of the different durational values of notes given the context. Both (a) and (b) show an example in mensural notation and its modern transcription below.

The context-dependent duration of mensural notes, together with the separate-parts layout of most mensural music (e.g., the choirbook layout shown in Figure 1), makes it difficult to know what notes are sounding at the same time in the different voices. We implemented an algorithm to compute the duration of notes based on the context and present the piece lined up in a score [9]. This algorithm is referred to as "automatic voice alignment" or "automatic scoring up" of mensural music. After scoring up the voices, it is still necessary to account for errors (e.g., missing or wrong values for notes and rests) to have a correct score. The scoring up of the piece helps to identify OMR and scribal errors that are obscured by the separate-parts arrangement of the music.

2.2 The Music Recognition Encoding and Transcription OMR Framework (MuRET)

There are a few OMR frameworks for early music, including the OMR workflow used by the SIMSSA project through the Rodan workflow manager with the Neon editor [10–13], the OMMR4all framework [14], Aruspix [15],

and MuRET [16, 17]. MuRET, a framework developed by David Rizo at the University of Alicante as part of the Hispamus Project [18], is the only one with support for handwritten mensural notation. [3]

As with other OMR tools, MuRET provides information on the pitch and shape of notes as part of its workflow and allows the user to correct the recognized symbols. It also has support for encoding the imperfect / perfect / altered durational values of mensural notes, though these values are not retrieved automatically—as in the case of pitches and note shapes—and instead have to be entered manually in **mens—a Humdrum format for mensural notation [19]—using MuRET's interface.

At the end of the OMR process, the user can export the encoded music into MEI (Music Encoding Initiative)—a symbolic file format that has support for encoding mensural notation [20]. It is possible to export two kinds of MEI files in MuRET, *score-based* and *parts-based*. The score-based file has the voices stacked and aligned based on the duration of the notes; however, for the notes to be correctly lined up, the user must have provided the durational values for the notes in **mens (i.e., include imperfections and alterations). The parts-based file provides the music encoded as separate parts (just as in the original sources), encoding only pitch and note-shape information for each note. The information about the notes' imperfect, perfect, or altered values is calculated by the next tool in the MIR pipeline, the MP Editor, which will return the score-based Mensural MEI file.

2.3 The Measuring Polyphony Editor (MP Editor)

The MP Editor is an online editor for mensural notation [21], developed under the Measuring Polyphony Project directed by Karen Desmond. [4] Until recently, this was the only mensural notation editor that performed automatic voice alignment, [5] a functionality that I implemented. The MP Editor takes in a series of notes (i.e., pitches and note shape) and automatically lines up the voices into a score using a re-implementation of the scoring-up script in [9]; additionally, after scoring up the voices, the MP Editor allows the user to perform editorial corrections. In a previous paper, I presented the work done to use MuRET's parts-based output as MP Editor's input, which allows for a complete and semi-automatic pipeline of the scoring up of each piece of the GuatC 1 corpus [23].

2.4 The Dissonance Filter (DF)

The goal of this article is to evaluate the efficiency of using counterpoint error markers while making editorial corrections in the last step of the MIR pipeline. On a previous paper, I presented the work done to integrate humlib—Humdrum's data-parsing library—within the MP Editor [23], [6] which allows humlib's Renaissance dissonance filter to label the dissonant notes. [7] The complete list of dissonance labels available in the filter can be consulted on the Verovio Humdrum Viewer (VHV) page. [8] In the MP Editor, the DF marks the dissonances in the score, and makes a distinction between the legal (e.g., passing tones, lower/upper neighbours, and suspensions) and illegal dissonances, rendering the former in blue and the latter in orange. From the set of dissonance labels presented in the VHV documentation page, the ones considered illegal (and rendered in orange font) are *Z*/*z*, *Y*/*y*, *L*/*l*, and *x*. For an example of how the DF labels the dissonances in the MP Editor, see Figures 3–5.

3. METHODOLOGY

3.1 Data Preparation

We randomly selected fifteen pieces from the GuatC 1 manuscript, where each piece was either a mass movement or a short polyphonic piece. The fifteen pieces represent around 20% of the total corpus. To ease the editorial work in the MP Editor, we subdivided the long mass movements into smaller units that we called "self-contained units." Here, we are considering as a "long movement" anything that has more than two openings (i.e., four pages) in the manuscript. We defined the "self-contained unit" as the minimum number of consecutive sections (one or more) that start at a page beginning and end at a page ending. This definition was needed because we had to face the problem of handling sections whose beginning or end do not correspond to the beginning or ending of an image (i.e., a page) since MuRET can only produce an MEI output from a set of one or more selected images.

We obtained a total of 23 self-contained units and divided these into two datasets: a *DF Dataset* where the dissonance filter would be activated during the correction process, and a *NDF Dataset* where no dissonance filter would be used during correction. To guarantee a balanced dataset, we arranged for the DF and NDF datasets to have the same average number of measures, voices, and illegal dissonances. We also made sure that each dataset had close to the same number of CPDL transcriptions to use as a reference, providing another musician's interpretation of where the mistakes are found and how to fix them.

Table 1 shows the pieces in the two datasets. The first column contains the name of the self-contained unit (e.g., Missa9.2_Gloria1), which shows the mass number in the inventory table of the GuatC 1 found in [25] (e.g., Missa9 for the 9th mass in GuatC 1), the movement number and name (e.g., Missa9.2_Gloria1 indicates the second movement in the mass, which is always a *Gloria*), and the unit number within that movement (the first unit of the Gloria).

[3] https://muret.dlsi.ua.es/muret/#/home

[4] https://editor.measuringpolyphony.org

[5] Imperfections and alterations are entered manually in the editor from the Computerized Mensural Music Editing (CMME) project. The new Mensural Rhythm Interpretation Tool (MeRIT) automatically scores up the piece, but its focus is on introspection and pedagogical use and not on producing an edited score [22].

[6] https://github.com/craigsapp/humlib

[7] This filter was developed by Alex Morgan for the Josquin Research Project (https://josquin.stanford.edu). It is based on Peter Schubert's book on modal counterpoint [24].

[8] https://doc.verovio.humdrum.org/filter/dissonant/

3.2 Experiment Setup and Evaluation Procedure

The experiment was conducted by a Bachelor of Music student with a major in voice and a minor in early music. She has knowledge of mensural notation and counterpoint from courses in paleography and Renaissance musicianship, in addition to her participation in early-music vocal ensembles. She corrected each piece following these steps: (1) look at the ends of phrases and sections to see if the voices line up at the cadence in order to determine if there is a note value missing earlier in the piece; and (2) look at the notes preceding that cadence, this would mean looking at all these notes in the NDF Dataset, while focusing on the places with orange labels and the notes preceding them in the DF Dataset. She was also instructed to report the correction time for each piece, annotate any comments about the piece that she considered relevant, and provide the files downloaded from the MP Editor at the end of the correction process. Although most of the corrections at this point in the MIR pipeline should be editorial, we asked the experimenter to still keep an eye out for OMR errors.

We recorded the correction time per piece, the time invested in the correction of the pieces per dataset (DF and NDF), and the accuracy of those corrections. While the average correction time of the DF and NDF datasets is easy to obtain, analyzing the accuracy of the corrections is more involved. To study the accuracy of the corrections, we used three sets of files: (1) the OMR scored-up files obtained by uploading the OMR Parts-based MEI file into the MP Editor and exporting the score with no corrections; (2) the scores corrected by the experimenter; and (3) the CPDL scores. We compared the OMR scores against the experimenter's scores to identify the experimenter's corrections. And we compared the experimenter's scores against the CPDL scores to identify discrepancies between the two transcriptions. [9] While the CPDL scores cannot be considered ground truth, they record another musician's ideas about mistakes in the sources, and help in the process of checking the experimenter's corrections. Whenever we found a discrepancy, we analyzed both versions (the experimenter's and the CPDL's) and chose the best solution, always favoring the one that removed "true" illegal dissonance labels and that guaranteed imitation and motivic consistency. [10] Here, we are distinguishing between "true" and "false" illegal dissonances, where **true** illegal dissonances are notes that are correctly labelled as such (i.e., true positives) and, on the other hand, **false** illegal dissonances are actually legal dissonances that are incorrectly classified by the DF (i.e., false positives). We also reuploaded the experimenter's files into the MP Editor and activated the DF on her files to check if there were any orange labels left to determine whether these were counterpoint errors missed by the experimenter or if they were "false" illegal dissonances. We found a few instances of these false illegal dissonances as reported in Section 4.1.

[9] The OMR and the experimenter's scores are encoded in MEI, while the CPDL scores are in MusicXML. Therefore, to compare them, we wrote transformation scripts for both formats to convert them into text files that encode the notes in each voice as a sequence of tokens and then compared these text files using a *diff* tool.

[10] Imitation refers to repeated melodic motifs in different voices, typical of sacred polyphony.

4. RESULTS AND DISCUSSION

There are two types of results in this experiment: (1) the average correction time of the NDF and DF datasets, which can be seen in Table 1; and (2) the experimenter score files, which are stored in GitHub. [11]

NDF Dataset					
Self-contained Units	CPDL	Number of			Time (min)
		M	V	IllD

4.1 Discussion

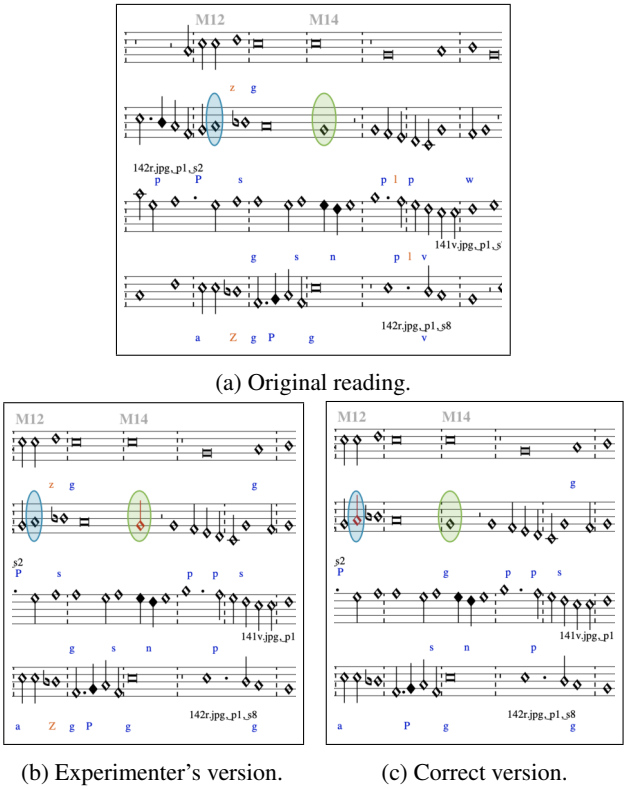
By analyzing the corrections made to the individual pieces and looking at their correction times, the following points become apparent:

1. **The use of the DF reduces the correction time.** As shown in Table 1, the use of the DF reduces the correction time from 12.4 to 6.8 minutes, almost halving it. However, the standard deviation of the DF Dataset is high compared to the one in the NDF Dataset. This is due to an outlier in the DF Dataset. While the correction time for all pieces in the DF Dataset is in the 1–10 minute range, the Missa10.3_Credo3 correction time is 30 minutes. Details about this mass will be provided later in point 4 below. Removing this outlier from the DF Dataset reduces the average correction time to 4.7 minutes (and the standard deviation is reduced from 8.0 to 3.4). Eliminating the outlier reduces the correction time with the DF to almost a third of the correction time for the NDF. Moreover, for pieces that have around the same amount of information—number of measures, voices, and illegal dissonances—and that did not require any corrections (see grey entries in Table 1), the reduction in time when using the DF is considerable. The pieces in grey with 26 and 29 measures took the experimenter 6 minutes to correct without the DF, and 1 minute with the DF. Similarly, the pieces with 48 and 44 measures took the experimenter 15 minutes without the DF and 1 minute with the DF, despite the fact that the latter (the piece in the DF data) has an extra voice.

2. **The use of the DF increases accuracy in the correction.** There were numerous cases where the experimenter made a rhythmic change too late. [12] An example is shown in Figure 3. Figure 3a shows the original manuscript reading of Missa15.3_Credo2. Looking at this scored-up version of the piece, the experimenter noticed that the cadence to G at the end of the example was not correct and knew that she had to cut a minim in the alto voice sometime before the cadence. Her correction, halving a semibreve in measure 14, is shown in Figure 3b. This change still resulted in an illegal dissonance, however, shown in Figure 3b by the orange "z" under the *Bb* in the bass (not shown in the experimenter's NDF dataset). The rhythmic change should have been made a few measures before (in measure 12), as shown in Figure 3c. While the experimenter's correction removes all following illegal dissonances (Figure 3b), it still leaves the ones preceding it. The DF would have shown her where to look—just before the first orange label—to change the note value. This change matches the CPDL correction.

3. **The DF not only aids in identifying scribal errors but also OMR errors that affect the voice alignment.** For pieces where MURET missed a note, or assigned the wrong value of a note or rest in the manuscript, the DF helped to identify the missing or incorrect symbol. [13] Although these pieces were part of the NDF Dataset (where the DF was not used during the experiment), applying the DF on the scored-up OMR file could have saved the experimenter some time as the orange labels help in noticing these errors. By finding the first orange label and checking the manuscript around that spot, the experimenter would have realized that a note/rest in the manuscript was missing (or had the wrong value) in the rendered file.

4. **Style issue – Eighteenth-century works.** The DF was not designed to handle eighteenth-century compositional style. Mass 10 is the only mass in the corpus that we know was composed in the eighteenth century. In many of its self-contained units, one can see the use of seventh chords and ties. [14] In this mass, the DF did not work well, because dissonances that are illegal in Renaissance style are legal in the eighteenth century. The experimenter pointed out a passage in Missa10.3_Credo3, which took her 30 minutes to correct. She invested a lot of time trying to figure out how



(a) Original reading.

(b) Experimenter's version.

(c) Correct version.

Figure 3: Missa15.3_Credo2 beginning at measure 12. The circled semibreve in measure 14 is the one halved by the experimenter, while the circled semibreve in measure 12 is the one that should have been halved. **Clefs from top to bottom:** G, G, suboctave G, suboctave G.

[12] This happened in Missa7.4_Sanctus2, Missa15.3_Credo2, and Missa16.4_Sanctus3.

[13] This happened in Missa9.2_Gloria1, Missa9.2_Gloria2, and Missa10.3_Credo1.

[14] Seventh chords are found in Missas10.1_Kyrie0 (measure 4), Missa10.3_Credo1 (measures 11, 12, and 39), Missa10.3_Credo3 (measure 20), and Missa10.5_AgnusI0 (measure 16). While ties are found in Missa10.3_Credo1 and Missa10.3_Credo3.

to get rid of the orange labels and finally left the passage as it was. This was the correct decision as this passage combines Baroque and Renaissance styles, with seventh chords (see Figure 4), such as the third inversion seventh chord over the red "D," shown by the orange "y."

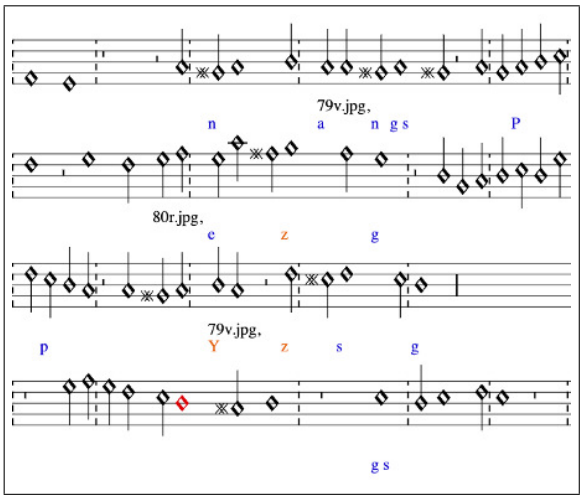


Figure 4: Passage where the experimenter invested a lot of time in Missa10.3_Credo3. It is a combination of Renaissance and Baroque style with fake suspensions and seventh chords. **Clefs from top to bottom:** G, suboctave G, suboctave G, F.

5. **False illegal dissonances.** Rearticulations, minims and semiminims doubling the pitch class of the agent, and extremely short notes like fusas are wrongly labelled as illegal dissonances. This is an issue to correct on the dissonance filter.

Finally, our methodology of re-uploading the file corrected during the experiment, activating the DF, and looking for illegal dissonances left allowed us to catch an error missed by both the experimenter and the CPDL transcriber. Moreover, our methodology of looking for imitative textures allowed us to easily correct this error (see Figure 5).

5. CONCLUSIONS

In this paper, we presented a MIR pipeline designed to obtain corrected symbolic scores for the pieces of a set of Guatemalan choirbooks, and we tested it on the first of these books (GuatC 1). We also presented a way to facilitate correcting the results of the last step of this pipeline, the automatic alignment of the mensural voices recognized by the OMR, conducted in the MP Editor. We used the dissonance filter from the humlib library within the MP Editor to highlight illegal dissonances according to the rules of Renaissance counterpoint. Our findings reveal that using the dissonance filter as a counterpoint error marker for the scoring up of Renaissance music facilitated the spotting of scribal errors and even some OMR errors that went undetected in the previous step of the MIR pipeline. Using the MP Editor and the dissonance filter, the user can see the scored-up OMR file, look for the first illegal dissonance

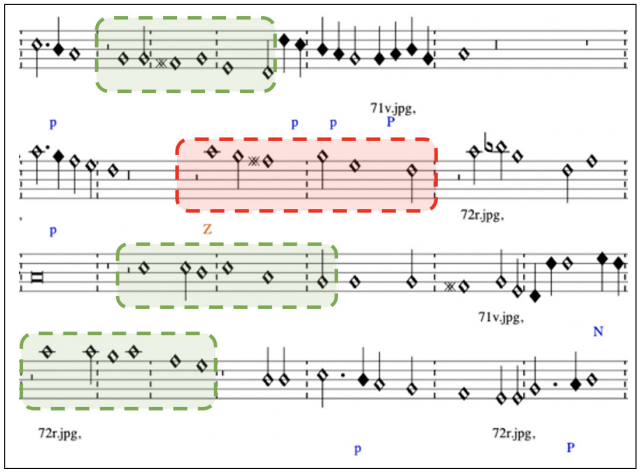

Figure 5: Experimenter and CPDL version of the Christe section of Missa10.1_Kyrie0 with the DF turned on. The alto's A marked by an orange Z label is an undetected error by the experimenter and the CPDL transcriber. Moving this note down to a G results in imitation of the other voices, marked in green boxes. **Clefs from top to bottom:** G, suboctave G, suboctave G, F.

(i.e., the first orange label in the MP Editor), and evaluate if there is an OMR or a scribal error at or before this point. The use of the DF reduces the correction time (to almost a third) and increases the accuracy of the correction process for pieces written in Renaissance style. Further improvements in the time and accuracy of the corrections could be obtained by improving the DF (i.e., resolving the issue of false illegal dissonances). The DF proved to be sensitive to changes in style, as shown in the eighteenth-century mass of the corpus that combines Baroque and Renaissance styles. Future work consists of extending the filter to work on non-Renaissance music.

In conducting this work, the first author has collaborated with the developers of MuRET, MP Editor, and humlib, improving these tools' support for mensural notation and allowing for their interoperability. Interested students and scholars can use the presented MIR pipeline to retrieve editorial music scores for other mensural sources semi-automatically. The OMR part of the proposed pipeline can be substituted by any other OMR tool for mensural notation (e.g., Aruspix) as long as its output conforms with the input expected by the MP Editor [23]. Although this experiment was small, it already showed promising results. The following steps would include replicating these findings with more musicologists and exploring other counterpoint errors (e.g., parallel perfect intervals).

6. ACKNOWLEDGEMENTS

This work draws on research supported by the Fonds de recherche du Québec – Société et culture (FRQSC, Bourse au doctorat en recherche, 13D - Musique, 2019-B2Z-261749) and the Social Sciences and Humanities Research Council of Canada (SSHRC). Special thanks to the developers of the various tools involved in the MIR pipeline,

David Rizo (of MuRET), Juliette Regimbal (of the MP Editor), and Craig Sapp (of humlib), as they assisted in the process of allowing for the interoperability of these tools. Thanks to Alexander Morgan, who developed the dissonance filter for the Josquin Research Project; to Geneviève Gates-Panneton, who was the experimenter and provided valuable feedback for this paper; and to Professor Peter Schubert, who served as an expert consultant for questions regarding modal counterpoint. Finally, thanks to Timothy de Reuse and Andres Lou for their help in editing this paper.

ABSTRACT

Musical scores are generally analyzed under different aspects, notably melody, harmony, rhythm, but also through their texture, although this last concept is arguably more delicate to formalize. Symbolic texture depicts how sounding components are organized in the score. It outlines the density of elements, their heterogeneity, role and interactions. In this paper, we release a set of manual annotations for each bar of 9 movements among early piano sonatas by W. A. Mozart, totaling 1164 labels that follow a syntax dedicated to piano score texture. A quantitative analysis of the annotations highlights some characteristic textural features in the corpus. In addition, we present and release the implementation of low-level descriptors of symbolic texture, that are preliminary experimented for textural elements prediction. The annotations and the descriptors offer promising applications in computer-assisted music analysis and composition.

1. INTRODUCTION

1.1 Texture and symbolic texture

Musical texture generally refers to two distinct levels of abstraction used to describe musical content [1]. On the one hand, *sound* related texture, that can be referred to as *orchestral texture*, results from orchestration, instrumentation and timbral characteristics of instruments and performances. On the other hand, *symbolic texture*, or *compositional texture*, results from the organization of notes, chords and voices in the musical score. Naturally, these notions are closely related, and Hérold studies both textural and instrumental factors of timbre [2], highlighting the impact of compositional texture on the final sound field. Symbolic texture, which is the focus of the dataset presented in this paper, can be described through high level musical concepts such as layer separation, diversity of sonic activities, layer roles, note density and interactions [3–7]. For instance, in piano music, an accompanying chord sequence can be performed in various ways, each one being identified by a specific texture contributing to a stylistic identity. Symbolic texture stands at the center of the compositional process and can sometimes be understood as a notion of style [8]. Musical style is however commonly associated with a whole piece [9] or section whereas the notion of symbolic texture considered in this work tends to describe much shorter time spans in the musical score.

1.2 Related work

Computational methods to analyze symbolic texture have been elaborated in various musical styles including classical string quartet music [10] and modern popular guitar music [11]. Given the wide range of playing modes offered by the instrument, piano music brings unprecedented challenges for the task of in-score texture identification. The present work builds on a recent formal syntax elaborated to classical piano music modeling [7]. As a crucial parameter of musical style, symbolic texture has also recently raised an important attention in the tasks of music generation [12] and style transfer [8,13], where musical texture is efficiently learned by deep neural networks but with limited perspectives of explicit categorization and musicological interpretation. Alternatively, the dataset proposed in the present work promotes a pedagogical and transparent expression of symbolic piano texture, aiming at facilitating its use to design computational tools intended to assist music pedagogy, analysis and composition.

The MIR – Music Information Retrieval – community dedicates an important part of its work effort in building musical expert annotations accompanying music datasets to facilitate training and evaluation of computational models. The classical repertoire, in particular its piano music, gives raise to a number and variety of annotation needs given the richness of its musical language. Key regions, cadences, phrases and harmonies were annotated in the Mozart piano sonatas from the New Mozart Edition (Neue Mozart Ausgabe) [14]. As other representative initiatives, the TAVERN dataset includes harmony and phrase annotations on Mozart and Beethoven's piano variations [15] and the Fugue dataset includes form annotations specific to this genre [16]. Beyond piano music, classical string quartets have also raised a number of key, harmony and structure annotation efforts including repertoires of Haydn [17], Mozart [18] and Beethoven [19, 20]. Although a corpus has been proposed in [21], symbolic texture has still rarely

Figure 1. Examples of texture annotations using the syntax defined in [7]. a) K. 283.III m.1-2: the melody is doubled at the third (`M2p`), and moves in parallel motions (`p`) over a static layer with repeated notes (`S1r`); b) K. 279.I m.35: in addition to a melodic layer with scale motive (`M1s`), a short (sparse, '_') homorhythmic layer appears, without affecting the vertical global density whose value remains 1 on the overall measure (`1[...]`); c) K. 279.I m.6: a typical example of Alberti bass, described as `HS1` harmonic and static layer of density equal to one, and a possible division into two sublayers; d) K. 279.III m.157-158: a concluding formula with melodic (horizontal movements), harmonic (verticality) and static (regularity and emphasis), high vertical density, with an octave motion (`o`) optionally detailed in the sublayer decomposition. A comma separates the dense texture from the contrasting silence ('_') in the last measure.

been the subject of consequent corpus annotations, due to the variety of musical features it involves and the rarity of formal specification.

1.3 Motivation and outline

In order to provide to the community consistent data to study symbolic texture in Western classical piano music, we release a dataset of manual annotations describing symbolic texture at each bar of 9 movements of Mozart Piano Sonatas, totaling a set of 1164 annotated measures. The corpus and the annotation process are detailed in Section 2. Section 3 provides statistics on the textural labels annotated in the dataset. Finally Section 4 presents preliminary results of texture prediction by a machine learning model.

2. PRESENTATION OF THE DATASET

2.1 Syntax for the annotations of symbolic texture

We follow the syntax proposed in [7] to describe textural properties of piano music. More precisely, the texture of a score region is annotated by a text label expressing a set of features with the following conventions:

Diversity. The overall texture is split into independent textural layers that are described individually, separated by a `/`. They are ordered by descending register.

Example: The label `M1/H2` includes two layers, as in examples a, b and c in Figure 1.

Function. The *function* of each layer is expressed with a combination of three specific labels being `M` for *melodic* function, `H` for *harmonic* function, and `S` for *static* function like pedals and ostinati.

Example: The label `M1/H2` includes one layer with a melodic function and one layer with an harmonic function. As an other example, the label `HS1` includes one single layer having both a harmonic and a static function like a persistent arpeggio.

Density. The *density* of a layer, also called *thickness* [1], corresponds to the number of voices it includes, expressed by an integer right after the function.

Example: The label `M1/H2` includes one melodic layer with one voice and one harmonic layer including two voices.

Global density. The *global density* of a region corresponds to its global number of voices and is indicated before brackets surrounding the whole label. It is an approximation of the average number of notes perceived simultaneously. In most cases, the global density is equal to the sum of the layer's density, in which cases its notation is optional because redundant.

Example: The label `3[M1/H2]` indicates a global density of 3 and can be simplified into `M1/H2`. However, the label `2[M1/H2]`, which can occur in certain types of sparse regions, cannot be simplified.

Internal organization of a layer. Additional elements can indicate the presence of relationships between voices: homorhythmy (`h`), parallel motion (`p`), octave (`o`) or characteristic musical figures: sustained notes (`t`), repeated notes (`r`), oscillations (`b`) or scales (`s`).

Example: The label `M2p/HS3hr` can describe a melody doubled at the third accompanied by repeated three-note chords.

Sublayer decomposition. Each layer can optionally be decomposed into sublayers notated between parentheses.

Example: In the label `M1/HS1(S1/M1)` (see Figure 1.c), the second layer `HS1` itself includes one *static* sublayer and one *melodic* sublayer enabling for example the expression of a single voice accompaniment consisting in an alternation between a single repeated pitch and a moving melodic line.

Sparsity. When a layer does not last during the full measure (as in Figure 1.b), or has too low horizontal density, it is considered as *sparse* and notated with '_'. This symbol is also used to annotate empty bars.

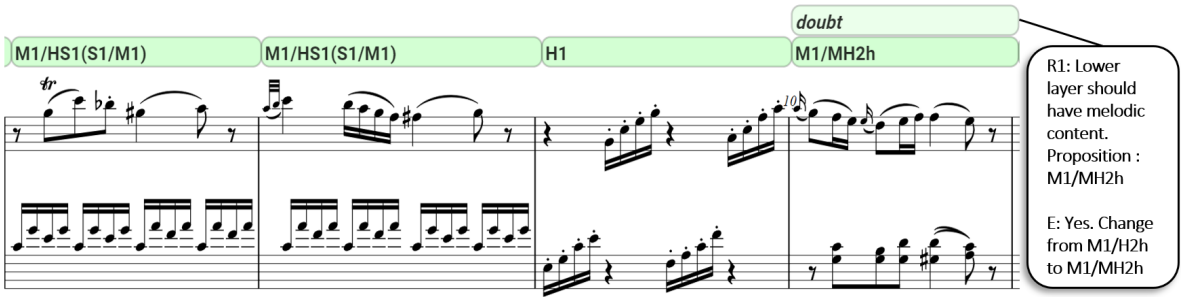

Figure 2. Excerpt of the first movement of Mozart's Piano Sonata n.2 (K. 279, m.7-10) as seen on the web application used to annotate and review the dataset. Each annotated label can be put in doubt by the reviewer: once a `feedback` is opened over one given measure, comments can be added to exchange with the annotator. Feedbacks have three states: *raised* (in white – just submitted by a reviewer), *in conflict* (red – waiting for a consensus) and *resolved* (green, as in the figure).

Corpus ID: corpus:MIR:mozartpianosonatas:texture:2022:version1.0
Raw Corpus **Definition:** existing corpus of real symbolic items. Digital Scores of Mozart's Piano Sonatas following the *Neue Mozart-Ausgabe (NME)* from Mozart Annotated Sonatas [14]. 9 annotated movements in 3 sonatas (K. 279, K. 280, K. 283). **Sampling:** Western classical style piano music, available data, all movements in Sonata Form. **Type of media diffusion:** original files in .mscx and .tsv (Tab Separated Values), annotations in .tsv, .txt and .dez (Dezrann format).
Annotations **Origin**: manual **Concepts definition**: concepts and syntax for texture annotations from [7]. **Annotation rules**: annotation guidelines provided with the dataset. **Annotators**: one annotator (expert knowledge in music and piano), 2 reviewers with the same background. **Validation/reliability**: review, one for each movement. **Annotation tools**: Dezrann web-interface [24].
Documents and Storing **Identifier and storage**: Köchel number, scores from NMA (Neue Mozart Ausgabe) reference edition, Git repository of the dataset by [14] in musescore and TSV format, annotation files on a Git repository [1] and online on Dezrann [2].

Table 1. Description of the annotated dataset.

2.2 Annotated corpus

Following the syntax presented in Section 2.1, we release manual annotations of texture at the bar level in the 3 movements of the 3 sonatas K. 279, K. 280 and K. 283 by W. A. Mozart, totaling a set of 1164 bar annotations in the 9 movements. Those early sonatas were all composed in the end of the year 1774, which presumes a style consistency and limits the shift of compositional practice that could be induced by the evolution of piano manufacture. Moreover, these movements present an interesting diversity in tonality, rhythmic signature and tempo, while covering a large variety of textures. All those movements are in Sonata Form, which opens perspectives to pursue research on the links between texture and form [22].

Table 1 synthesizes the properties of the dataset following the conventions proposed in [23].

2.3 Annotation procedure

2.3.1 Granularity of the annotations

Textural segments can have highly variable duration, which tends to complicate their annotation. As a compromise to facilitate statistics and computational processing of the annotations, we propose in this work to annotate a single texture label for each bar, as indicated in the proposition of syntax [7]. In some cases where the texture strongly shifts in the middle of a bar, a comma (`,`) is used to segment the label in two parts. In particular, this situation may occur on boundaries between musical phrases. By contrast, a texture can also remain unchanged over several consecutive bars, which will lead to a repetition of a same texture label over these bars.

2.3.2 Annotation and reviewing methodology

This section describes our annotation protocol which was inspired by [25] and illustrated in Figure 3. One expert E annotated all the measures of the 9 movements with texture labels on Dezrann [2], a web platform dedicated to the annotation of musical analyses on scores [24]. The annotations were committed to a Git repository to trace the different stages of annotation and reviews. A Python script [3] was used to systematically check that the labels were consistently formed before to proceed to the review phase, relieving the reviewers from syntax checking to concentrate on the textural decomposition. Two reviewers R_1 and R_2 (distinct from the expert), with strong musical background and piano music knowledge, as well as knowledge of the texture syntax used, reviewed those annotations on Dezrann. They added a `feedback` label each time they disagreed or were unsure of the annotator label choice, detailing the reasons of the doubt and possibly providing a new proposition for the label. The expert E then studied all the doubts, resolved the obvious ones and discussed with the two reviewers to reach a consensus on the remaining labels.

Over the 1164 initial annotations of the annotator, 31% raised a reviewer feedback and 22% (256) were updated in

[1] `http://algomus.fr/data`
[2] `http://dezrann.net`
[3] `http://algomus.fr/code`

the end. This substantial number emphasizes the importance of the reviewing phase as well as the complexity of texture annotation due to its variety and the high expressivity of the syntax. Besides correcting possible omissions or typos in the labels, the majority of conflicts ensured a more homogeneous and precise use of the syntax in the whole dataset – in each movements and between them. Hence, most of the discussions between the annotator and the reviewers involved several measures: consecutive ones sharing similar texture, cyclic resurgence of thematic materials (for example in both exposition and recapitulation of sonata form) or comparable textures across pieces. Note that in some cases (like in music analysis in general), it is possible to have different interpretations of the textural layers in a musical passage. The goal of the review here was not to blur those distinct possible analyses but to provide consistent labels that made sense for all.

2.3.3 Syntax knowledge and annotation reproducibility

The annotator followed the syntax recalled in Section 2.1 with the help of a catalog of common textural configurations provided in [7]. As shown in Section 2.3.2, the texture of a bar can sometimes be interpreted in various ways, leading to different labels. The consideration of the neighboring bars can also impact the texture estimation. To limit inconsistency in the labels, we provide annotation guidelines in addition to the dataset. These guidelines typically indicate the order of consideration of the different textural elements when estimating a label. They aim at encouraging a sense of normalization in the annotations, although such a normalization has not been strictly formalized. This aims at helping futur annotators to understand and reproduce the annotation labels. Since the web platform used allows to share several analyses of the same musical piece, divergent labels could be further used ultimately to propose alternative analyses and diversify the dataset for machine learning applications.

3. CORPUS ANALYSIS

3.1 Common textures and layers

Among the 1164 annotated bars, 16.6% include two labels instead of one due to a substantial shift of texture in the middle of the bar (see Section 2.3.1), resulting in 1357 textural configurations. From this set, we can extract 2317 non-empty textural layers. Among the most common layers, we find simple single-voice melodies (`M1`) which totaled 24.9% of all written layers, followed by melodies with scale motives (`M1s`, 7.0%, see Figure 1.b) and with parallel motions (`M2p`, 3.7%), generally doubled at the third (see Figure 1.a) or at the sixth.

Another important family of textural layers encompasses repetitive accompaniment figures like arpeggios, in which notes of the current harmony are played one by one (`HS1`, here). A famous example is the *Alberti bass*, an idiomatic pattern which alternates notes in low-high-middle-high order (see Figure 1.c and the first half of Figure 2) and is typical of Mozart's piano music. The combination

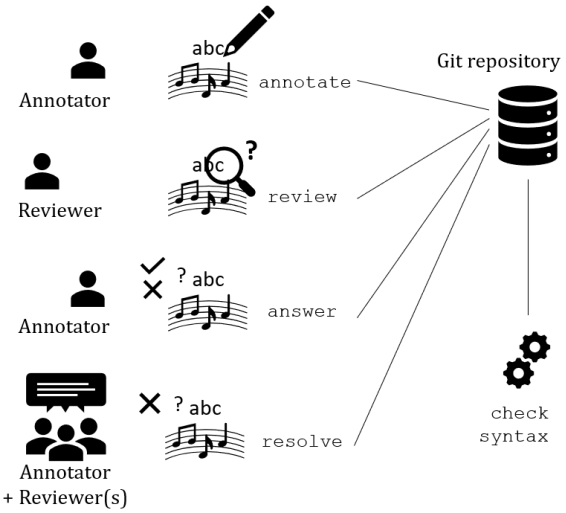

Figure 3. Annotation protocol. Once each measure of a given piece has been annotated (1), these labels are read by a reviewer (2) who can emit a 'doubt' on questionable annotations, along with a justification or a proposal of correction. Then, the annotator treats each doubt, by either resolving it or argumenting towards another solution (3). Finally, conflicts that remained unresolved are discussed between the annotator and reviewer(s) until a consensus is found (4). At each step of the process, the correctness of the syntax is automatically checked and the changes are committed to a Git repository.

of basic melody `M1` and single-voice accompaniments `HS1` is the most represented in the dataset, with 7.3% of all annotated labels.

3.2 Textural elements in labels

Symbolic texture labels are highly expressive and rich in information. We call *textural elements* the set of unary attributes, each one notated with a dedicated character, that can appear in our labels. We consider that a bar includes a textural element if it appears at least once in the whole label. For example, a bar includes the textural element `h` (homorhythmy), if the whole texture, or at least one of its layers, is homorhythmic (and therefore annotated with `h`). In the case of two successive textural configurations described in one label (`A, B`), the presence of the element on one side is sufficient to consider its presence in the whole label. The textural elements are all listed in Table 2.

Unsurprisingly, a vast majority of the dataset (94.6%[4]) contains a layer with at least one melodic function (`M`). Following on function combinations, 20.2% of labels only contain melodic layers (presence of the element `M` and absence of `H` and `S`). The coincident presence of the three functions concerns 23.5% of the labels and the most common combination is made of melodic and/or harmonic layers without any static (`S`) ones (34.1%) as it is the case in a typical melody plus accompaniment section. Finally, the proportion of measures with harmonic layers (textural

[4] The proportions of all annotated textures and textural elements are provided in the dataset repository: `http://algomus.fr/data`.

element `H`) varies between annotated movements, notably according to the tempo: this percentage is 26% higher in slower movements (the second of each full sonata) than in the average of the 6 others (84.4% versus 58.2%).

3.3 Density and diversity

We compute the diversity and the global density of each annotated textural configuration. As detailed in Section 2.1, the diversity corresponds to the number of stacked layers while the global density corresponds to the approximate number of monophonic voices that can be heard simultaneously. Figure 4 puts in relation these two values for the set of annotated labels. The diagonal is assimilated to polyphony where each voice sounds like a new distinct musical idea, an individual layer. On the contrary, the bottom row, with diversity of value 1, corresponds to monophonic texture; thus, any note is contributing to the same unique musical entity. This case is common at the end of structural parts and cadences, typically in homorhythmy (see Figure 1.d). Homophonic textures, for example combinations of a main melody and accompaniment, are found between these two areas. Among the annotated non-empty textural configurations, 29.2% lay in the $2|2$ combination of diversity|density, including the common case of melody and singe-voice accompaniment, presented earlier. Textures in $2|3$ and $2|4$ (three or four voices merged into two layers) illustrate denser homophonic variants, in which a melody may be doubled at the third or at the sixth, or an accompaniment made of simultaneous notes (in homorhythmy). The combinations above the diagonal correspond to situations where the number of layers is higher than the number of voices ($2|1$ or $3|2$). This can happen when two distinct lines alternate in antiphony (call & response): several textural layers are perceived whereas their notes do not overlap.

The diversity, which corresponds to the number of layers, rarely exceeds 2. However, Figure 4 shows that a systematic separation into two layers, which follows an intuitive organization of the score content between the two hands of the pianist, would not be sufficiently representative of the corpus.

In other repertoires, the number of voices – the vertical density – could be globally higher. Bach three-voice inventions would be mainly categorized as a continuous $3|3$ polyphony, and some works of the Romantic Era including very large chords would be extremely dense vertically. Hence, it is easy to imagine that this textural space, similarly to the one described in [4], is prone to convey strong stylistic content. Moreover, the evolution of texture throughout a single piece of music could be modeled as a trajectory in this space, which offers promising future analytical perspectives.

4. APPLICATION: PREDICTION OF TEXTURAL ELEMENTS

We present in this section preliminary experiments of texture prediction.

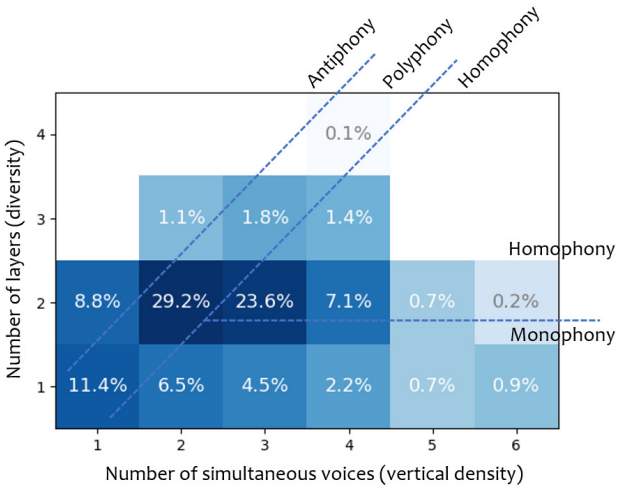

Figure 4. Repartition of textural configurations of the dataset according to their density and diversity. We divided this textural space into areas corresponding to the main texture types evoked in Section 3.3: monophony, homophony, polyphony and antiphony [4, 26]. Empty textures (silence) are not taken into account in this figure.

4.1 Symbolic textural descriptors

To facilitate the prediction of textural elements in musical scores, we propose a set of 62 high level features computed on the raw musical score. Some of these were inspired from previous works including [27] and were complemented with original ones especially elaborated for the modeling of high level textural concepts in polyphonic piano scores. The Python implementation of these descriptors is publicly released [5] . Provided code enables to compute the descriptors in *Stream* objects from the Music21 Python library [28] as well as note lists directly stored in TSV (Tab Separated Values) files, as in [14] [6] .

The selected descriptors are computed at different levels of the musical content: pitches, onsets or temporal slices. Temporal slicing is equivalent to the action of `Stream.chordify()` method in the Music21 library, also called salami-slicing [29]. For elements followed by the symbol '*', we compute average, deviation, median, and extremal values.

Pitches. We compute the total number of distinct pitches, the number of pitch classes, the notes duration*, the notes MIDI pitch* and an indicator of pitch reuse.

Onsets. We compute the total number of onsets, the number of simultaneous pitches by onset*, the regularity*, the harmonic intervals and the number of gaps* between pitches – where a *gap* is detected when the interval between two simultaneous notes is larger than a fourth [3].

Slices. We compute the number of slices, the number of simultaneous pitches*, the number of gaps*, the distance pitch ambitus*, the proportion of consonnant intervals (minor and major third, perfect fourth and perfect fifth), the proportion of rests and the longest rest.

Table 2. F1-scores of the logistic regression models for the prediction of each textural element, compared to – respectively – a uniform random model and a model that always predict the presence of the textural element. F1-scores are averaged on the 9 folds of the cross-validation.

4.2 Description of the models

Different machine learning models were compared to predict the presence of textural elements presented in Section 3.2 from the set of 62 descriptors detailed in Section 4.1. Descriptor values are given to the model as vectors of 62 floats extracted from each measure. The prediction of the presence of each textural element was formulated as a binary classification task leading to a dedicated model for each of the 14 textural elements. Whereas modern data-driven machine learning approaches tend to favor neural networks for their power of abstraction, we stick to simple Logistic Regression models applied on preprocessed high level features as they seemed more adapted to the limited size of our training set and are more easily interpretable. We used Scikit-learn [30] implementation with L-BFGS solver, a maximum of 100 iterations and L2-regularization. Decision Tree classifiers and Support Vector Machine with linear kernel were also tested without significant improvements. In all our models, output classes weights are balanced with respect to their proportion in the dataset. The evaluation criterion is the F1-score, using cross-validation with *leave-one-piece-out* strategy to avoid overfitting due to similarities and repetitions inside movements.

4.3 Results and interpretations

The results are presented in Table 2. We observe that the presence of melody (`M`) is very well detected (F1-score of 0.912), despite being highly unbalanced in the dataset (94.6% of labels contains at least one layer with a melodic function). Harmonic or static functions are quite more difficult to predict. They were also more difficult to annotate: the determination of these functions also involves a part of subjectivity, despite the efforts made in the reviewing process to ensure the consistency of annotations.

The predictions of notes simultaneities and semblant motions (`h`, `p`, `o`) obtain fair results. We could have expected better from them, as well as for `t` (sustained notes) and `r` (repeated notes), since they only involved rare divergences during reviews, their determination being more straightforward. Furthermore, they are closer to the use of defined descriptors – notably those which are related, for instance, to the number of notes played at the same time or the presence of certain harmonic intervals in onsets or slices. The success of predicting `h+` compared to specific relationships `h`, `p` or `o` is meaningful: considering the fact that parallel motions are specific cases of homorhythmy, it seems more practical and sound to focus on this more general case.

The poor results of models to predict oscillation `b` can be justified by the limited proportion of positive examples in the dataset (around 5.1%). Finally, the difficulty of annotating scale motives (`s`) in practice is reflected in their prediction result (F1-score of 0.36). From slow descending sequences of neighboring pitches to cells of short-duration notes that share the same repeated contour: many variants of this element can be found in the corpus, some of which were making consensus difficult to reach between annotator and reviewers. This issue can be adressed in the definition of the syntax as the need to refine the criteria and guidelines for the annotation of targeted concepts. The scale patterns sometimes span over wider regions than the duration of a bar, making the descriptors inadequate in this case. Providing a larger context to our models therefore appears as a promising perspective to improve the detection of this textural element.

5. CONCLUSION AND FURTHER WORKS

We provide an open dataset of texture annotations that specifically handles piano classical music. This dataset contains annotations of 9 movements of Mozart's piano sonatas, all in Sonata Form, and annotation guidelines are provided in order to allow for an easy extension of the dataset by the community. It could be completed with other movements of Mozart's piano sonatas, but also with more diverse piano music from the Classical Era. An extension of the texture syntax to consider specific textures from other periods would also certainly bring new insights for the study of composition styles.

The dataset can be used for musicological purposes, for instance to study the links between texture and a variety of annotations – harmony, modulations, cadences, phrases and section boundaries – that are common subjects of interest in the MIR community. It also opens perspectives in MIR for computer-aided analysis and composition. As a first application, we implemented a set of textural descriptors and used them for the prediction of textural elements, obtaining encouraging results. An in-depth analysis of the relations between the textural descriptors and textural elements could help improving the prediction, especially on harmonic, static layer detection, or scale motives. This work will also allow to study the evolution of texture in the musical pieces and to better integrate this dimension for automatic generation of music following textural scenarios.

6. ACKNOWLEDGEMENT

We would like to thank Nathalie Hérold for fruitful discussions during the initial phase of the project. We also thank the Algomus team and the anonymous reviewers for their helpful feedback. This research is partly funded by Région Hauts-de-France.

ABSTRACT

Violin performance analysis requires accurate and robust f_0 estimates to give feedback on the playing accuracy. Despite the recent advancements in data-driven f_0 estimators, their application to performance analysis remains a challenge due to style-specific and dataset-induced biases. In this paper, we address this problem by introducing *Violin Etudes*, a 27.8-hours violin performance dataset constructed with domain knowledge in instrument pedagogy and a novel automatic f_0-labeling paradigm. Experimental results on unseen datasets show that the CREPE f_0 estimator trained on *Violin Etudes* outperforms the widely-used pre-trained version trained on multiple manually-labeled datasets. Further preliminary findings suggest that (i) existing data-driven f_0 estimators may overfit to equal temperament, and (ii) iterative re-labeling regularized by our novel *Constrained Harmonic Resynthesis* method can simultaneously enhance datasets and f_0 estimators. Our dataset curation methodology is easily scalable to other instruments owing to the quantity of pedagogical data online. It also supports a range of MIR research directions thanks to the performance difficulty labels from educational institutions.

1. INTRODUCTION

Accurate f_0 tracking is fundamental for violin performance analysis due to the prime role of intonation in violin mastery. Musicians regard intonation and pitch accuracy as the most important criteria for assessing a string performance [1], and most of the previous work on violin performance analysis also focus on vibrato and intonation [2–5]. A study on intonation patterns of artist-level violinists [4] found that highly-regarded musicians deviate significantly from equal-temperament while remaining coherent in their intonation preferences in the close vicinity of just-noticeable difference (95% confidence intervals within just 6 cents). Another study found that violinists' intonation can be better approximated by other tuning systems, e.g., Pythagorean, rather than the standard equal-temperament [2]. From an engineering perspective, intonation analysis is reliable only if the f_0 estimates are more precise than the intonation consistency of the player. Thus, these studies imply that an f_0 estimator suitable for violin performance analysis needs to conform to a frequency precision higher than 6 cents and remain consistent irrespective of the player's deviation from equal temperament.

Alongside frequency precision, an f_0 estimator has to fulfill two more requirements for reliable performance analysis: (i) robustness to octave errors that result from the complex frequency response of the violin body and (ii) high temporal precision that can handle fast string crossings common in violin performance. However, in the current paradigm, there is a trade-off in complying with these two necessities: Most of the f_0 estimators leverage temporal post-processing stages in order to eliminate octave errors at the expense of temporal precision (e.g., Viterbi for the f_0 estimator of PRAAT [6], pYIN [7], and CREPE [8]; a custom filtering for Melodia [9]). Moreover, the Viterbi implementations of some f_0 estimators are even more restrictive: pYIN does not allow a jump bigger than 2.5 semitones between consecutive frames, and that number is 2.4 semitones for CREPE. These restrictions are detrimental to violin performance analysis, as it is common to see very fast and abrupt string crossings in violin repertoire (e.g., 21 semitone jumps in Figure 2).

Despite the above-mentioned problems, monophonic f_0 estimation is considered a mature task in MIR literature, mainly owing to the high accuracies reported in benchmark datasets. Data-driven f_0 estimators claim 96-99% accuracies in datasets such as MIR-1k [10] and MDB-stem-synth [11], which are all highly restricted in terms of performance virtuosity. Although these numbers seem promising in theory, this is not what we found when we use these f_0 estimators in the real-life analysis of advanced-level violin performances. In this paper, to better address the real-world needs of performance analysis using data-driven methods, we introduce the *Violin Etudes* [1], a 27-hour large-scale monophonic dataset comprised of pedagogical violin performances by professional violin players. We also provide our methodologies for dataset curation and automatic f_0 labeling and show the strength of our approach by outperforming the pre-trained version of CREPE f_0 estimator on its own train data.

2. RELATED WORK

2.1 Monophonic f_0 Estimation

F_0 estimation is an essential step for many tasks in music and speech processing. Early f_0 estimators were handcrafted methods [6, 7, 12–19], but today data-driven methods [8, 20–24] are preferred following the general trend of deep learning. Both in handcrafted and data-driven techniques, f_0 estimation literature can be classified into two main approaches: time-domain and frequency-domain. Time-domain approaches used to utilize techniques such as auto-correlation during the times of handcrafted signal processing [6, 7, 12–15], while nowadays end-to-end deep learning methods directly use the time domain signal as their input [8, 20, 23, 24]. Frequency-domain approaches, on the other hand, were used to apply spectral analysis and select spectral peaks with signal processing [16–19]; but recently data-driven frequency-domain approaches require a spectrogram derivative as their input signal [21, 22]. A final important concept to mention here is self-supervised f_0 estimation, adopted by SPICE [22] and DDSP-inv [24]. Although the f_0 estimation strategy used in this paper is based on supervised learning, our combined procedure of iterative f_0-labeling is analogous to a self-supervision applied post-training.

2.2 Automatic f_0-labeling

To guarantee the f_0 label correctness for semi-automatically labeled datasets, Salamon et al. created an analysis-synthesis method [11] which forces the audio to represent any f_0 error in the annotation. The method was used for creating the resynthesized MDB-mf0-synth and Bach10-mf0-synth datasets. However, applying this method to unlabeled datasets is yet to be explored.

2.3 Large Scale Performance Datasets

Collecting large-scale datasets from community platforms has long been an important data source for research on action recognition and multimodal learning. The data collection procedure most often involves searching for keywords on YouTube, generally without collecting further metadata other than the query term itself. To our knowledge, the three main instrument performance datasets collected in this fashion are aimed at self-supervised source separation and spatial localization: MUSIC dataset [25] consists of solo and duet performances spanning over 11 instrument categories, including 53 solo violin performances. They extended the dataset for the task of video-to-audio synthesis with additional solo performances and constructed the MUSIC-Extra-Solo dataset [26] which include 213 solo violin performances, some of which include backing track. In a similar but more constrained scenario, the Solos dataset [27] is formed by searching for 13 classical instruments and the word 'audition' on YouTube and includes 66 solo violin performances in approximately 400 minutes. However, none of these datasets provide any label or metadata on the musical content: whether they are monophonic, include different renditions of the same score, the player or recording conditions, or the supposed difficulty of the performance. The only label is the instrument name.

A more constrained and informed large-scale data collection endeavor is the GiantMIDI-piano dataset [28] where the authors queried YouTube with the piano repertoire they collected from International Music Score Library Project (IMSLP) and later transcribed the audio into MIDI. By including more meta-data such as the composers, work titles, and style, the dataset is more suitable for musical analysis. However, it is also susceptible to MIDI transcription errors. The *Violin Etudes* dataset introduced in this work has similarities to this controlled approach, but in an even more restricted scenario: By collecting query words from the pedagogical repertoire, we have control over the performance difficulty. By keeping track of the performer and providing multiple renditions for the same etudes, we control the expressivity and recording conditions. Last but not least, by manually curating and removing the works, including double stops and chords, we ensure monophony and control the timbre.

3. VIOLIN ETUDES DATASET

From the 16^{th} century onwards, music pedagogy has been creating teaching curricula that guide the students from the very early stages of their journey to the professional level. Inspired by how humans learn an instrument, we present the *Violin Etudes* dataset, the first large-scale MIR dataset rooted in instrument pedagogy. Etudes and caprices form the backbone of the traditional violin method and are defined as study pieces presenting "a technical problem or challenge in the context of a musical setting" [29]. Alongside being vital for education, these pedagogical materials have an unparalleled potential as datasets for intelligent systems, especially MIR applications. They most often come with inherent difficulty labels and are organized in human curricula, which can be used for autonomous learning. Composers often provide textual descriptions on the purpose of the study and techniques involved (e.g., Figure 3), and they are still actively researched by instrument pedagogues on their technical content e.g. [30–32]. They are most often for solo instruments, which is favorable for signal processing. And most importantly, there are hundreds of instrument teachers actively recording their reference performances of their teaching material, which supports the much-needed data for deep learning applications.

3.1 Data Collection

While previous large-scale YouTube data collection endeavors mainly focus on data for self-supervision, we opted for a more controlled approach in curating the material and stored metadata that would be used as ground truth in many topics such as expressive performance analysis and performance difficulty analysis. The individual violin methods are selected from the standard violin curriculum by a trained violinist, but interested readers are encouraged to search for *'violin (or flute/trumpet/piano...) etudes'* to see how easily they can create similar lists, e.g., [33–36].

method	n_{unique}	n_{player}	n_{Σ}	t_{Σ}
Suzuki, Vol. 1-5	40	4	158	248.8
Dancla, Op. 84	27	2	59	131.9
Wohlfahrt, Op. 45	41	6	357	458.1
Sitt, Op. 32 Vol. 1-3	34	2	60	140.1
Kayser, Op. 20	5	8	40	81.9
Mazas, Op.36	12	4	35	100.7
Dont, Op. 37	10	3	30	68.1
Kreutzer, Études	24	4	95	229.8
Fiorillo, Op. 3	13	3	34	72.1
Rode, Op.22	7	5	35	82.5
Dont, Op. 35	7	2	14	31.7
Gavinies, Matinées	6	2	8	24.6
Total	**226**	**21**	**925**	**1670.2**

Table 1. Pedagogical methods ordered in approximate difficulty. n_{unique}: number of unique monophonic studies, n_{player}: number of distinct players, n_{Σ}: recording count per method, t_{Σ}: recording duration in minutes per method.

The most effort was spent on curating a monophonic [2] subset of these works by manually going through the scores on IMSLP and discarding all the works that include even a single double stop or chord, which corresponds to manually removing 264 of 490 studies [3]. The remaining 226 monophonic pedagogical works are summarized in Table 1 in their usual order of use in the violin curriculum.

The videos of the selected works are collected from YouTube by querying method/etude names followed by manually identifying the most reliable content creators, and then searching with queries including their names. Some videos, especially in the beginner repertoire, include different studies as multiple chapters within the same recording. These chapters are split and the audio recordings are extracted from the source videos with the highest possible quality, resulting in 925 performances.

3.2 Metadata

For each recording, we provide metadata with player ID, study No., which method/etude book it belongs to, and piece-wise difficulty rankings from multiple sources. Since difficulty is a subjective term, sources sometimes disagree on the ranking of these materials, but there are some common patterns: Suzuki Vol. 1-2 are always considered the easiest of all, with Dancla, Wohlfahrt, Suzuki Vol. 3-5 being the next. Rode, Gavinies, Fiorillo, and Dont Op. 35 form the hardest cluster. Whilst difficulty grades change from source to source, the progressive ordering within each book is universally accepted, e.g. study No. 30 from a method is always considered as harder than No. 2. Hence, *Violin Etudes* can be considered as a performance difficulty analysis dataset similar to [37].

The performers in the dataset are manually confirmed to be highly-skilled violinists, mostly violin teachers creating content for their students. As shown in Figure 1, our dataset includes performances from 21 players and is also quite skewed in favor of Players 01 and 02. Although this is a limit of the dataset from one aspect, with more than 5 hours of monophonic recordings for Player02 and 7 hours for Player01, these subsets include enough data to train violin synthesizers. In Table 1, we can see that we have a total of 925 reference performances for 226 monophonic violin studies. With some exceptions, each study has multiple renditions which allow high-level music research such as expressive performance analysis (exemplified briefly in Section 5.1), or low-level audio representation learning as exemplified in the f_0 estimation experiments in Section 5.2.

Despite its many strengths, the current state of *Violin Etudes* has two main flaws. Although the scores are included, only Mazas and Kayser etudes are in a machine-readable format, and we do not have their aligned scores. As repertoire gets harder, it gets harder to find non-commercial reference recordings. Thus, recording distribution in the dataset is limited by method popularity and difficulty, e.g., Matinées in Table 1 is only 24 minutes.

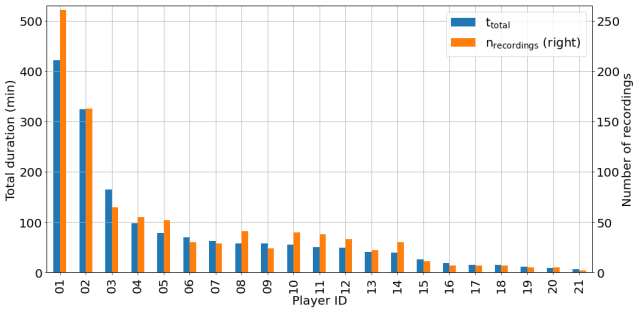

Figure 1. Total performance duration (left) and number of recordings (right) per PlayerID.

4. AUTOMATIC F_0 LABELING

The f_0 labels in the Violin Etudes dataset are automatically generated through a novel iterative f_0-labeling strategy based on two assumptions: (i) the recordings are monophonic, i.e. we can apply harmonic analysis with respect to an initial $\hat{f}_0$ estimate, and (ii) all the frames have a similar harmonic structure, i.e. violin is the sole instrument. After obtaining raw $\hat{f}_0$ estimates through a data-driven f_0 estimator, we search for harmonic peaks around the $\hat{\mathbf{f}}_{0:N}$ multiples of the $\hat{f}_0$ estimate for each frame through a modified version of Spectral Modeling Synthesis (SMS) [38]. We then force the harmonics to follow the $\hat{f}_0$ label similar to the analysis/synthesis framework of Salamon et al. [11], with additional novel constraints on instrument modeling and harmonic consistency to silence low-confidence segments. The remaining data is smaller in amount, yet it is more reliable to be used in the training of a new f_0 estimator. We then retrain the f_0 estimator using these resynthesized versions and extract new f_0' estimates, and repeat the process. Thus, as exemplified in Figure 2, both the f_0 estimator's performance and the dataset's f_0 label quality are enhanced simultaneously by interacting with one another.

[2] Here monophonic simply refers to *single note at a time*, i.e. removal of superposed notes, rather than the musicological definition.

[3] Unlike the use of violin in popular music, the classical and pedagogical violin repertoire exhaustively include double stops and chords.

4.1 Constrained Harmonic Resynthesis

First introduced by Serra et al. [38], Spectral Modeling Synthesis (SMS) has had widespread adoption in audio signal processing, including a recent revival with differential Digital Signal Processing (DDSP) [39]. We adopt the harmonic model from SMS to create constrained f_0 labels where we force the synthesis to follow the label or simply silence the frame if it does not satisfy the constraints.

4.1.1 Harmonic Analysis

Waveforms in 44.1kHz are analyzed with 1025-sample Blackman-Harris windows and hop size of 128 using `harmonicModelAnal` function from the SMS-tools [38]. The DSP-based f_0 detection algorithm of the `harmonicModelAnal` is replaced with our external $\hat{f}_0$ estimates; and harmonic amplitudes, frequencies, and phases are searched around the $\hat{\mathbf{f}}_{0:39}$ with a harmonic deviation slope of 0.001. We refer to [38] for further details.

4.1.2 Instrument-modeling Constraint (IC)

Instrument timbre defines the harmonic amplitudes $\mathbf{A}_{0:39}$ we see on top of an $\hat{f}_0$ estimate. Thus, if we know the instrument model, i.e. $P(\mathbf{A}_{0:39}|\hat{\mathbf{f}}_{0:39})$, we can assess the correctness of an estimate from harmonics. We use this idea as an additional layer of regularization of the label quality and removal of automatic-labeling artifacts. We learn an approximate model for violin resonance structure by linearly dividing the violin frequency range into N regions and fitting elliptic envelopes to the first 12 harmonic amplitudes for each of these N regions, where we experimented with $N = 50$ and 100. If this elliptic envelope model detects an anomaly in the harmonic amplitudes, we silence the frame.

4.1.3 Harmonic Consistency Constraint (HCC)

As we will show in Figure 4, an f_0 estimator is prone to overfitting problems associated with its training set distribution. To remedy this and ensure a reliable spectral distribution for our labels, we employed the Two-Way-Mismatch (TWM) procedure [19] between harmonic peaks $\hat{\mathbf{f}}_{0:39}$ and $\hat{f}_0$ candidates around the initial $\hat{f}_0$ estimate. For each voiced segment, 33 pitch candidates are selected in the range $(\hat{f}_0 - 16c, \hat{f}_0 + 16c)$ with 1 cent intervals. The candidate with the lowest Two-Way-Mismatch-error is selected to be the new $\hat{f}'_0$ estimate if its TWM-error is smaller than 5.0, and if this Harmonic Consistency Constraint is not satisfied, the frame is silenced. Finally, the constrained harmonic frequencies $\hat{\mathbf{f}}'_{\mathbf{0:39}}$ are set to the *exact multiples* of this final $\hat{f}'_0$ estimate before resynthesis.

4.1.4 Sinusoidal Synthesis

The constrained harmonics are resynthesized using the sinusoidal model from SMS [38]. Any segments shorter than 50ms are muted before synthesis to reduce artifacts. Furthermore, for each resynthesized recording, we also resynthesize its replicate with pitch shifts: both harmonics and f_0 labels are shifted with random microtonal pitch shifts in the range of 5-55 cents to ensure the statistical diversity of our labels. We found that training f_0 estimator with shifted versions of the recordings increases the stability of the estimator against equal temperament deviation.

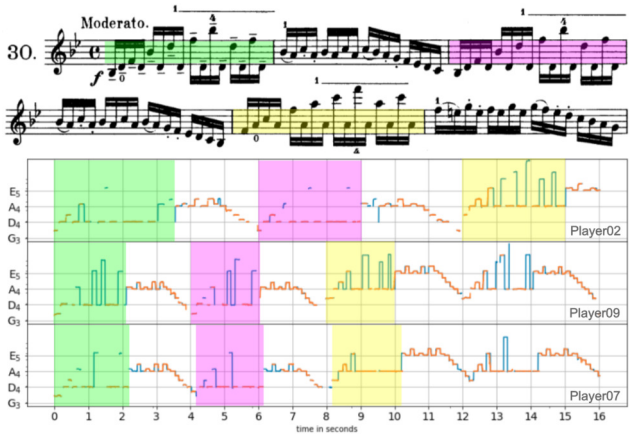

Figure 2. Iterative f_0 labeling exemplified in Kreutzer Etude No.30 performed by Players 02, 09, and 07. Constrained harmonic resynthesis acts as a barrier to wrong f_0 estimates and creates discrepancies in the initial f_0 contours (orange). Notice that most of these discrepancies are filled after the first iteration of finetuning (blue), especially in the highlighted string crossings.

4.2 Iterative Refinement of f_0 Labels

Initial f_0 tracks of the dataset are generated via the CREPE [8] convolutional f_0 estimator with 1 ms intervals and a custom Viterbi decoding to incorporate some heuristics we know about the violin repertoire. CREPE has 360 bins in its final layer with 20 cents between consecutive bin centers, i.e., states. In their implementation, they apply Viterbi with constant state observation probabilities without utilizing the confidences given by the algorithm. We replaced this by decoding with CREPE confidences as posteriors, similar to standard ANN-HMM posteriorgram decoding [40]. Using our prior knowledge of violin repertoire, we decided the Viterbi transition probabilities empirically as a weighted sum of two Gaussians to allow for fast string jumps while encouraging continuous f_0 contours: Gaussian with $\sigma_1 = 6$ semitones in Equation 1 enables fast string jumps, whilst continuous contours are encouraged by weighting the other Gaussian ($\sigma_2 = 40$ cents) with 9.

$$Pr(s_j(t+1)|s_i(t)) = \frac{1}{30\sqrt{2\pi}} \exp\left(-\frac{1}{2}\left(\frac{s_j(t+1) - s_i(t)}{30}\right)^2\right) + \frac{9}{2\sqrt{2\pi}} \exp\left(-\frac{1}{2}\left(\frac{s_j(t+1) - s_i(t)}{2}\right)^2\right) \quad (1)$$

After the initial f_0 estimates are obtained, (audio, f_0) pairs go through the Constrained Harmonic Resynthesis which silences out the wrong estimates as described in Section 4.1. The remaining (constrained audio, constrained f_0) pairs are used for finetuning of the f_0 estimator, which produces new estimates as exemplified in Figure 2. This iterative labeling process can be thought of as an Expectation-Maximization hybrid akin to ANN-HMMs [40].

	Violin		Other Inst.	
	RPA50	RPA5	RPA50	RPA5
Pretrained [8]	96.4	68.3	**96.2**	68.1

HCC + IC50	**96.7**	84.0	94.6	**76.5**
HCC + IC100	**96.7**	**84.2**	94.8	75.7
Sawtooth	68.3	49.5	56.8	37.2

Table 2. The pre-trained CREPE compared with training-from-scratch on different versions of *Violin Etudes*. Tests are conducted on the unseen URMP dataset. HCC: Harmonic Consistency Constraint. IC: Instrument-modeling Constraint. Sawtooth: Single-timbre control group.

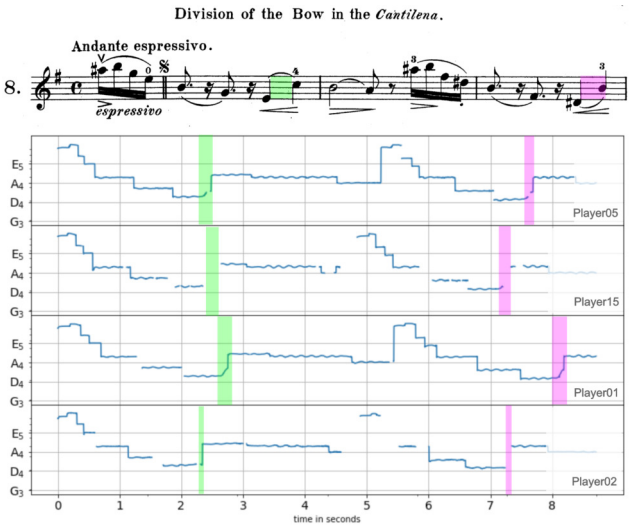

Figure 3. First line of Mazas Etude No. 8 with constrained f_0 labels of 4 performances. From the composer's words, we see that this etude targets teaching *division of the bow in the Cantilena*. f_0 tracks are automatically extracted with the method described in Section 4. Highlighted hand position changes are discussed in Section 5.1

5. EXPERIMENTS

5.1 Qualitative Performance Analysis

In this section, we give two brief examples of how *Violin Etudes* enable research on the pedagogically-motivated analysis of reference performances. In Figure 3, Mazas Op.36 No.8 with f_0 tracks of 4 different renditions can be seen: We can observe that both Players 05 and 01 have very expressive slides at the position changes indicated with green (E_4-C_5) and pink ($D_4^\sharp$-B_4), while Player02 landed into these notes directly -note that such analyses are not possible for corpora annotated with pYIN [7] or CREPE [8] since their Viterbi implementations smooth every jump. But, our method, too, has flaws: analysis of Player15 for the same section is inconclusive due to our design choice of removing unreliable automatic f_0 estimates.

Having multiple reference recordings also enable the analysis of performance tempo. In Figure 2, we see that Players 09 and 07 agree on a considerably faster pace for *Moderato* on Kreutzer Etude No.30, while Player02 play the same study a lot slower and sticks to this choice throughout the performance. Although we did not include it here, studying bowing technique analysis is also possible in *Violin Etudes*. Following the textual descriptions, players record some etudes with bowing variations. The most extreme case of this is the Player01 recording Wohlfahrt etudes with all the bowing variations, resulting in a subset of 171 recordings where some studies were repeated with up to 15 bowing variations. Moreover, the dataset allows for analyzing intonation and tuning patterns of professional violin teachers thanks to the high frequency precision of our f_0 estimates, which we will discuss in the next section.

5.2 Monophonic f_0 Estimation

Here we study the label quality of *Violin Etudes* in the context of f_0 estimator training. We train the commonly-used CREPE [8] f_0 estimator in our data, and compare it with the pre-trained version [4] trained on the following six manually-labeled and synthetic datasets: MIR-1k [10], MedleyDB [43], MDB-STEM-Synth [11, 43], Bach10-mf0-synth [11, 42], RWC-Synth [7], and NSynth [44].

We use *Violin Etudes* only for training and validation with 80/20 split, and train with a batch size of 32 and early stopping on validation accuracy. We conduct the tests on two unseen datasets where we evaluate the raw pitch accuracy (RPA, in %) with two thresholds: the conventional RPA50 quarter-tone accuracy, and our benchmark RPA5 fine-grained accuracy. Owing to the high-frequency precision requirements for performance analysis, this second metric considers the estimate accurate only if it is within 5 cents of the performance. We report frame-level accuracies without Viterbi, and separately evaluate on violin and other instruments for discussion. Since the models trained solely on violin range do not see other pitch classes, we calculate accuracies over violin range for the unseen instruments, i.e., we compute a combined accuracy from all the other instruments except violin, where the ground $f_0 \geq 190$Hz.

5.2.1 *Effect of Instrument-modeling Constraints*

In these experiments, we compare models trained on different variants of *Violin Etudes* in order to study the effectiveness of the constraints introduced in Section 4.1. Tests on the unseen URMP dataset are provided in Table 2. We see that all the three versions of *Violin Etudes* surpass the pre-trained model decisively on fine-grained accuracy RPA5 by more than 15% improvements, and increasing the number of filters from 50 to 100 in Instrument-modeling Constraint (IC) leads to marginally better results. IC also reduces the RPA50 on unseen instruments, implying that the estimator focuses excessively on the target instrument. Interestingly, one of the most conclusive results from these experiments was in the Sawtooth synthesis of the *Violin Etudes* f_0 tracks: model trained with sawtooth performs significantly better in violin compared to others, which may be due to the similarity of violin timbre to sawtooth or the effect of repertoire pitch distribution.

[4] Full CREPE model weights are taken from `https://github.com/marl/crepe/raw/models/model-full.h5.bz2`

	URMP Dataset				Bach10-mf0-synth (from train set of [8])

Table 3. Comparison of finetuning and training-from-scratch on *Violin Etudes*, tested on two instrumental datasets.

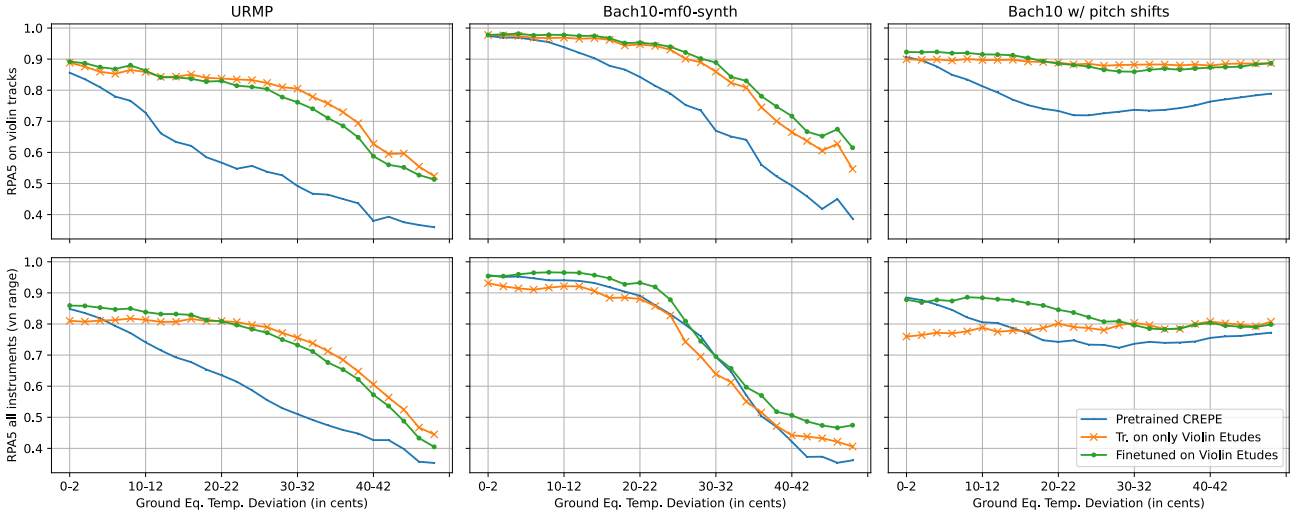

Figure 4. Fine-grained f_0 accuracy (RPA5) summarized on a grid. Music performance analysis requires precise f_0 estimates even if the player deviates from the equal temperament. However, training data-driven f_0 estimators on standard MIR datasets may induce an *auto-tuning effect*. Top: Violin-only tracks. Bottom: Over all the instruments. Left: URMP [41] dataset unseen to all the models. Center: Bach-10-mf0-synth [11, 42] from train set of [8], yet unseen to ours. Right: The conclusive experiment where we ensure the same statistics by applying microtonal pitch shifts to the Bach10 dataset.

5.2.2 *Finetuning and Generalization*

In Table 3, we study finetuning on *Violin Etudes* by testing on two datasets: alongside URMP, this time including Bach10-mf0-synth [11, 42], one of the 6 train sets of the pre-trained CREPE. We tested the estimators on the entirety of the datasets since they do not come with inherent train/test splits. We see that the finetuned model performs the best overall and remains reliable in all scenarios, including other instruments. However, interestingly, finetuning was generally more unstable and took longer to train: while the models converge after seeing around 20% of our dataset in training-from-scratch experiments, finetuning took twice as long on average. As the most interesting result of these experiments, Table 3 illustrates that our model trained on only *Violin Etudes* outperforms the pre-trained CREPE by 5.6% RPA5 on the violin tracks of its own train set.

5.2.3 *Equal Temperament and the Auto-Tuning Effect*

In Figure 4, we show that the drastic gap between the RPA5 and RPA50 performances of pre-trained CREPE can be explained by equal-temperament deviation, even on its own train data. On the other hand, our models are more robust, especially for violin-only evaluation in Figure 4. To show that this dependency is not caused by the annotation quality of the test datasets, we also experimented with microtonal pitch-shifted versions using RubberBand [5]. Yet, all our results show the importance of microtonal label distribution while training data-driven f_0 estimators. We name this phenomenon *dataset-induced auto-tuning effect*.

6. CONCLUSION

In this paper, we present *Violin Etudes*, a large-scale, comprehensive dataset for f_0 estimation and performance analysis. Our dataset curation method is easily extendable to other instruments thanks to two main novelties: 1) Reliance on pedagogy and community-driven platforms ensure abundance of material and metadata suitable for many high-level music research directions. 2) Our novel automatic f_0-labeling paradigm allows iterative refinement of labels while significantly improving the data-driven f_0 estimator as a by-product. Observing that the CREPE model converges after seeing just 20% of the *Violin Etudes* and still outperforms its pre-trained version, we argue that our dataset curation method would allow training more complex f_0 estimators that can specialize better for the needs of performance analysis. In the future, we are going to use this dataset for learning accompaniment-aware f_0 estimators and synthesizers, while further extending the *Etudes* dataset family with woodwind and brass instruments.

ABSTRACT

In this work we present a new approach for the task of predicting fingerings for piano music. While prior neural approaches have often treated this as a sequence tagging problem with independent predictions, we put forward a checklist system, trained via reinforcement learning, that maintains a representation of recent predictions in addition to a hidden state, allowing it to learn soft constraints on output structure. We also demonstrate that by modifying input representations — which in prior work using neural models have often taken the form of one-hot encodings over individual keys on the piano — to encode *relative* position on the keyboard to the prior note instead, we can achieve much better performance. Additionally, we reassess the use of raw per-note labeling precision as an evaluation metric, noting that it does not adequately measure the *fluency*, i.e. human playability, of a model's output. To this end, we compare methods across several statistics which track the frequency of adjacent finger predictions that while independently reasonable would be physically challenging to perform in sequence, and implement a reinforcement learning strategy to minimize these as part of our training loss. Finally through human expert evaluation, we demonstrate significant gains in performability directly attributable to improvements with respect to these metrics.

1. INTRODUCTION

While sheet music is often very specific as to *what* notes a musician must play, it can also be vague about *how* to play them. Composers generally write notation that focuses on describing the desired musical output, but leave the specifics of how to achieve this with their instrument up to the performer, as these details are outside the scope of their role in the creative process or in some cases beyond their expertise. The piano is an instrument which requires an extensive amount of decision-making on the performer's part. In order to perform a piece of music, a pianist must either consciously or intuitively select which finger to use to play every note in the song. Notes may overlap in duration or even have simultaneous onsets. Since any key on the piano can potentially be played by any finger, there are an exponential number of ways one could perform any given piece; of these however, the majority would be uncomfortable, difficult to play at full tempo, or even physically impossible [1]. The challenge of deciding the most ergonomic fingering to use can be nontrivial for less experienced pianists, who would not yet have the ability to quickly map common musical patterns to conventional fingering strategies, and might produce more consistent and accurate performances if provided with them [2].

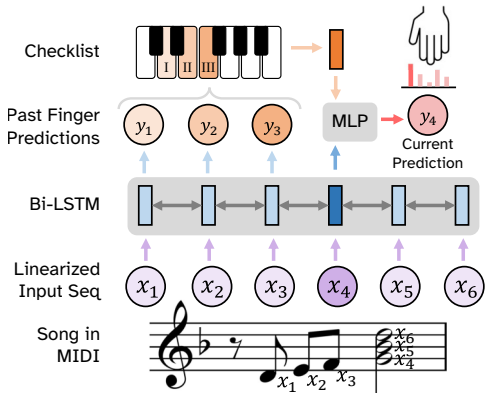

Figure 1. Visualization of the checklist model. Notes are embedded and then passed to a Bi-LSTM which outputs contextualized embeddings at each timestep. A checklist encodes where the fingers that have recently been used are located based on prior predictions. These are both fed into an MLP which predicts the next finger.

However recent work has shown that the use of machine learning techniques may be able to assist in this regard [3–6]. Automatic piano fingering prediction is the task of inferring finger assignments for each note in a symbolic representation of a piano song, given knowledge of which hand is meant to play each note. Human players generally prefer fingerings that balance physical comfort and efficiency [2], yet these criteria are difficult to quantify and highly subjective [7]. Decisions are simultaneously constrained by the current placement of the musician's fingers, and by how that decision may in turn affect possible options for the notes that follow. And while the spatial location of the notes on the keyboard is arguably the most salient factor, timing is also crucial; certain fingerings might be easy for a set of consecutive notes, but impossible if the same notes are in a chord.

Berg-Kirkpatrick, "Checklist Models for Improved Output Fluency in Piano Fingering Prediction", in *Proc. of the 23rd Int. Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

Prior approaches to this task have largely treated it as a sequence tagging problem, where the input at each step is simply the pitch of the note and the output is a softmax over indices corresponding to each finger, and have employed methods analogous to those used for part of speech tagging such as LSTMs and HMMs. However, these techniques are limited in their capacity to model output dependencies, and also disregard the amount of elapsed time between notes which can greatly affect a prediction's performability.

We propose an autoregressive approach, where prior predictions are fed back into the network in order to encourage the model to produce fingerings that are not just accurate on average, but also locally *fluent* and therefore playable. We do this using a checklist which indicates which fingers have either recently been or are currently in use, and where they are on the keyboard relative to the note at the current timestep. By directly exposing this information, the model can more easily learn to restrict its predictions to fingers that are actually free, and also make decisions more directly influenced by the hand's physical placement. We also experiment with an approach that only feeds back in the most recent prediction, as well as an autoregressive tagger which maintains a neural representation of prior predictions using an encoder network.

Furthermore, the evaluation metrics used in prior work do not always correlate with what a pianist might intuitively perceive as "good" predictions. In fact there are many types of desirable (or undesirable) patterns that may emerge in a model's output, which a simplistic metric such as labeling precision may not actually reflect. We demonstrate that it is possible for two models with nearly identical labeling precision to differ dramatically in the frequency of specific types of output subsequences that are physically challenging to play. Therefore, we evaluate on a battery of metrics that collectively convey a more holistic and interpretable overview of fingering quality.

Since these metrics are not always correlated with the labeling precision that a cross entropy loss optimizes, we also investigate incorporating them explicitly into our loss function at train time. While these scores are non-differentiable, we show that reinforcement learning techniques—which have previously seen success in sequence generation tasks outside of music—can successfully optimize them. This, in conjunction with our checklist approach, ensures that the model not only has direct access to the information it would need to avoid undesirable output patterns, but is also encouraged to do so.

Finally, we conduct human evaluations and qualitative analysis which confirm that our approach improves predicted fingerings in ways consistent with our modeling choices, and also suggest directions for future work.

In summary our contributions are as follows: (1) We provide a comparison of various input representations for LSTM models (2) We put forward checklist based approaches which directly incorporate information from previous decisions (3) We introduce several additional metrics which track fluency of output, and demonstrate how to train directly on them using reinforcement learning.

2. RELATED WORK

While constraint-based models for automatic piano fingering have long existed [1], the standardization as a machine learning task which we follow was formalized by [3], which introduced the PIano fingerinG (PIG) dataset, put forward LSTM and HMM baselines (following prior work using HMMs [8, 9]), and has since been followed up on by others. [4] demonstrated the value of pretraining on even a noisy automatically annotated dataset, although they focused on basic LSTM models and evaluated exclusively on labeling precision. [5] put forward the idea of representing inputs based on relative difference in pitch rather than absolute pitch, and also showed improvements from the use of a constrained transition matrix, albeit one that was built off of prior knowledge of the task. [6] recast fingering as an information retrieval problem, although they focused on the Czerny corpus instead of the PIG dataset.

Our work also draws from research into implicitly learning output structure by feeding prior decisions into the computation of future predictions. There are classic examples of graphical models that condition predictions both on inputs at the current timestep and outputs at the previous [10]. Recent work on explicit checklists in neural settings, such as by [11] found success using a structured agenda that tracked ingredient usage in conditional cooking recipe generation. Our checklists are however more transient; outputs can be removed from the checklist if enough time has passed. We also track not just the presence of outputs, but information about how they were used.

There is also much work on the use of REINFORCE [12] for sequence generation tasks. While [13] performed several tasks including summarization, translation, and image captioning, but required a critic model for stabilization, [14] developed a self-critical method for captioning that did not require this additional network. [15] applied a similar technique to abstractive news summarization. Reinforcement learning has also been applied in a musical setting [16], including the REINFORCE algorithm specifically [17, 18], but most of these have focused on music generation rather than downstream prediction of performance-oriented attributes such as fingerings.

3. MODEL

We now describe the basic layout of the models we compare, and detail the specific variations between them. First, we will formalize the basic model contract and explain the basic architecture components that most of them share.

At a high level, each model takes in a MIDI-derived representation of either the left or right hand of a complete piano song, and outputs a predicted finger for each note. More formally, we are given an input sequence of notes $\mathbf{x} = \{x_1, ..., x_N\}$, where each $x_i = (p_i, t_i^-, t_i^+)$ is a tuple consisting of a pitch $p_i \in \{1, ..., 88\}$ as well as a corresponding onset time $t_i^- \in \mathbb{R}_{\geq 0}$ and offset time $t_i^+ > t_i^-$. From $\mathbf{x}$ we must predict a corresponding sequence $\mathbf{y} = \{y_1, ..., y_N\}$ where each $y_i \in \{1, 2, 3, 4, 5\}$ is an index representing the finger used to play x_i from thumb to pinky respectively.

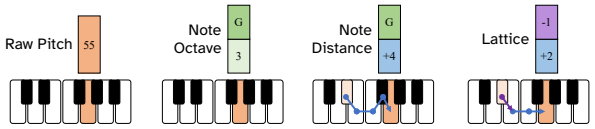

Figure 2. Examples of the input representations we compare. Note that the labels on the vectors are *indices* corresponding to sub-embeddings shared across notes.

To this end, each predictive model defines a distribution $p(\mathbf{y}|\mathbf{x};\theta)$, generally parameterized by an LSTM variant. Under our non-checklist simple Bi-LSTM baseline, the individual y_i are conditionally independent given $\mathbf{x}$: $p(\mathbf{y}|\mathbf{x};\theta) = \prod_{i=1}^{N} p(y_i|\mathbf{x};\theta)$. However for our autoregressive models, the likelihood factorizes according to chain rule: $p(\mathbf{y}|\mathbf{x};\theta) = \prod_{i=1}^{N} p(y_i|\mathbf{y_{<i}}, \mathbf{x};\theta)$

As shown in Figure 1, the notes are first embedded, and then passed to a Bi-LSTM which outputs a contextualized representation. This contextualized representation is optionally concatenated with a d dimensional vector representation of the checklist $\mathbf{c} \in \mathbb{R}^{N \times d}$ before being passed to an MLP which outputs a softmax distribution over finger indices. We can think of the checklist as a function of the past and current notes as well as the past finger predictions $c_i(\mathbf{x}_{\leq i}, \hat{\mathbf{y}}_{<i})$. The model is trained to optimize the cross entropy loss between this distribution and the true labels.

3.1 Input Representations

We now discuss four different strategies to encode the song into an input sequence of vector embeddings (illustrated in Figure 2). These each expose different information to the model which can significantly affect performance.

Raw Pitch: This approach simply represents each note by its pitch p_i, assigning a learnable embedding to each value. This was done by most previous neural implementations [3, 4], and requires learning 88 vector embeddings.

Note $\oplus$ Octave: Given the fact that a piano keyboard's layout is identical across octaves, we might believe that more important than the exact key being played is the named note itself (e.g. knowing that the next note is a `G#` might be more useful in predicting which finger to use than knowing that it is the MIDI pitch 68). To this end we also evaluate the use of an input representation that consists of an embedding corresponding to the named note concatenated with an embedding corresponding to the octave.

Note $\oplus$ Relative Distance: If finger choice is primarily a function not of the note's pitch but of its location on the keyboard relative to the other notes in the song, then directly exposing that information saves the model from having to infer it. For this representation, we concatenate an embedding for the named note with one corresponding to the change in pitch $p_i - p_{i-1}$ (see Figure 2). Since large distances between notes require physically lifting the hand from the keys, an act which eliminates any sequential constraints, we cap step sizes at 15 semitones. [5] used a similar approach without the named note embedding.

Lattice: We finally evaluate a "lattice" representation based on the one introduced by [3] (note that this was only used in that work for HMMs and not neural models). As shown in Figure 2, we can think of this as a two-dimensional encoding of relative position, where the first dimension corresponds to the number of white keys between notes (i.e. the *horizontal* distance), and the second dimension indicates if we have moved from a white key to a black key or vice versa (i.e. the *vertical* distance). These dimensions are each embedded with corresponding vector embeddings, with a horizontal cutoff of 9 steps. This is the default representation where not otherwise specified.

3.2 Checklist Formulation

To encourage the model to produce fluent predictions, rather than simply choosing the most likely finger at each timestep independently, we also consider a series of extensions that feed recent predictions into the MLP alongside the contextualized embeddings produced by the LSTM, in the form of a vector embedding $c_i(\mathbf{x}_{\leq i}, \hat{\mathbf{y}}_{<i}) \in \mathbb{R}^d$.

Autoregressive Tagger: We start with a baseline autoregressive variant of our simple Bi-LSTM model in which the forward half of the Bi-LSTM acts as an encoder over prior predictions as well as notes. In this setup, we do away with the Bi-LSTM over notes $\mathbf{x}$, and instead replace it with a forward LSTM $f(\mathbf{x}, \hat{\mathbf{y}})$, and a backward LSTM $b(\mathbf{x})$. At each timestep i, the MLP is fed the concatenated output of both LSTMs $f_i(\mathbf{x}_{<i}, \mathbf{y}_{<i}) \oplus b_i(\mathbf{x}_{\geq i})$.

Prev Finger Embedding: As a precursor to a full checklist, we also experiment with a neural variant of a Maximum Entropy Markov Model (MEMM) [10]. Under this setup, we map the predicted label of the previous timestep $\hat{y}_{i-1}$ to a corresponding vector embedding, and concatenate this with the contextualized embedding of x_i produced by the Bi-LSTM, before passing the result to the MLP. This approach only takes into account the most recently used finger and ignores timing, but also requires the fewest additional model parameters.

Binary Checklist: This checklist embedding is a 5 dimensional vector, where each dimension corresponds to a finger. The ith dimension is set to 1 if that finger has recently been predicted for a note of a higher pitch than the current, a -1 if it has recently been predicted for a lower note, or a 0 otherwise. We empirically find that "recent" is best defined as within 100 milliseconds.

Distance Checklist: This representation is a concatenation of 5 vector embeddings, one for each finger. These finger embeddings use the lattice input representation strategy, where the first half corresponds to the horizontal distance between the note that that finger was recently predicted for and the current one, and the second half corresponding to the vertical distance. If a finger has not recently been used, its section in the checklist vector will be filled by a learnable "dummy" embedding.

4. LEARNING AND EVALUATION

Next we will detail the additional metrics that we introduce, and show how by using reinforcement learning we can train our model to optimize some of them directly.

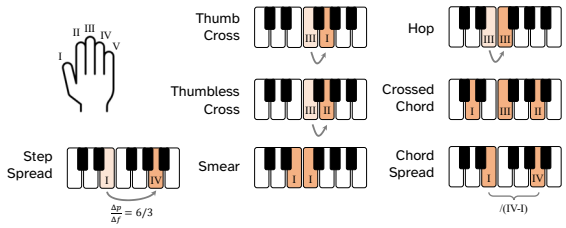

Figure 3. Fingering patterns tracked by our fluency metrics. Arrows and shading indicate sequential notes.

4.1 Fluency Metrics

We now describe the metrics we use to measure model performance. While research into pianists' fingering strategies shows that decisions are mostly motivated by minimizing ergonomically unfavorable patterns [2, 7], prior work has primarily evaluated on per-note labeling precision averaged over annotators, referred to as M_{gen} (albeit with some different strategies for handling disagreements between annotators [3]). However, by simply checking if each prediction agrees with any annotator's label for that note in isolation, we miss whether the model's predictions are coherent with one another. For instance, a model may output two adjacent fingers which each agree with an annotator's label, but not the same one, creating a pattern that is harder to play than if it had solely aligned with one of them, despite these having the same M_{gen} score. Also, a model may output a sequence that agrees with none of the annotators but is at least playable, and yet receives the same score as a physically impossible sequence. This is especially an issue for songs labeled by fewer annotators.

To address this, we expand the scope of our evaluation to include metrics that also measure how *fluent* model predictions are within themselves. To this end, we track statistics on the frequency of several types of output pattern that would increase the physical difficulty for a human performer, but may not be reflected in the raw labeling precision score. This allows us to more holistically compare models in ways that are both attentive to sustained agreement with annotators, and also expose the specific ways in which their predictions are more or less playable. Visual examples of these are provided in Figure 3 for clarity.

4-gram: Anchored 4-gram precision is the proportion of subsequences of four consecutive notes that were all predicted correctly with respect to a single annotator. This metric measures output coherence, but is still directly tied to the gold labels. Where M_{gen} scores plateau as they approach the inter-annotator agreement of 71.4, 4-gram precision has more headroom and better stratifies models.

Thumb/Thumbless Crosses and Crossed Chords: Thumb crosses are where a note lower in pitch than the previous is played with a "higher" finger or vice versa, one of those two fingers being a thumb. These shift the hand up or down the keyboard without fully lifting off of the keys. We also track crosses where neither finger is a thumb, which is much less common due to their difficulty. We refer to cases where two fingers are crossed and the notes overlap in time as crossed chords. These are only performed under very specific circumstances, as most chords are not physically playable with crossed fingers.

Hop: These are cases where one finger is used to play two different consecutive notes. While not intuitively difficult, these do not allow the player to rest their hand in a fixed spot, and make distances harder to accurately judge, limiting the maximum tempo of a piece, similar to how hunt-and-peck typing is generally slower.

Smear: In a smear, more than one note within a chord is played by a single finger. These are generally utilized when two adjacent keys are both in the chord, but because of the placement of the other notes it is hard to use two separate fingers. While these are extremely rare in our gold labels, naive baselines tend to produce them quite frequently.

Step/Chord Spread: Step spread tracks how far the player must stretch their fingers apart while playing. Specifically, it is the average number of semitones per finger separating any two adjacent but not overlapping notes. For example, if a song contains an `E` followed by the `B` a fifth above it, the step spread would be 7 for a model that predicts playing them with fingers 1 and 2 respectively, but only a 3.5 for a model that predicts 1 and 3. We measure similar cases where the notes do overlap in time as chord spread. A large average chord spread is more challenging since it requires stretching the hand over a larger distance.

4.2 Loss Functions

Having defined our model as above, we can train it on the cross entropy loss between the predicted distribution $p(\mathbf{y}|\mathbf{x};\theta)$ and the gold labels by simply backpropagating to obtain parameter gradients and taking gradient descent updates on our training set. Autoregressive models are teacher forced at train time (i.e. conditioned on gold labels from prior timesteps in lieu of the model's own previous predictions), and we decode with beam search at test time.

However, while training on cross entropy can yield strong performance on labeling precision, we find that this is not consistently correlated with other non-differentiable metrics which we may also wish to optimize with respect to. We therefore also investigate using a supplemental loss function based on the REINFORCE algorithm [12] which measures the frequency of undesirable fingering patterns in predicted outputs. While REINFORCE is traditionally associated with environment navigation, it has seen success in sequence generation tasks as well [13–15].

Under this framework, the loss function is formulated as an expected reward, which we approximate by sampling a sequence $\tilde{\mathbf{y}}$ from our output distribution (using ancestral sampling) and weighting its reward by its likelihood.

$$L = \frac{(\bar{r} - r(\mathbf{x}, \tilde{\mathbf{y}}))}{N} \sum_{i=1}^{N} \log p(\tilde{y}_i | \tilde{\mathbf{y}}_{<i}, \mathbf{x}; \theta)$$

Where $\bar{r}$ is the rolling average reward over the past 50 examples, serving as our reward baseline. In order to ensure stronger signal during training, we also calculate the REINFORCE loss over 10 note chunks at a time, rather than over an entire song as this would make the attribution of reward to specific decisions less direct. In our experi-

Model	Thumb Cross (#)	Thumbless Cross (#)	Crossed Chord (#)	Hop (#)	Smear (#)	Step Spread (s/f)	Chord Spread (s/f)	4-gram (Acc)	M_{gen} (Acc)
Gold	331	58	28	155	7	2.78	2.64	100	100
Bi-LSTM (MIDI) [3]†	228	84	47	485	148	2.63	2.56	66.7	27.8
Bi-LSTM (Note $\oplus$ Octave)	**257**	90	**36**	394	135	**2.69**	2.61	67.0	28.3
Bi-LSTM (Note $\oplus$ Rel Dist)	218	87	52	390	101	2.65	2.59	69.1	32.2
Bi-LSTM (Lattice)	217	**43**	40	**334**	**74**	2.66	**2.62**	**69.6**	**33.1**

Table 1. Results on PIG test set for Bi-LSTM model with different input representation schemes. The first row represents the value of each metric under the gold fingerings produced by human annotators. Values in bold are the closest to the gold labels' score for that metric. †This model is based specifically on the neural approach used in [3], but is our own implementation of it. It was similarly reimplemented by [4] in their work. Units for most metrics are simple frequency counts, except for spreads which are in semitones per finger, and 4-gram and M_{gen} which are accuracies.

ments, we set the reward to be a function of the number of hops and smears (see Section 4.1):

$$r(\mathbf{x}, \mathbf{y}) = \exp(-\#\{i : x_i \neq x_{i+1}, y_i = y_{i+1}\} - \#\{i : y_i = y_{i+1}, t_i^+ > t_{i+1}^-\})$$

Because training solely on the REINFORCE objective can lead the model towards degenerate solutions that trivially minimize undesirable patterns while compromising predictive accuracy, we take an approach similar to [15] and [19] where both loss functions are summed into a mixed training objective. This provides a reasonable tradeoff between the predictive signal of cross entropy, and the pressure towards fluent output given by REINFORCE. Mixed objective runs are warm-started on just the cross entropy loss to avoid degenerate solutions.

5. EXPERIMENTAL SETUP

5.1 Implementation Details

We use 2 layer LSTMs and 2 layer MLPs with a hidden size of 1024, and a dropout of 0.2 in both of these networks. We use d=256 for our input embedding size. Beam search is performed to decode autoregressive models at test time using a beam size of 10. Models are trained using the Adam optimizer [20] with a learning rate of $1e{-}4$. Our code is implemented in PyTorch `1.8.1` [21] and trains on an NVIDIA 2080ti GPU in roughly 12 hours.

5.2 Data

We train and evaluate on the PIano fingerinG dataset (PIG) [3] which contains 150 piano songs written by 24 composers. Each song has up to 6 fingerings produced by human pianists, yielding 309 annotated songs in total. Because of the imbalance in the dataset's original splits, we use alternate splits created by [4] which increase the relative size of the train and validation sets. As a baseline we compare to a reimplementation of the LSTM model of [3] (which was also reimplemented by [4] in their experiments), albeit with the same architecture of our other systems. We also show results from the third order HMM implementation of [3], although the more similar neural models are our primary point of direct comparison.

We employ similar preprocessing as prior work. Rather than modeling left and right hands separately, we reflect the pitches of all left hand parts and reverse the corresponding finger labels, thereby constructing a second "right hand part" which we treat as an independent song. This prevents overfitting by halving the label space. To handle chords, i.e. multiple notes with identical onsets, we simply arpeggiate them from lowest to highest pitch. Otherwise, notes are ordered by onset. We do however retain the original timing information for constructing accurate checklists.

6. RESULTS

6.1 Input Representation Ablation

We start by investigating the effects of input representations on a simple Bi-LSTM baseline model that outputs independent prediction probabilities at each timestep. Table 1 shows our results across all metrics. Overall the lattice representation does best, followed by note $\oplus$ octave. This matches our hypothesis that learning a separate embedding for each note on the keyboard leads to overparameterization, and that modular representations are more effective. We also see that relative distance based embeddings lead to fewer hops and smears specifically, which makes sense given that it allows the model to more easily observe when notes are or are not repeated, and therefore whether repeating the same finger would make sense.

6.2 Checklist Models

We see in Table 2 that the checklist models tend to do best overall, with Binary Checklist using REINFORCE getting the highest 4-gram score among LSTMs. All the autoregressive systems significantly outperform the Bi-LSTM baselines, but with different tradeoffs in terms of the output patterns we measure. REINFORCE minimizes the number of hops and smears compared to just cross entropy, and in doing so can sometimes boost other metrics as well.

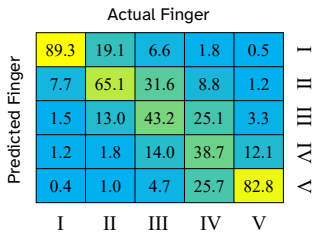
Note that M_{gen} fails to fully reflect what are at times substantial differences in model output made apparent from the other metrics. For instance, the Prev Finger Embedding produces fewer hops, smears, and crossed chords than the Autoregressive tagger, likely indicating that it would be far easier for a human to perform despite having worse M_{gen}. This is especially apparent when comparing the checklist models to the Bi-LSTM baselines. Also while

Model	Thumb Cross (#)	Thumbless Cross (#)	Crossed Chord (#)	Hop (#)	Smear (#)	Step Spread (s/f)	Chord Spread (s/f)	M_{gen} (Acc)	4-gram (Acc)
Gold	331	58	28	155	7	2.78	2.64	100	100
Bi-LSTM (MIDI) [3]†	228	84	47	485	148	2.63	2.56	66.7	27.8
HMM-3 [3]‡	220	32	31	196	84	2.84	2.72	**70.2**	**39.5**
Autoregressive Tagger	278	88	49	**168**	58	2.74	2.67	68.3	36.7
(+REINFORCE)	274	66	49	59	18	2.70	2.63	68.7	36.5
Prev Finger Embedding	271	**56**	40	127	30	**2.78**	2.67	68.1	35.5
(+REINFORCE)	283	53	54	53	**12**	2.81	2.76	68.4	36.5
Binary Checklist	227	72	**26**	332	74	2.67	2.58	69.3	35.8
(+REINFORCE)	261	49	**26**	217	42	2.69	**2.64**	69.5	37.1
Distance Checklist	274	72	37	195	37	2.80	2.69	68.8	36.6
(+REINFORCE)	**284**	78	41	134	32	2.75	2.68	69.0	36.1

Table 2. Results on PIG test set for various autoregressive setups, shown with and without using REINFORCE to minimize hops and smears (see Section 4.2). ‡ A third order HMM implementation by [3] is also included – while it ranks similarly as in prior work against LSTMs by M_{gen}, it falls behind on other metrics.

the HMM does strongly on M_{gen} and 4-gram, we only see its deficits when we look at other metrics which reveal subtle issues such as an especially high finger spread and number of smears, and low utilization of thumb crosses.

6.3 Label Confusion



This figure shows the confusion matrix for predictions by the Binary Checklist model with REINFORCE. The distribution of misclassifications is fairly different for each finger; adjacent fingers are more likely to be confused than ones that are further apart, reflecting a degree of interchangeability in how pianists use them. We also see that thumb and pinky predictions are most accurate, perhaps because being at the ends of the hand makes them less versatile.

6.4 Human Evaluation and Conclusion

Model	Physical Comfort	Mechanical Efficiency	Ease of Learning
Bi-LSTM (MIDI) [3]	1.6	1.4	1.6
Binary Checklist (+REINFORCE)	**2.8**	**2.5**	**2.9**

Table 3. Human evaluation ratings across various criteria.

Since the ultimate success criteria of our task is to produce fingerings that are well-suited to human performance, we also present results from a small scale round of human evaluation. Specifically, we recruited a college professor of piano with a doctorate in piano performance (who was not involved with the creation of the original dataset) to assess the outputs of two models—the Bi-LSTM (MIDI) [3] and Binary Checklist with REINFORCE—according to three main criteria: physical comfort, mechanical efficiency, and ease of learnability. The pianist was asked to score the models' outputs with respect to each of these categories on a scale of 1-3 for all 10 songs in the validation set (composed by Brahms, Mendelssohn, and Rachmaninoff).

We show the models' average ratings per category in Table 3. The strong contrast suggests that the checklist model is not just predicting gold label fingers more frequently (shown by M_{gen}) but also that it is producing more locally coherent outputs in a way that substantially improves performability. Furthermore, the correlation of human judgements with our proposed metrics indicates that they are meaningful measurements of output quality.

The pianist also provided qualitative observations which we summarize. He noted that both systems performed best on simpler, repetitive passages such as those found in Mendelssohn. Our model also reportedly produced fewer difficult stretches, which we expect as it is directly aware of interval distances in its input representation. Another observed issue was that the Bi-LSTM's fingerings did not consider tempo, often containing sections that would be impossible to play fast enough, especially for Rachmaninoff pieces. We suspect our model's advantage is from the checklist's dependence on absolute timing, not just the ordering of notes. The pianist also reported that our model more frequently used the same fingering for repeated notes and chords, whereas the Bi-LSTM would often change fingerings without reason, which can also likely be explained by our conditioning on recent predictions instead of decoding them independently. Quantitatively, we found that REINFORCE was able to reduce the number of hops and smears, which was confirmed by the pianist to have a significant impact on playability, emphasizing the importance of integrating these into the training loop instead of purely relying on a traditional likelihood loss.

Finally, he noted that the models particularly struggled on successive chords (as opposed to stepwise passages). Chord transitions require fingerings that are not just comfortable in isolation but also connect together. This requires the model to reason about *voices* within the same hand, something which may require moving beyond a framework that treats songs as linear sequences of individual notes, and is more sensitive to polyphony.

ABSTRACT

Reading, much like music listening, is an immersive experience that transports readers while taking them on an emotional journey. Listening to complementary music has the potential to amplify the reading experience, especially when the music is stylistically cohesive and emotionally relevant. In this paper, we propose the first fully automatic method to build a dense soundtrack for books, which can play high-quality instrumental music for the entirety of the reading duration. Our work employs a unique text processing and music weaving pipeline that determines the context and emotional composition of scenes in a chapter. This allows our method to identify and play relevant excerpts from the soundtrack of the book's movie adaptation. By relying on the movie composer's craftsmanship, our book soundtracks include expert-made motifs and other scene-specific musical characteristics. We validate the design decisions of our approach through a perceptual study. Our readers note that the book soundtrack greatly enhanced their reading experience, due to high immersiveness granted via uninterrupted and style-consistent music, and a heightened emotional state attained via high precision emotion and scene context recognition.

1. INTRODUCTION

In 1975, a short repetitive piece of orchestral music gained notoriety for inducing fear in its listeners, putting them in a suspenseful state of impending doom. Today, it still induces the same reaction, right when the iconic shark of the movie *Jaws* appears on screen. Movie composers, such as John Williams who created the *Jaws* theme, have long been aware of the impact music has on its listeners. Well-placed music can accentuate scenes to raise the emotional stakes or foreshadow upcoming events; ill-suited music can even suggest that something evil is afoot [1]. When taken as a whole, the musical imagery afforded by such soundtracks greatly complements the movie watching experience. In this paper, we attempt to answer whether we can create a similar experience for books (*cf*. Fig. 1).

Automated Dense Soundtrack Construction for Books using Movie Adaptations", in *Proc. of the 23rd Int. Society for Music Information Retrieval Conf.*, Bengaluru, India, 2022.

Figure 1. We aim to transport readers to a musical universe by building a dense and coherent book soundtrack that is borrowed from movie adaptations.

Not unlike movies, reading literature can be an incredibly transportive process that puts one in a meditative state, while actively engaging their imagination and mind [2]. Apart from the lack of visuals, books share many similarities from a music composer's perspective: they have recurring themes, characters (allowing for unique *leitmotifs* [3]), and even long-drawn emotional and narrative arcs that can be teased and reinforced musically. Still, it is uncommon to see soundtracks that are tailored for books; it is up to the reader to curate their own playlist and craft their experience. Inconvenience aside, this requires the reader to preempt the type of music expected for a book's chapter and switch songs at relevant plot points. This is simply infeasible. In this work, we resolve these issues by proposing the first automatic system to build a dense soundtrack that plays throughout the entire reading duration of a book.

Specifically, we focus on building a soundtrack for books with movie adaptations. This allows us to draw on the corresponding movie soundtrack and take advantage of the composer/director's musical intents and instincts for the *same story*. However, adapting the soundtrack is far from trivial due to missing alignment between book parts and music segments. Our approach resolves this by finding scenes in the movie adaptation that match parts of the book and searching for music that plays in that movie scene. This results in high quality, narrative specific matches that amplify the reading experience. We conduct our experiments on *Harry Potter and the Philosopher's Stone*, cho-

sen due to its popularity and Academy Award nominated soundtrack. We evaluate the quality of our soundtrack by asking participants to read two music-accompanied chapters of the book followed by a semi-structured interview.

Our contributions can be summarised as follows: (i) We propose the first fully automatic approach for constructing book-long soundtracks. (ii) Our pipeline matches the story in the book and movie to lift musical cues from the movie adaptation. Gaps in this alignment are filled through an emotion-driven music retrieval system. (iii) A perceptual study of the soundtrack validates our proposed approach and provides further insights into soundtracking for books.

2. RELATED WORK

Soundtracking for books. Methods for constructing book (or story) soundtracks can be divided into two: generative or retrieval based. Generative approaches typically parse the text for concepts and provide that as input to a music generation pipeline. Topic extraction followed by sentiment analysis [4] or density estimation of emotion-related words [5] are used to generate melodies. On the other hand, retrieval based approaches, mine text for semantic concepts that are used to retrieve ambient music (sometimes with pitch correction) [6] or apply similar ideas to Twitter texts [7]. The general idea of cross-modal text-to-audio retrieval [8] is adapted for tag-based music [9] or characterises documents and music as a distribution over emotions [10]. Recently, Won *et al*. [11] propose a joint emotion-driven embedding space for story sentences and music enabling cross-modal retrieval. However, understanding emotions conveyed in a book depends on the larger narrative requiring a context of more than a few sentences. Thus, while [11] could be used to construct dense book soundtracks in theory, the potential switching of music and resulting change in emotion every few sentences may not result in a good user experience.

Unlike above approaches, we focus on retrieving music from the soundtrack of a book's movie adaptation. Our approach assembles coherent music for books by considering large chunks of the book chapter, aligning them with movie scenes, and finding matched music pairs. We fill in the gaps (only unmatched chapter segments) by relying on emotion-based matching. To the best of our knowledge, we are the first to perform narrative-specific music retrieval and *weave* a soundtrack for the entire book.

Multi-modal music recommendation systems use cues such as user location, time, and environmental information to play music in day-to-day life [12] or even traffic conditions for music in cars [13]. Perhaps closest to our work, PICASSO is a fine example of a ranking model trained on pairs of matching music and movie-clips (images, subtitles) that is used to provide music recommendations for image slideshows or audio books [14]. Instead, our work focuses on producing a *dense* book soundtrack by aligning narrative components of the book with the movie adaptation. This results in high precision narrative matches and ensures a coherent soundtrack adapted from the same story.

3. ASSEMBLING SOUNDTRACKS FOR BOOKS

A large book may take several (variable) hours for a reader to complete. Within the book, there are multiple chapters, each having sections indicated by the theme, emotion, or location. An ideal soundtrack should respect these scene boundaries and change accordingly. On the music front, while different tracks from the soundtrack are typically homogeneous, they are rarely played in their entirety in the movie at a single stretch. A track may include the score for the setup, conflict, climactic moment, and resolution for a certain storyline, which composers will selectively play at opportune moments to maximise emotional payoffs.

We use the movie adaptation as an intermediary between the two that links plot points from the book with snippets of music from the soundtrack album. We first divide each modality - the book, music soundtrack, and the movie into smaller segments (Sec. 3.1). Then, we obtain clues about the soundtrack associated with each plot point in the book by aligning both the book and soundtrack to the movie (Sec. 3.2). Finally, we weave together the music for the book by combining movie-based and emotion-based matches (Sec. 3.3). Fig. 2 illustrates this overall flow.

3.1 Segmenting the Book, Music, and Movie

We discuss methods for segmenting the book chapters $\mathcal{B}_i$ in a book $\mathcal{B} = [\mathcal{B}_1, \ldots, \mathcal{B}_L]$; identifying cohesive musical segments within each track M_j of the album $\mathcal{M} = [M_1, \ldots, M_P]$; and identifying scene boundaries for a movie $\mathcal{V} = [V_1, \ldots, V_Q]$ that facilitates the alignment.

Book narrative segmentation. We divide the text in a book chapter based on narrative-relevant factors such as theme, location, activity composition, character constellation, or even time [15]. Due to the absence of large datasets for this task, we adopt an unsupervised approach, temporally weighted hierarchical clustering (TW-FINCH) [16], recently shown to be successful on video activity segmentation. For a chapter $\mathcal{B}_i$, we encode each paragraph using a pretrained language model $\phi_{LM}(\cdot)$ (specifically MPNet [17] that performs well for sentence embeddings and semantic search [18]), and cluster semantically similar and spatially close paragraphs to produce disjoint partitions,

$$\{\mathcal{B}_i^p\}_{p=1}^{K_i} = \text{TW-FINCH}\left(\phi_{LM}(\mathcal{B}_i)\right) . \quad (1)$$

We align individual segments $\mathcal{B}_i^p$ with music segments.

We also considered a few baselines but ignored them due to inferior results. TextTiling [19] tended to uniformly partition chapters while TopicTiling [20] often resulted in over-segmentation. In contrast, our approach yielded segments that mostly respected narrative shifts.

Keystrength based music segmentation. As mentioned earlier, the entire track M_j from an album is (almost) never played in a portion of the movie. Hence, similar to book chapters, we focus on creating homogeneous emotionally-cohesive track segments that can be played continuously.

A key feature that music segments are required to reflect are emotions that the director/composer intends to convey. Since we expect homogeneity in music segment

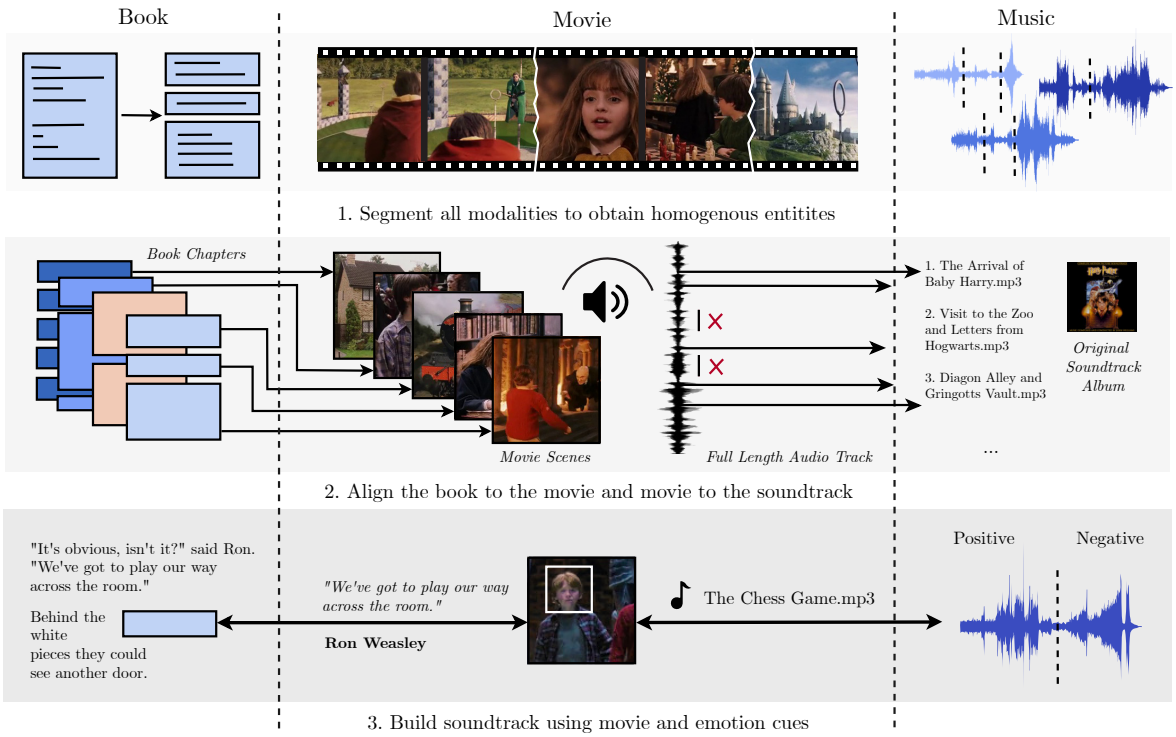

Figure 2. **Overview of approach.** We present a novel technique to build a musically rich book-length soundtrack. We accomplish this by first segmenting the book, its adaptation, and music into smaller homogenous chunks. These segments are then matched with the movie acting as an intermediary for text and music, thereby producing the final soundtrack.

emotions, *keystrength* [21] is a good attribute as it captures the tonal properties of music, and tonal changes likely suggest emotional shifts (*e.g.* major to minor mode suggesting a potential shift from positive to negative valence [22]). *Keystrength* as extracted via the MIRToolbox [23] gives us a probability for each possible key resulting in a 24 dimensional vector (12 major and 12 minor keys). We use a window size of 10 seconds with an 85% overlap, that helps ignore minor local variations in the track while retaining larger shifts. We then compute a self-similarity matrix [24] of the time-varying keystrength vector which is then used to calculate the novelty curve, with a kernel size of 64 [24]. The peaks in the novelty curve determine points of change. Finally, we use those peaks as our segment boundaries to produce L_j music segments $\{M_j^c\}_{c=1}^{L_j}$ (see Fig. 3).

Movie scene detection. As a third step, we segment the movie into narrative-coherent scenes $[V_1, \ldots, V_Q]$ using the approach described in [25]. First, the movie is divided into shots (consecutive video frames from the same camera). Then, a dynamic programming algorithm is used to find scene boundaries (a scene consists of multiple shots) so as to maximise intra-scene similarity.

Summarising, we denote $\mathcal{B}_i^p$ as the segment of book chapter $\mathcal{B}_i$; M_j^c as the music segment from track M_j; and V_q as the q^{th} scene from the movie $\mathcal{V}$.

3.2 Aligning the Book, Movie, and Music

We first align the book with the movie adaptation using a new two-stage coarse-to-fine alignment scheme. Then, we also align the movie audio to the soundtrack album.

Chapter-scene coarse alignment. We first assign a set of scenes from the movie to each book chapter. We use an approach similar to [26] where pairwise similarities are computed between a book chapter $\mathcal{B}_i$ and a video scene V_q via character histograms and matched dialogues. The chapter-scene relationship is then encoded as a graph (each node represents a chapter-scene pair), with edge weights representing similarity scores. Calculating the shortest path over this graph provides the alignment between all chapters and scenes. Additional details are provided in the Appendix.

Paragraph-scene refinement. The coarse alignment cannot be used directly for soundtracking as a chapter $\mathcal{B}_i$ contains distinct segments $\mathcal{B}_i^p$ that likely need different music. Thus, in addition to sparse dialogue matches, we compute similarities between sentences in the chapter segment $\mathcal{B}_i^p$ and frames of the video scene V_q using a pretrained vision-language model (CLIP [27]). To improve the quality of CLIP matching scores, we prune dialog and mundane sentences from the chapter segment using a TF·IDF based scoring system. This emphasises relatively rare characters and objects that are likely to give stronger matches than commonly occurring ones. We also retain sentences with a high *concreteness* index [28] that measures how likely a word can be seen or experienced (in contrast to *abstract* words). Finally, we take the top remaining sentences, encode them with CLIP, and calculate cosine similarity with all CLIP encoded video shot frames in the chapter's scenes (see Fig. 4). Scenes with a score higher than θ are assigned to the text segment using a mapping function,

$$A(\mathcal{B}_i^p) = \{V_q : \text{CLIP}(\mathcal{B}_i^p, V_q) > \theta\}\,. \tag{2}$$

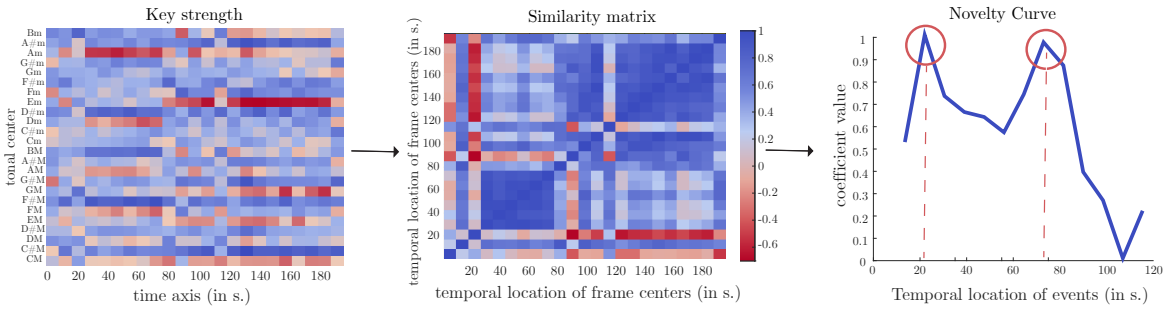

Figure 3. **Music segmentation pipeline.** We segment all tracks from the soundtrack to ensure a cohesive listening experience. We extract keystrength [21] that captures tonal properties of a soundtrack (left), compute the self-similarity matrix (center), and use that to calculate the novelty curve [24]. The peaks of this curve are used to segment the track.

Aligning the movie audio track with the soundtrack album. We identify the music in the movie by passing its audio track through Shazam [1] , a popular commercial audio-fingerprint based search application [29] using its free public API. This results in high-precision estimates for the music played every few seconds. While any audio fingerprinting approach would perhaps work, we found that Shazam was quite accurate in the presence of background noise and dialogue, which is pervasive in movies.

3.3 Weaving the Book Soundtrack

Post alignment with the movie, book chapter segments $\mathcal{B}_i^p$ belong to one of two sets: (i) those associated with at least one movie scene $\mathcal{S} = \{\mathcal{B}_i^p : |A(\mathcal{B}_i^p)| \geq 1\}$; and (ii) those without, $\bar{\mathcal{S}} = \{\mathcal{B}_i^p : A(\mathcal{B}_i^p) = \varnothing\}$. Recall, $A(\mathcal{B}_i^p)$ is the set of aligned video scenes to a book segment (*cf*. Eq. 2).

Extracting emotion labels. For all text segments $\mathcal{B}_i^p$, we classify each paragraph into positive, neutral, or negative using a BERT-based emotion classifier ϕ_{BERT}, trained on Reddit comments [30]. A majority vote across paragraphs is used to assign the emotion label to the chapter segment $E_{\text{book}}(\mathcal{B}_i^p) = \text{mode}(\phi_{\text{BERT}}(\mathcal{B}_i^p))$. For a music segment, similar to [5], we encode it's emotion as valence, $E_{\text{music}}(M_j^c)$, based on the mode of the song (major or minor). This is based on literature that indicates that tracks in minor tend to be associated with negative emotions and tracks in major with positive emotions [22]. We also tried approaches that predict emotion from audio [11, 31], but they didn't work as well for our application.

Importing music snippets from the video scene. For every text segment $\mathcal{B}_i^p \in \mathcal{S}$, we extract the movie timestamps corresponding to the matched dialogues or CLIP-based frame-sentence pairs. We use the audio-search to identify the overall track M_j being played at any of the above timestamps in the movie (in a small neighbourhood). A specific music segment M_j^c is chosen by matching emotion predictions *i.e.* $E_{\text{book}}(\mathcal{B}_i^p) = E_{\text{music}}(M_j^c)$ (we pick one randomly if there are several segments). While we can pick emotion-matching music segments without the book-movie alignment, it will likely result in spurious matches.

Emotion-based retrieval. For the chapter segments that are not aligned with any video scene, $\bar{\mathcal{S}}$, and those in $\mathcal{S}$ that did not find an emotion compatible soundtrack, we assign a random music segment among the set of emotionally compatible compositions. Note that while we can pick any music segment (even from different movies), we restrict to the soundtracks for this movie maintaining the composer's stylistic coherence.

4. RESULTS AND EVALUATION

Our approach is designed to be applicable to books that have mostly faithful movie adaptations in terms of few matching dialogues, a relatively similar plot, and at least some matching characters. We evaluate it on the first book and movie pair in the *Harry Potter* series, *Harry Potter and the Philosopher's Stone*.

4.1 Harry Potter: A Case Study

Our unsupervised text segmentation approach splits 17 chapters into 87 segments, with an average of 5.11 segments per chapter. Assuming a reading speed of 250 words per minute, each segment requires a ~4 minute track, for a total soundtrack duration of ~6 hours. Music segmentation

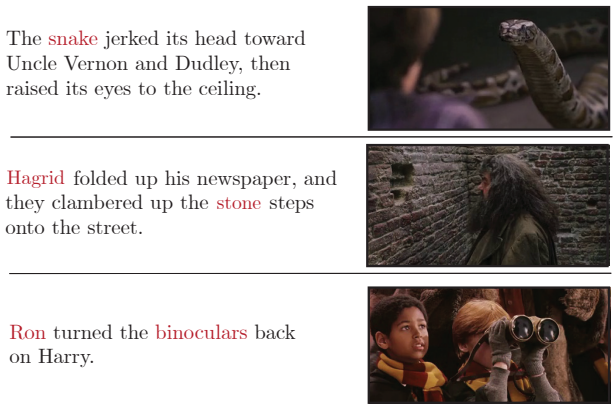

Figure 4. **CLIP-based paragraph-scene alignment.** Aligned examples of automatically selected visual sentences and their video frames in the scene using the vision-language model CLIP [27] in a zero-shot setting. Text highlights are words that we think that caused the match.

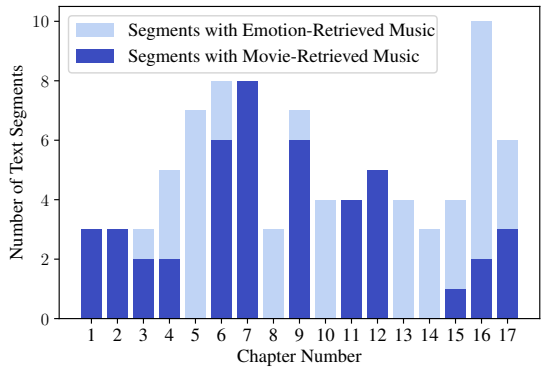

Figure 5. **Number of chapter segments with movie- vs. emotion-retrieved music.** Several chapters in the book are well represented in the movie and are predominantly soundtracked using movie cues. For others, we use an emotion-based retrieval method to build a soundtrack.

of 19 tracks from the soundtrack album results in 47 audio chunks with an average duration of ~52 seconds. For the movie, we obtain 120 scenes using the scene detection algorithm. Computing the book-movie alignment results in a strong chapter-scene alignment, with 82% accuracy, calculated as the percentage of movie shots correctly assigned to a chapter [26].

For the fine-grained alignment, 34 chapter segments have dialogue matches, while the CLIP based refinement results in a 130% improvement in the number of chapter segments associated with the movie; only 9 segments remain unmatched. After performing the final book-music alignment, 45 chapter segments have music imported from a matching video scene through the book-movie alignment. The remainder 42 segments are soundtracked using music segments fetched via emotion matching. See Fig. 5 for a chapter-wise distribution.

4.2 Experiment Design

As the primary goal of our method is to improve the reading experience, we obtain user feedback by setting up semi-structured interviews with 10 individuals, who each read two chapters of the *Harry Potter* book. We randomly picked one chapter for each person while the final book chapter was read by all. We chose the final chapter as it represents all aspects of our method: it includes music retrieved via movie cues as well as pure emotion based retrieval, apart from being a key chapter in terms of the plot. This allows us to fairly evaluate the effectiveness of our soundtrack at a book level as reading these chapters takes around an hour for each participant.

All participants are asked to read these chapters consecutively and answer a series of questions about several aspects of the reading experience. No user data is collected through this process and user consent is collected prior to recording the interviews. The study was also authorised by the author's institutional ethics committee.

Reading application. A bottleneck with playlist based approaches for soundtracking books is that they require user-input to transition at appropriate instants. We resolve this by creating an application that plays music in the background of the displayed text. Our application loops the music segment infinitely and cross-fades to the next as the reader moves on to the next text segment. This ensures complete immersiveness and lets participants with *varying* reading speeds truly enjoy the soundtrack. For readers to have a first-hand experience, we package this application for a few chapters at the project page.

Participant information. A total of 10 individuals (18-22 age range, 6 male, 4 female) volunteered for the study. Each participant had previously read the *Harry Potter* book without music and happened to be familiar with the movie as well. We also provided each participant with a small monetary reward as compensation for their time.

4.3 Findings

The soundtrack improved immersiveness. All participants reported that the soundtrack improved the immersiveness of the reading experience. This is remarkable as all participants noted that they typically do not listen to music while reading. Some participants were more receptive to the soundtrack than others and spoke glowingly about the movie-like immersion afforded by the music. These participants could recognise that the music played was similar to the score at the relevant movie scene. Others, who were positive but less movie-inclined, focused more on how the music *"set the environment"* (P4). Phrases such as *"set the mood"*, *"intensified the emotion"*, *"fit the vibe"*, and *"enhanced the experience"* were common among such participants.

> *"The music provided insight into the tone of the chapter and [...] beyond imagination, provided a soundtrack to what was read"* (P1)

Surprisingly, some participants reported that the first section of the random chapter that they read first threw them off initially, suggesting that there is an adjustment period to this experience. These participants reported that they were very comfortable with later sections (*"after the first 10-12 lines"* - P2) once they had gotten into a reading flow.

The soundtrack helped visualise the book. Some participants could recognise that the music played was similar to the score at the relevant movie scene. These participants were especially appreciative of the soundtrack and stated that it helped *"visualise the book, with movie like visuals"* (P1). Such participants typically appreciated the music's cohesiveness and were likely referring to the pleasing soundscape laid out by our soundtrack. One participant explicitly pointed out that the soundtrack helped visualise character interactions and that without, it would have just been *"two characters talking"*.

Many were also receptive to the recurring motifs and themes that appeared throughout, such as the central *Harry Potter* theme and stated that it helped imagine the fictional

world. Only one participant, P3, expressed complete disagreement with the music played in a text segment, for ironically the same reason, stating that the signature *Harry Potter* motif distracted them. Barring this, the same person spoke warmly about the remaining soundtrack, suggesting that the overtness of the motif, which permeates culture today, may be subject to individualistic preferences.

Music helped focus.

> *"I get distracted when reading so it helped me focus on certain parts"* (P5)

When describing the immersiveness of the reading experience, three participants specifically pointed out that the music helped them read continuously, without distractions that are typically present when reading in the absence of a soundtrack. It should be noted that few participants who described an aversion for listening to music during typical recreational reading specifically pointed out that they avoid pop music, suggesting that instrumental music, in general, may be better suited for reading purposes.

Moderate repetition is not a concern. Most participants noticed repetitive music in some text segments that they read but only brought it up when explicitly asked. One participant suggested playing a different, similarly composed track instead of repeating the music, but in agreement with the rest of the pool, felt that repetition did not affect the experience. These participants also said that the repetition wasn't glaringly obvious and that it did not distract or take away from the immersion. It should be noted that repetition refers to the same track being played on a cross-fade loop while a person reads a text segment, due to variable reading speeds. Despite this, it is noteworthy that our musical segments are homogeneous enough to be played repeatedly and that the text segments are narratively cohesive to warrant such repetition. When specifically asked about the diversity of the music played, all participants expressed positive opinions and noted that the tracks kept changing as and when required.

Narrative transitions mirrored in music. Many participants engaged in a conversation with the authors post-interview about how the soundtrack was built. All such participants were startled by the fact that the entire process was completely automatic. Their surprise was primarily due to the fact that the music was automatically matched with relevant areas in text and that it transitioned at appropriate narrative points.

> *"It actually made the experience better as the transition put you in the mood for the expected emotion - from melancholy to sad."* (P9)

When asked specifically about these narrative transitions during the interview, all participants agreed that it was emblematic of emotional or narrative shifts. Since the last chapter was common across all participants, there was strong consensus about the narrative shifts here especially, with participants noting that the music increased in tension as the final hero-villain clash developed and that it eased into more mellow, tender music once it was resolved.

> *"When the tension built in the plot, the music transitioned to match it."* (P1)

Some participants explicitly appreciated the foreshadowing made possible by the music, as suspenseful music at the start of a segment would precede a similar narrative plotline. Others simply elaborated on their earlier comments about the immersiveness and re-emphasised the high congruency between text segments and the matched music.

Low-arousal music preferred. We asked participants to describe the emotional suitability of the music, specifically, and in line with prior answers, and received a favourable response. The few critiques that were present revolved around the energy/arousal of the music played at certain instances. Some participants were dissatisfied with segments that were high in arousal, even though the valence matched, as it broke the immersion. They described how this music distracted them from reading and drew too much attention to the track itself. This is likely an important factor to consider for future work on soundtracking books.

Movie-based music cues stronger than emotion-based cues. At the end of the interview, participants were asked to describe their favourite and least favoured pieces of music from the two chapters, if any. The best segments were split between music retrieved via movie cues and those retrieved via emotion matching, with the former being more prominent. On the other hand, the least favoured segments, often mentioned only after the author's insistence, were typically emotion-based matches that were described in terms of their neutrality. This finding suggests that our approach can effectively retrieve narrative-specific music and that such a system is perhaps well-suited for book soundtracking, as opposed to pure emotion-based methods.

5. CONCLUSION

We presented a novel system to automatically weave a book-length soundtrack, using the music present in the relevant movie adaptation. Perceptual validation of the constructed soundtrack for the first book and movie pair of the *Harry Potter* series provided very positive feedback that validated several proposed design decisions and techniques for text, movie, and music processing. Participants in our perceptual study were particularly receptive to music that was fetched via the movie and uniformly stated that it improved the immersiveness of the reading experience, and even transported them to the fictional world.

Future work. While our method has been successful in generating a soundtrack for a book with a movie adaptation, it needs to be modified to make it work on books without adaptations. Future work can potentially use our approach to investigate common trends across books to determine new cross-narrative rules. Our approach can also be extended for human-in-the-loop collaborative soundtrack construction applications, though such a use case is beyond the scope of this work.

6. ACKNOWLEDGMENTS

We thank Siddarth Baasri for his valuable input in analysing motifs present in the *Harry Potter* soundtrack and Saravanan Senthil for illustrating Fig. 1.

MUSIKA!
FAST INFINITE WAVEFORM MUSIC GENERATION

Marco Pasini **Jan Schlüter**
Institute of Computational Perception, Johannes Kepler University Linz, Austria
marco.pasini.98@gmail.com jan.schlueter@jku.at

ABSTRACT

Fast and user-controllable music generation could enable novel ways of composing or performing music. However, state-of-the-art music generation systems require large amounts of data and computational resources for training, and are slow at inference. This makes them impractical for real-time interactive use. In this work, we introduce Musika, a music generation system that can be trained on hundreds of hours of music using a single consumer GPU, and that allows for much faster than real-time generation of music of arbitrary length on a consumer CPU. We achieve this by first learning a compact invertible representation of spectrogram magnitudes and phases with adversarial autoencoders, then training a Generative Adversarial Network (GAN) on this representation for a particular music domain. A latent coordinate system enables generating arbitrarily long sequences of excerpts in parallel, while a global context vector allows the music to remain stylistically coherent through time. We perform quantitative evaluations to assess the quality of the generated samples and showcase options for user control in piano and techno music generation. We release the source code and pretrained autoencoder weights at github.com/marcoppasini/musika, such that a GAN can be trained on a new music domain with a single GPU in a matter of hours.

1. INTRODUCTION

Generating raw audio remains a difficult task to perform, considering the high temporal dimensionality of waveforms. Recently, a number of techniques based on deep learning architectures have been proposed: however, they often present limitations such as low generated music quality, lack of general coherence between distant time frames and slow generation speed. Regarding unconditional audio generation, autoregressive models are able to generate high quality audio with long-range dependencies; however, the sampling process is extremely slow and inefficient, which hinders possible real-world applications. On the other hand, non-autoregressive models can reach real-time generation, while they struggle to synthesize samples with satisfactory sound quality and are only able to generate samples of a fixed duration.

Considering the current shortcomings of non-autoregressive audio generation systems, in this work we propose Musika, a GAN-based system that allows fast unconditional and conditional generation of audio of arbitrary length. We achieve this by combining the following contributions:

- The use of a raw audio autoencoder which allows to encode samples into lower-dimensional invertible representations that are easier to model. We engineer the autoencoder with the specific goal of maximizing inference speed and minimizing training time, by relying on the generation of magnitude and phase spectrograms with low temporal resolution and an efficient adversarial training process
- The use of a latent coordinate system for the task of infinite-length audio generation
- The addition of a global style conditioning which allows the infinite-length generated samples to be stylistically coherent through time
- The possibility to perform both unconditional and conditional generation, with a variety of different conditioning signals, such as note density and tempo information

By avoiding auto-regression, generation can be fully parallelized and works much faster than real-time even on CPU.

2. RELATED WORK

A popular family of generative models for audio consists in autoregressive models, such as WaveNet [1], SampleRNN [2] and Jukebox [3]. WaveNet was the first model to show that autoregressive generation of raw audio waveforms is possible, and uses dilated convolutions to acquire a large receptive field over the input sample. SampleRNN is a model consisting of a hierarchical stack of recurrent units that are able to model the waveform at different resolutions, and thus capture a larger context and reduce the computational cost required to model the next sample. Jukebox uses a hierarchical VQVAE [4, 5] to encode raw samples into a sequence of discrete codes at different levels. It then uses autoregressive transformers [6] to both generate new top-level samples and upsample them to the lower

Fast Infinite Waveform Music Generation", in *Proc. of the 23rd Int. Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

levels, accepting different features, such as lyrics, as conditioning. While autoregressive systems can achieve satisfying audio quality and long-range coherence, they suffer from extremely slow generation, as audio samples are produced sequentially. For example, Jukebox requires more than eight hours to generate one minute of audio on a V100 GPU. As an exception, RAVE [7] achieves real-time synthesis by encoding raw audio of a specific domain with a variational autoencoder [8] into a compact latent space and using a lightweight autoregressive model to generate codes: however, the short receptive field of the autoregressive model does not allow to model dependencies over distant time windows in the generated audio.

Non-autoregressive models avoid the slow sequential generation, but are mostly employed for *conditional* audio synthesis. For example, several works focus on the task of inverting a low-dimensional audio representation (often a mel-spectrogram) back to the original waveform, which constitutes a building block of modern text-to-speech (TTS) systems [9–11]. In contrast, literature on long-form non-autoregressive unconditional audio generation is scarce. Systems such as WaveGAN and SpecGAN [12], GANSynth [13], DrumGAN [14] and MP3Net [15] attempt to generate audio of a fixed length using various architectures of Generative Adversarial Networks [16] (GANs). WaveGAN and SpecGAN represent the first works in which a GAN is successfully applied to audio, in the waveform and spectrogram representations, respectively. GANSynth generates instantaneous frequency (IF) and magnitude of spectrograms with high frequency resolution of short monophonic instrument notes [17], showing that generating IFs and magnitudes instead of waveforms is advantageous for highly harmonic sounds. DrumGAN synthesizes drum sounds using the real and imaginary components of a complex STFT spectrogram and demonstrates the effectiveness of this audio representation, first introduced in [18]. Finally, MP3Net achieves minute-long coherent piano music generation using Modified Discrete Cosine Transform (MDCT) spectrograms as audio representations and Progressive GAN [19] as the model: however, the generated samples suffer from low perceived audio quality. To the best of our knowledge, UNAGAN [20] is the only non-autoregressive GAN-based system capable of generating audio of arbitrary length. The model takes a sequence of noise vectors as input and uses a hierarchical structure to achieve short-term coherence in the generated mel-spectrograms, which are then inverted to waveform using a pretrained MelGAN vocoder [9]. However, the model only generates single-channel audio and the independent sampling of noise vectors cause the generated samples to lack coherence through time.

Contrary to autoregressive models, the majority of GAN-based unconditional audio generation models are only able to synthesize audio samples of a fixed length. However, in the field of computer vision, several recent works propose models capable of generating images of arbitrary size, by synthesizing single image patches in parallel and assembling them into the final image. This process results in a fast and efficient generation of images on modern hardware. The two most notable contributions to this line of work are InfinityGAN [21] and ALIS [22]. InfinityGAN generates in parallel single patches that are coherent with each other by disentangling global appearance, local structures and textures, which are then fed into a generator, together with coordinate information, to synthesize the final patch. ALIS proposes the use of latent vectors as anchor points for the coordinate system of the model: the resulting generator is equivariant and can thus produce coherent patches from interpolations of different latent codes. However, both of the methods rely on prior knowledge regarding the particular image domain that is being generated: the experiments are conducted on a dataset of images of landscapes, where the image features of a single patch are spatially invariant on the horizontal dimension and thus permit infinite length generation along the horizontal axis.

The process of generating sequences of encoded representations has been explored in different previous works [4, 5, 23] for both image and audio data. However, these works focus on encoding samples to a discrete set of codes using vector-quantized variational autoencoders, and propose to model sequences of codes using autoregressive models. On the other hand, [24] proposes to autoencode molecules with a basic autoencoder, to then generate sequences of continuous-valued latent vectors with a GAN. This approach manages to circumvent the problematic behaviour of GANs when applied on discrete data [25], in this case molecules in the SMILES format. Similarly to this work, we propose to generate latent representations of audio with the aim of making the generation and training process faster, and achieving coherent generated samples over long time windows.

3. METHOD

Let $\mathbf{x} = \{x_1, ..., x_T\}$ be the waveform of an audio sample. We aim to encode a waveform $\mathbf{x}$ into a sequence of latent vectors $\mathbf{c} = \{c_1, ..., c_{T/r_{time}}\}$ with time compression ratio r_{time}, sampled at a lower sampling rate than the original waveform. We use an autoencoder model to perform this task, such that a reconstruction of the original waveform can be obtained from the encoded latent vectors.

We then aim to model the distribution $p(\mathbf{c})$ with a Generative Adversarial Network (GAN). We employ a latent coordinate system that is used as conditioning for the generator G to generate sequences of latent vectors of arbitrary length. We additionally condition the generator with a variety of conditioning signals, such that the generation process can be guided by human input. Finally, the generated sequence of latent vectors is inverted to a waveform with the previously trained decoder.

3.1 Audio Autoencoder

Considering the inherent high dimensionality of waveforms, generating long sequences of raw audio samples is prohibitively expensive. A frequently used audio representation in the field of speech processing and music informa-

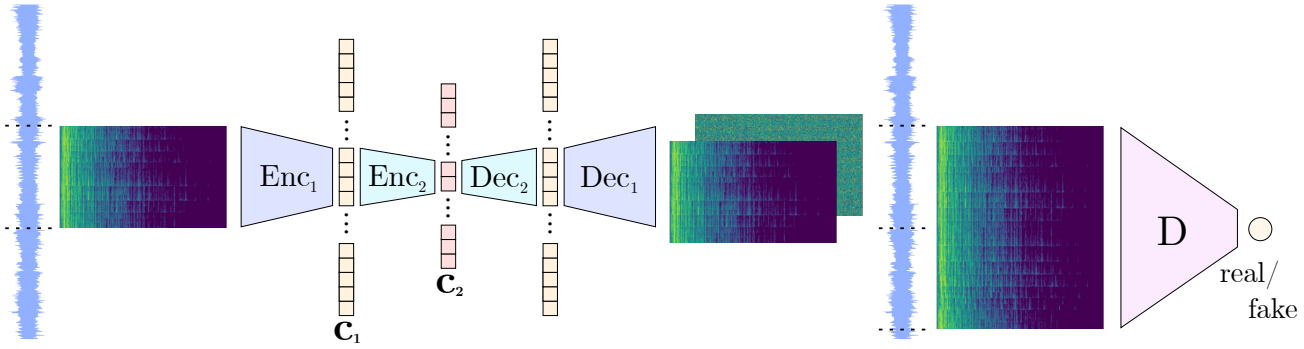

Figure 1. The proposed 2-level audio autoencoder. A log-magnitude spectrogram is used as the encoder input, while the decoder outputs magnitude and phase spectrograms which are then inverted with iSTFT to the waveform domain. A discriminator evaluates the magnitude spectrogram of two adjacent excerpts passed through the autoencoder. This training process removes both phase errors (which would manifest after the iSTFT and STFT) and boundary artifacts.

tion retrieval is the Short-Time Fourier Transform (STFT) spectrogram: while the phase component of the spectrogram is usually discarded, in case of audio synthesis applications both magnitude and phase components are necessary to perform the inverse STFT (iSTFT) and obtain a waveform.

We design an audio autoencoder with the aim of minimizing inference and training time while maximizing the compression ratio allowing to reconstruct samples with reasonable accuracy. Our proposed autoencoder takes a log-magnitude STFT spectrogram as input, and outputs magnitude and phase spectrograms which can be inverted to a waveform. Parallel to our work, iSTFTNet [26] also proposes to improve the inference speed of the model by generating magnitude and phase of a STFT spectrogram: however, they only report experiments using spectrograms with very high temporal resolution and low frequency resolution, while our proposed autoencoder reconstructs spectrograms with low temporal resolution and high frequency resolution. This should result in an even higher inference speed for similarly-sized models. In practice, we separately train two stacked autoencoders; this allows a higher compression ratio with satisfactory reconstruction quality, especially for more complex music domains. Similarly to RAVE [7], we utilize a two-step training process:

3.1.1 First training phase

We first train the model to autoencode log-magnitude spectrograms, not producing phases for now. We use a L1 loss function for the reconstruction task:

$$\mathcal{L}_{(Enc,Dec),rec} = \mathbb{E}_{s\sim p(s)}||Dec(Enc(s)) - s||_1$$

where Enc and Dec are the encoder and decoder, and s is a log-magnitude spectrogram of a waveform w.

3.1.2 Second training phase

In the second phase, we freeze the encoder weights and have the decoder produce a phase spectrogram as well, such that we can reconstruct a waveform through an iSTFT. We add an adversarial objective to aid the modeling of both the magnitudes and phases, ensuring the waveform is of perceptually satisfactory quality. Since directly modeling phase spectrograms with deep learning models is known to be difficult [13, 18], we propose to model the phases indirectly, by encouraging waveforms whose magnitude spectrogram must appear realistic. Specifically, we compute a log-magnitude spectrogram $\tilde{s}$ from the reconstructed waveform $\tilde{w}$:

$$\tilde{w} = iSTFT(Dec(Enc(s)))$$
$$\tilde{s} = \log(|STFT(\tilde{w})|^2 + \epsilon)$$

The reconstructions $\tilde{s}$ are fed to a discriminator D, using the hinge loss [27] to distinguish them from originals s:

$$\mathcal{L}_D = -\mathbb{E}_{s\sim p(s)}[min(0, -1 + D(s))] - \mathbb{E}_{s\sim p(s)}[min(0, -1 - D(\tilde{s}))]$$

The decoder is trained to fool the discriminator:

$$\mathcal{L}_{Dec,adv} = -\mathbb{E}_{s\sim p(s)}D(\tilde{s})$$

Note that we can calculate spectrograms from the reconstructed waveforms with different hop size and window length than used for the spectrograms fed to the autoencoder. We leverage this by including the multi-scale spectral distance [7, 28] in the objective of the decoder:

$$\mathcal{L}_{Dec,ms} = \mathbb{E}_{w\sim p(w)} \sum_{hop}^{N} \log(||\,|STFT_{hop}(w)| - |STFT_{hop}(\tilde{w})|\,||_1)$$

where hop indicates a choice of hop_size and fft_size.

In total, we train the discriminator with $\mathcal{L}_D$, and the decoder with a linear combination of three losses:

$$\mathcal{L}_{Dec} = \mathcal{L}_{Dec,adv} + \lambda_{rec}\mathcal{L}_{Dec,rec} + \lambda_{ms}\mathcal{L}_{Dec,ms}$$

3.2 Latent Coordinate System

We use a GAN to model sequences of latent vectors produced by a trained audio encoder. In order to generate independent audio samples that can be seamlessly concatenated with each other along the temporal axis, we condition the generator with the latent coordinate system proposed by [22], originally introduced to generate landscape

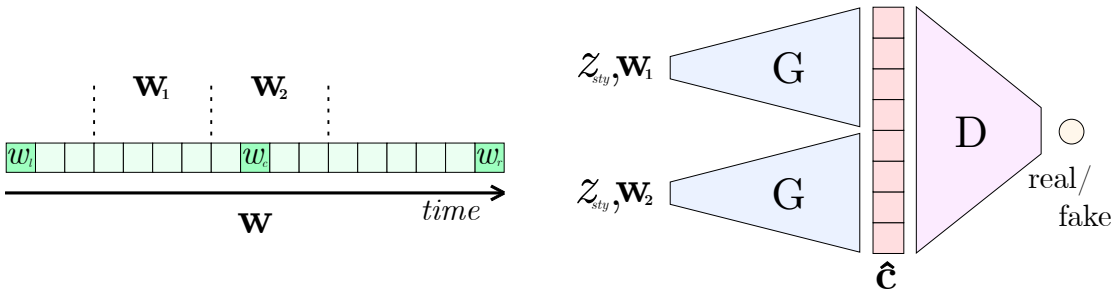

Figure 2. The proposed latent GAN training process. Two adjacent latent coordinate sequences are randomly cropped from the linear interpolation between three anchor vectors. They are then used as input to the generator, together with a shared style vector and a conditioning signal in the case of a conditional model. The discriminator takes as input the two concatenated generated sequences and a real sequence of latent vectors.

images of infinite width. Specifically, during training we sample three noise vectors w_l, w_c, w_r with dimension d that are used as anchor points (left, center, right anchors) to guide the generation process. With seq_len being the length of the sequence of latent vectors that is produced by the generator, we linearly interpolate the three anchor vectors to create a sequence of coordinate vectors of length equal to $4 \cdot seq\_len + 1$:

$$\mathbf{w} = [w_l, ..., (1-k)w_l + kw_c, ..., w_c, ..., w_r] \in \mathbb{R}^{4seq\_len+1 \times d}$$

To generate sequences that are temporally coherent with each other, we follow [22]: we randomly crop a sequence $\mathbf{w_{12}}$ of $2 \cdot seq\_len$ coordinate vectors from $\mathbf{w}$, divide it into two sequences $\mathbf{w_1}, \mathbf{w_2}$ with length seq_len, generate two patches using each sequence as conditioning, concatenate the two patches along the time axis, and feed the resulting generated sample of length $2 \cdot seq\_len$ to the discriminator. This process is illustrated in Figure 2. It allows the generator to align the sequence of latent coordinates with the generated sequence of latent vectors. Specifically, the discriminator forces the generator to learn that adjacent sequences of latent coordinates must result in adjacent sequences of latent vectors, which can be temporally concatenated resulting in a coherent final sample without artifacts at the boundaries of the generated patches.

Similarly to InfinityGAN [21], when generating adjacent sequences of latent vectors, we also condition both generations on a single random vector z_{sty}: during the learning process, this vector serves as conditioning for the global style of the generated samples. Specifically, while the latent coordinate vectors allow the generator to produce sequences of latent vectors that can be seamlessly concatenated along the temporal axis, the global style vector allows the final concatenated sequence of possibly infinite length to be stylistically coherent throughout. Without the global style vector, any temporal context available to the generator would completely change every $4 \cdot seq\_len$ samples of a sequence, resulting in a final generated sample which continuously changes style through time.

Formalized, we have

$$\hat{\mathbf{c}} = concat[G(\mathbf{w_1}, z_{sty}), G(\mathbf{w_2}, z_{sty})],$$

where $\hat{\mathbf{c}}$ is a stylistically and temporally coherent sequence of latent vectors of length $2 \cdot seq\_len$, and G is the generator model.

At inference time, a latent coordinate sequence of the desired length is created. The coordinate sequence is prepared in the same way as during the training phase, by placing a latent anchor vector at positions that are multiples of $2 \cdot seq\_len$, and by linearly interpolating these anchor vectors to calculate in-between vectors. A single random global style vector is also sampled. Each generation considers a seq_len crop and the global style vector as conditioning, and finally all generated latent vectors are concatenated together in the appropriate order. This process can be performed in a parallel manner, thus resulting in a fast generation on modern hardware.

4. IMPLEMENTATION DETAILS

4.1 Audio Autoencoder Architecture

We first train an audio autoencoder with a relatively low compression ratio, then train a second-level autoencoder that encodes the first-level latent vectors, as shown in Figure 1. During the training of the second-level autoencoder, we utilize the same training strategy and objective as explained in section 3.1, by propagating gradients through the frozen weights of the previously trained first-level decoder and adversarially discriminating between samples reconstructed by both decoders and samples reconstructed by only the first-level decoder. Both model architectures are fully convolutional, and we do not use any padding in both encoders, such that possible boundary artifacts in the encoded representations are avoided. We utilize 1d-convolutions considering the frequency bins as different channels for both encoders and decoders: this is usually not efficient regarding total number of model parameters when compared to using 2d-convolutions across the two spectrogram dimensions, but can result in a much faster inference time. We use 2d-convolutions for the discriminator, as inference time for this model is not a priority. We use $tanh$ as the activation for the bottleneck layer of both encoders. Regarding the multi-scale spectral distance loss, we use $hop\_size \in [64, 128, 256, 512]$ and we always choose $fft\_size = 4 \cdot hop\_size$, while the discriminator takes as input log-magnitude spectrograms calculated with

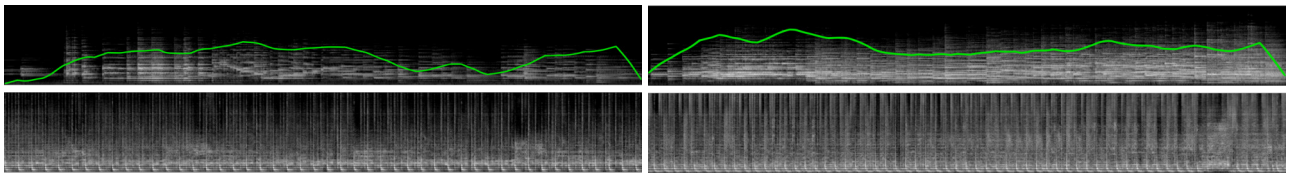

Figure 3. Log-melspectrograms of generated piano and techno samples from the conditional models. For the piano samples (top row), we indicate the corresponding note density conditioning with a green line. Note density signals were generated using a random walk algorithm. The tempo used as conditioning for the techno samples (bottom row) is 120 bpm and 160 bpm, respectively. Each sample is 23 seconds long. Visit marcoppasini.github.io/musika to listen to the examples.

$hop\_size = 256$ and $fft\_size = 6 \cdot hop\_size$. As proposed by [29, 30], two consecutive reconstructed spectrograms are concatenated along the temporal dimension and fed to the discriminator, such that concatenated reconstructions do not suffer from boundary artifacts. During training, spectrograms calculated from 0.76 s of audio are used as input to both autoencoders. We use spectral normalization [31] on the weights of the discriminator. Regarding the training loss weights, we use $\lambda_{rec} = 1$ and $\lambda_{ms} = 4$. We choose Adam [32] as the optimizer with learning rate of 0.0001 and $\beta_1 = 0.5$, and train the first-level autoencoder for 1 million iterations with batch size of 32 for both training phases, and the second-level autoencoder for 400k iterations with batch size of 32 for both training phases.

4.2 Latent GAN Architecture

We choose to adapt the FastGAN [33] architecture to our specific task. The FastGAN architecture promises fast convergence with limited amounts of data. To achieve this, it proposes a Skip-Layer channel-wise Excitation (SLE) module in the generator, for more direct propagation of gradients, and proposes to strongly regularize the discriminator with an added self-supervised reconstruction objective. We adapt the proposed architectures to use 1d-convolutions instead of 2d-convolutions and we simplify the added reconstruction objective of the discriminator, by using a single lightweight decoder which reconstructs the whole input of the discriminator. Differently from FastGAN, we do not use Batch Normalization [34] in both the generator and discriminator, while we apply the variation of Adaptive Instance Normalization [35] (AdaIN) called Spatially Aligned AdaIN (SA-AdaIN), originally proposed in [22], after each convolutional layer in the generator. To generate stereo samples, the generator produces two latent vectors at each timestep, one for each audio channel, stacked on the channel axis. We use Cross Channel Mixing (CCM), first introduced in [36], to randomly mix channels of the stereo stacked latent vectors before being fed to the discriminator. In our experience, this technique helps reducing collapses during training. Both anchor and style vectors are sampled from a normal distribution with zero mean and unit variance, and have dimension d of 64. We use R1 gradient penalty [37] as regularization, and Adam with learning rate of 0.0001 and $\beta_1 = 0.5$ as the optimizer. We train for 1.5 mio iterations with a batch size of 32 for all experiments. Training takes 23 h on a RTX 2080 Ti GPU.

Model (Faster than real-time)	**GPU**	**CPU**
Musika Uncond. Piano	972x	**40x**
Musika Cond. Piano	921x	**40x**
UNAGAN [20] Piano	28x	11x
Musika Uncond. Techno	**994x**	39x
Musika Cond. Techno	917x	39x

Table 1. Comparison of generation speed between the different models. For the Musika models, we include both the generation of the latent vectors and the decoding step to the waveform domain. We use a RTX 2080 Ti and a Ryzen 3950x as the GPU and CPU, respectively. We report the average of 100 trials.

Model	**FAD**
Musika Uncond. Piano	**1.641**
Musika Cond. Piano Rand.	2.150
Musika Cond. Piano Const. 0.15	2.584
Musika Cond. Piano Const. 0.30	3.400
Musika Cond. Piano Const. 0.45	4.389
Musika Cond. Piano Const. 0.60	4.839
Musika Cond. Piano Const. 0.75	5.434
UNAGAN [20] Piano	11.183

Table 2. FAD evaluation for generated piano music. We evaluate conditional Musika models using different constant values of note density as conditioning. We notice that FAD increases with higher note density.

5. EXPERIMENTS

Considering the relatively low compression ratio of the first autoencoder and thus its need to only encode low-level audio features, we find it possible to train a single universal model which we can later use for different music domains. As training data, we choose to use songs released and made freely available by South by SouthWest [1] (SXSW) in occasion of their yearly conference. The current collection consists of 17k songs of various genres, and for this reason it represents a fitting choice for training our universal model. We use the LibriTTS corpus [38] as additional training data, to steer the universal model into accurately synthesizing human voices, which are notoriously hard to model. Even though LibriTTS only contains speech, in-

[1] https://www.sxsw.com/festivals/music/

cluding it improves reconstructions of singing voice. We resample audio to 22.05 kHz for all experiments. We use single channel audio to train the audio autoencoders, as the latent GAN is able to generate stereo samples by using latent representations of the two mono samples stacked in the channel dimension as training data. We use $r^1_{time} = 256$ as the time compression ratio, which results in a sampling rate of the first-level latent representations of 190.22 Hz. Each of the encoded latent vectors has a dimension of 128.

5.1 Piano Music

We use the MAESTRO dataset [39], consisting of 200 hours of piano performances, to train a second-level autoencoder and a latent GAN. The final time compression ratio achieved by both autoencoders is $r_{time} = 4096$, which results in a sampling rate of the second-level latent representations of 11.89 Hz. The dimension of each latent vector is 32. We train both an unconditional and a conditional latent GAN. For both models, the generator outputs latent vectors with $seq\_len = 64$, which results in about 12 s of audio after decoding. For the conditional model, we apply the CNN-based onset detector [40] of the madmom Python library [41] to all audio files in the dataset. We then use Gaussian Kernel Density Estimation (KDE) with bandwidth of 0.004 on the detected onsets to estimate a continuous note density signal for each sample. This signal is log-scaled between 0 and 1 and serves as a conditioning signal for the conditional (and thus controllable) GAN.

5.2 Techno Music

To evaluate the performance of the system on a more musically varied domain, we scrape 10,190 songs categorized with the "techno" genre from *jamendo.com* and use them as training data. Considering the wide diversity of sounds that are present in the dataset, we train the second-level autoencoder with the same SXSW data used to train the first-level universal autoencoder. Comparing to what is achievable when training an autoencoder on a single and limited domain, such as piano music, a lower compression ratio is needed to reach a satisfactory reconstruction accuracy. However, this solution allows users to directly train a latent GAN on a new audio domain using the universal latent representations, without the need to train an autoencoder on the domain of interest. The final achieved time compression ratio is $r_{time} = 2048$, which results in a sampling rate of the second-level latent representations of 23.78 Hz. The dimension of each latent vector is 64. We train an unconditional and a conditional latent GAN model, both generating stereo latent vectors with $seq\_len = 128$, resulting in about 12 s of decoded audio. We use the Tempo-CNN framework [2] [42] to estimate the global tempo of each song in the dataset. Tempo information is then used as conditioning for the conditional model.

6. RESULTS

A comprehensive collection of generated audio samples is available on marcoppasini.github.io/musika. Since current quantitative evaluation metrics are not able to assess the overall compositional and musical quality of generated music, we strongly encourage the reader to listen to the provided samples while reading the paper.

We report the generation speed of the system trained on the MAESTRO and on the techno datasets in Table 1, on both GPU and CPU. We also use the Frechét Audio Distance [43] (FAD) metric to quantitatively evaluate the quality of the generated piano samples in Table 2. A UNAGAN [20] model that was trained on the same dataset is used as comparison. While our system is capable of generating stereo audio, UNAGAN can only produce single-channel audio. The unconditional model obtains the lowest FAD, while the conditional system results in higher FADs when using more intense note density values as conditioning. This is expected, since samples with low note density are more common than samples with high note density in the MAESTRO dataset. However, considering that audio is split in short 1 s samples to calculate embeddings, FAD is not designed to evaluate overall musical and compositional quality of samples, and to the best of our knowledge there are no available quantitative metrics to evaluate these characteristics. Piano and techno samples generated by the system seem to often demonstrate long-range coherence and successfully keep a fixed general music style through time. Both conditional models successfully generate samples that are coherent with the conditioning signal, as can be seen in Figure 3.

7. CONCLUSION

We proposed Musika, a non-autoregressive music generation system that generates raw-audio samples of arbitrary length much faster than real-time on a consumer CPU. An efficient hierarchical autoencoder allows to encode audio to a sequence of low-dimensional latent vectors, from which a waveform can be reconstructed. A GAN is then used to generate new sequences of latent vectors, using a latent coordinate system that allows for generation of samples of infinite length. A style conditioning vector is introduced to force the samples to be stylistically coherent through time. We successfully use the system to generate piano and techno music, and show that the generation process can be conditioned on note density and tempo information for piano and techno music, respectively. We finally show that the system achieves lower FAD than comparable systems on piano music generation while being faster. We release the source code and pretrained models, enabling users to generate samples of different music domains and test new conditioning signals with ease and using consumer hardware. We see our system as solving an important technical challenge – real-time music generation of sufficient quality, conditioned on user input – and hope it can serve as a basis for interactive real-world applications and for research into human-AI co-creation.

ABSTRACT

In this work, we propose a permutation invariant language model, SymphonyNet, as a solution for symbolic symphony music generation. We propose a novel Multi-track Multi-instrument Repeatable (MMR) representation for symphonic music and model the music sequence using a Transformer-based auto-regressive language model with specific 3-D positional embedding. To overcome length overflow when modeling extra-long symphony tokens, we also propose a modified Byte Pair Encoding algorithm (Music BPE) for music tokens and introduce a novel linear transformer decoder architecture as a backbone. Meanwhile, we train the decoder to learn automatic orchestration as a joint task by masking instrument information from the input. We also introduce a large-scale symbolic symphony dataset for the advance of symphony generation research. Empirical results show that the proposed approach can generate coherent, novel, complex and harmonious symphony as a pioneer solution for multi-track multi-instrument symbolic music generation.

1. INTRODUCTION

Symphony is one of the most complex and brilliant musical composition forms in human history, where many instruments are intertwined to express rich human emotions. The past decade has seen the rapid development and tremendous success of the symbolic music generation in both research and industrial field [1–3]. Most current works follow conventional text modeling and generation method by applying language model to sequences of symbolic musical events [4–6]. However, symphony modeling and generation still constitutes in itself a considerable challenge since symphony music sequences differ from text sequences in various aspects.

Natural language could be modeled as a purely linear sequence constructed strictly by a sequential order of words. Symphony scores, on the other hand, are usually viewed as two-dimensional symbolic sequences in which many notes can be played concurrently. Notes in a symphony score are **semi-permutation invariant**. More specifically, as shown in Fig. 1, the blue box indicates the musical instrument tracks, and the corresponding staves on the right side are permutation invariant. Similarly, the notes inside the red box are also permutation invariant. In contrast, notes in the upper yellow box are permutation variant since each note is played sequentially. Changes in the order of notes will impair the music itself. The yellow box at the bottom is a more complicated situation: a permutation variant note sequence in general containing permutation invariant notes. Simply flattening the score into a 1-D text-like sequence may damage the local structure of music [7]. To address this problem, we propose the Multi-track Multi-instrument Repeatable (MMR) representation with particular 3-D positional embedding in Section 3 which fully considers the properties of semi-permutation invariance in symbolic music scores.

Moreover, when comparing music scores with text, conventionally notes could be considered as characters, while intervals or chords are comparable to words. Modeling musical events at note level is a common practice [5,6,8,9]. However, this may be confronted with similar problems in char-level text generation, such as extremely long sequences and less meaningful individual tokens. Word-level tokenization suffers from large vocabulary size and out of vocabulary (OOV) problems. Byte Pair Encoding (BPE) [10, 11] subword tokenization is a tradeoff between word-level and character-level tokenization. Inspired by BPE, we propose the Music BPE algorithm in Section 4, which could automatically aggregate notes to intervals and chords as subwords without a pre-defined vocabulary and construct music sequences with richer semantics.

Generating symphony music with proper instruments for different tracks is another challenging task. Recent

Figure 1: A simple example of Multi Instruments & Multi Tracks & Repeat Instruments symphony score.

work like Arranger [12] focuses on instrumentation by learning to separate parts from the mixture in symbolic multi-track music. However, it does not incorporate music generation task. In this paper, we present a unique linear transformer decoder architecture for instrument classification with joint-task training, which allows the model to learn auto-orchestration rather than relying on instrument information as an pre-defined input source. [5, 13–15].

The contributions of this paper are presented as below:

- We propose a novel Multi-track Multi-instrument Repeatable (MMR) representation for symphony music, including particular 3-D positional embedding designed to address the semi-permutation invariant challenge in symphony generation. Our method is also compatible with all existing symbolic music ensembles, including but not limited to piano solo, quartet and pop band music.
- We propose a novel algorithm, Music BPE, to model the symbolic music at subword-level. Furthermore, we found that our Music BPE algorithm could aggregate notes to intervals and chords, which are consistent with common chords summarized by human musicians.
- We introduce SymphonyNet, a novel music generation model with joint-task training for instrument classification based on our proposed MMR representation and Music BPE. The model can learn the proper orchestration according to the distribution of the notes.
- We collect a symphony MIDI dataset, consisting of $46,359$ high-quality MIDI files with multiple instruments and tracks to advance researches on symphony generation with deep learning.

2. RELATED WORK

We organize some existing works in Table 1 in terms of five aspects of symbolic music modeling: time unit, representation method, backbone model, music type and the ability to model music with repeat instruments. Generation works are presented above and understanding works are presented below. Pianoroll, MIDI event timeshift, and Beat-based onset and duration are the mainstream time units in music generation and understanding tasks. However, Pianoroll divides music into fixed-length grids, and MIDI format provides overprecise timeshift events, both suffering from sparsity problems, which raises another handicap for applying deep learning models in this multi-track generation. Pop Music Transformer [8] is the first attempt to introduced the beat-based REMI representation in music generation. It supports variable-length duration of notes, which is more musically inspired. Compound Word [6], derived from REMI representation, classifies the sequence of REMI into note-related or metric-related events, which are then aggregated, greatly decreasing the sequence length.. This has engendered a new trend of beat-based symbolic music generation.

Language models are now prevalent in natural language processing tasks [18]. However, applying language models to the creation of multi-track music remains challenging. MuMIDI [5] and OctupleMIDI [9] models multiple attributes of one note in one sequence step and also incorporates instrument tokens for multi-track representation. However, if one musical piece contains more than one track for the same instrument, their representation could not distinguish them in different tracks. MMM [15] introduced a MIDI-event-like representation, creating a time-ordered sequence of musical events for each track and concatenating several tracks into a single sequence. However, MMM adopts time-delta tokens and fixed positional encoding which weakens the note-level correlation and structure between tracks. MuseBert [7] proposes a permutation invariant bert-like language model with generalized relative position encoding (RPE) which, however, is not compatible with multi-track music generation.

Though various symbolic music representation strategies have been proposed, few are compatible with multi-track music with repeatable instruments or tracks, such as the symphony. Furthermore, permutation invariance of music, as is discussed in Section 1, has scarcely been considered. To our knowledge, this work proposes the first representation and tokenization method to encode music with multiple repeatable instruments and multiple repeatable tracks and designs a universal and effective strategy for generating symphony music with permutation invariant language model.

3. MULTI-TRACK MULTI-INSTRUMENT REPEATABLE REPRESENTATION

To further analyze the symphony generation task, it is crucial to understand the difference between the symphony format and other genres of music.

- **Single Instrument in Single Track**. No more than one note is played at any timestep by one instrument. Also called monophonic music. e.g., flute.
- **Multi Instruments & Each in Single Track**. Only one

Name	Time Unit	Representation	Backbone Model	Type of Music	Instruments
DeepBach [1]	Fixed-length grid	N/A	Bi-directional RNN	Chorales	Fixed Ensemble

Table 1: An overview of time unit, representation, backbone model and music type in existing works, above for generation works and below for understanding works.

note for each instrument is played at any timestep. e.g., quartet singing.

- **Single Instrument in Multi Tracks**. There are multiple notes played in each timestep while only one instrument. e.g., piano.
- **Multi Instruments & Multi Tracks & No Repeat Instrument**. There are multiple notes played in each timestep. No constraint on the number of instruments and all instruments are unique. e.g., classical pop band with only drum, electric guitar and bass.
- **Multi Instruments & Multi Tracks & Repeat Instruments**. Instruments are not unique and multiple same instruments can play different notes on different tracks, e.g., symphony.

For the last case, it's a common practice to merge the same instruments into a single track in previous works. However, it may damage the intrinsic structure of symphony music. For example, this may cause a violin to play polyphonic notes, or even intermingle multiple melody lines. Our proposed Multi-track Multi-instrument Repeatable (MMR) representation models repeated instruments separately, which could capture more heuristic musical information within a single track. Since our MMR representation is aimed at symphony modeling, it is also compatible with all existing music ensembles.

3.1 Structural and Controlling Token

We consider that special tokens perform two primary functions in a symphony music generation task: 1) To represent the musical structures of notes. 2) To control the model output during the inference phase.

Score We use a pair of $[BOS]$ and $[EOS]$ tokens to designate the beginning and end of a symphony score.

Measure Different from [5, 8], we ascribe a pair of $[BOM_i]$ and $[EOM]$ to indicate the beginning and end of a measure, the character i to represent the total length of the current measure. The length of a measure is calculated by time signature, and we choose 32$^{\text{th}}$ note as the smallest unit of time. For example, a 4/4 time signature indicates four quarter notes length per measure, which is equal to the length of thirty-two 32$^{\text{th}}$ notes. In that case, character i equals 32, and the measure beginning token is $[BOM_{32}]$

Chord The chord token is a valuable indicator of how generally notes are arranged in the current measure. We pre-define 132 common types of chord token and pre-compute chord tokens with a rule-based algorithm proposed in [6], such as C major seventh chord marked as token $[C_{maj7}]$.

Track Unlike any previous works, we do not explicitly encode the track and instrument transformation in a single token. A change track token $[CC]$ only signifies the start of a new track for the latter controlling purpose. Section 5 will further explore the traits of tracks and instruments and the approaches of differentiating tracks.

Position A position token stands for the *onset* of a note within the measure, represented by the token $[POS_j]$. The following event tokens are controlled by the current position token until another position token shows up. The character j means the number of the current unit of time position. For example, a $[POS_{48}]$ indicates the 48$^{\text{th}}$ unit time position.

To summarize, structural and controlling tokens are designed to specify the general time-spatial features of notes, such as the time a note is to be played and the track it locates. In this work, these tokens are mandated with a sequential order, as a *measure* token shall be followed by a *chord* token, which altogether represents in a explicit way the measure order as shown in Fig. 3.

3.2 Note-Related Tokens

A note in music scores could be defined in five attributes: pitch, duration, onset, track and instrument. Pitch and duration are content-related and the others are position-related. The latter will be discussed in Section 5. To avoid the long-tail problem, we regard pitch and duration to be distinct note properties and construct two separate vocabularies for model input. Then we aggregate note pitches with identical duration and onset by our proposed Music

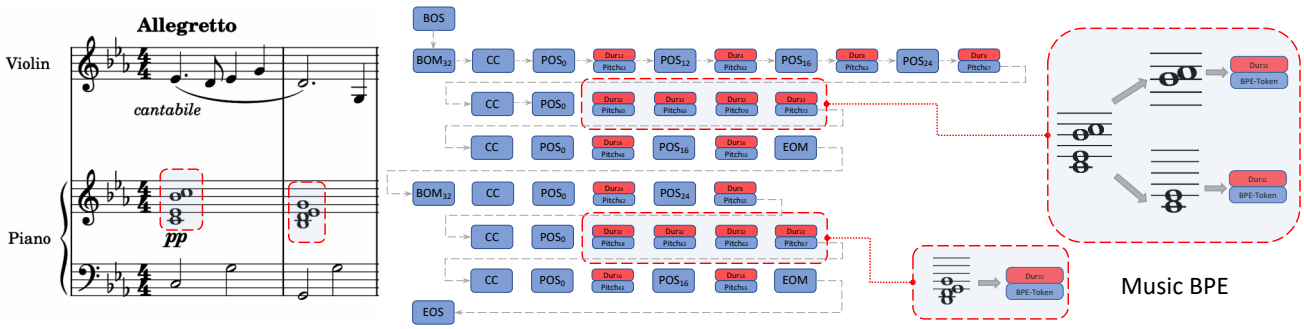

Figure 2: An example of MMR representation and illustration of Music BPE process

BPE algorithm, as will be described in the next section.

4. MUSIC BYTE PAIR ENCODING

As shown in Fig. 2, a complex chord is constructed by several notes at the same position in a measure, which can be deconstructed into two common and simple intervals. Unlike natural language, notes played at the same position are permutation invariant. Changing the order of notes in a chord does not affect its sound or meaning. For instance, a Chord C consists of ($C4$, $E4$, $G4$), which is equal to ($G4$, $C4$, $E4$). This intrinsic property may conflict with the typical natural language processing job, imposing a new constraint on the use of conventional tokenization methods such as standard BPE.

In this work, we propose a novel encoding approach, Music Byte Pair Encoding (Music BPE), for multi-track symbolic music sequence tokenization and preprocessing to exploit the semantics of music events and minimise the length of the input context from a representation standpoint. Different from the original BPE algorithm, our proposed Music BPE is based on **concurrence** of notes rather than **adjacency** of characters.

Our implementation of Music BPE is shown in Algorithm 1. As is mentioned in Section 1, a note has five attributes: *pi*tch, *du*ration, *po*sition, *tr*ack and instrument, while the instrument depends utterly on track within the same measure. Formally, in a piece of symbolic music, we define a maximum set of two or more notes

$$\{(pi, du, po, tr) \mid \text{where } du, po, tr \text{ is constant}\}$$

as a *mulpi* (multiple pitches), i.e., a maximum set of notes that have the same duration at the same global position and within the same track, equivalent to a "word" in the BPE algorithm.

We collect notes with the same global position and the same duration in the same track from each music piece to construct a bag of *mulpies*. The vocabulary list is initialized with 128 MIDI pitches, where each token represents a pitch-set containing a single pitch. Every time we locate all concurrent pairs of tokens in the bag of *mulpies*, merge the most frequent pair ('P_1', 'P_2') into a new symbol P and replace the pair with the new symbol in each *mulpi* until the vocabulary size reaches the maximum limit. A further discussion on the results of the Music BPE algorithm and its effectiveness on our symphony dataset will be presented in Section 5.

Algorithm 1 Music BPE

Input: A multi-set of *mulpies* B
Parameter: desired dictionary size n
Output: Merged dictionary V

Let $V = \{\{p\} \mid p \in [0, 128)\}$.
Let C be an empty multi-set
for all $mulpi \in B$ **do**
  $mulpi \leftarrow \{\{p\} \mid p \in mulpi\}$
  for all $\{P_1, P_2\} \subseteq mulpi$ **do**
    Insert (P_1, P_2) into C.
  end for
end for
while $|V| < n$ **do**
  Let (P_1, P_2) be the most frequent pair in C.
  $V \leftarrow V \cup \{P_1 \cup P_2\}$
  for all $mulpi \in B$ **do**
    if $\{P_1, P_2\} \subseteq mulpi$ **then**
      for all $Q \in mulpi - \{P_1, P_2\}$ **do**
        Delete $(Q, P_1), (Q, P_2)$ from C.
        Insert $(Q, P_1 \cup P_2)$ into C.
      end for
      $mulpi \leftarrow (mulpi - \{P_1, P_2\}) \cup \{P_1 \cup P_2\}$
    end if
  end for
end while
return V

5. SYMPHONYNET DETAILS

5.1 The 3-D Positional Embedding

Transformer [19] is the most used backbone for language model, which is designed *permutation invariant*: if the positional encoding is not added, disrupting the order of the inputs will yield the same output, for transformer model treats inputs as a *set* during self-attention. Therefore, considering this property of Transformer, we design a particular 3-D positional embedding to represent such a semi-permutation invariant feature as shown in Fig. 3. Event tokens follow a semi-permutation variant order on both the measure order and the note order axes. For example, notes played on the same position share the same note positional

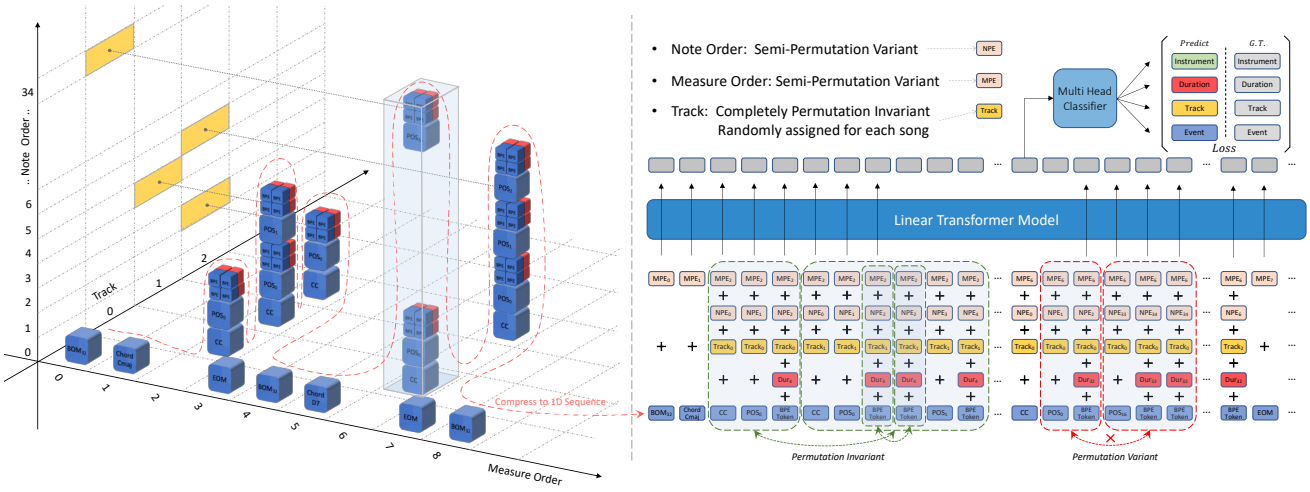

Figure 3: A illustration of the spatial and structural attributes of MMR sequence (left) and the way it is compressed and organized as model input (right).

embedding. In contrast, the track axis is entirely permutation invariant since we only need track embeddings to differentiate tracks other than a sequential order. We use the red curves to illustrate the musical moving trajectory of event tokens to better understand how we compress the spatial and structural sequence of the event tokens into one dimension and send them to the model. At last, we add all constructed embeddings vertically as the model input. To address the extraordinarily long symbolic music sequences challenge, we employ the linear transformer [20] as the backbone of our model to satisfy the length constraint. The model follows a decoder-only fashion, and we design different feed-forward heads for four attributes of musical events, which are **Instrument, Track, Duration, and Event** tokens as shown in Fig. 3.

5.2 Joint Task with Instrument Classification

We mask instrument information for every input token at the input side, and anticipate that the model will learn instrumentation from the output side with instrument loss. This will turn a succession of simple, blank notes into a fully orchestrated piece of music, analogous to colouring a black-and-white painting. This design is motivated by two primary concerns. First, we investigate the possibility if other instrument may play a certain instrument's note track. Therefore, that is a case for the model to determine to what degree the instrument fits the track's notes and how instruments interact with one another across tracks. For instance, it is allowed to substitute the piano for the marimba in some musical compositions. The intrinsic nature of a pre-assigned instrument for notes reduces the diversity of training data.

6. EXPERIMENTS AND RESULTS

This section introduces the novel symphony dataset we propose and presents two stages in the training process [1] . Secondly, we describe controllable methods to generate music under certain condition before we provide findings from Music BPE and compare them with the specific musical knowledge. Lastly, a human evaluation result analysis and scoring on several excerpts generated by different models will be presented.

6.1 Symphony Dataset

To tackle the obstacles of the symphony generation research, we gather a big corpus of symphonic music from multiple online sites and conduct a extensive data cleaning. The average duration of the 46,359 MIDI files containing multiple instruments and tracks, mostly symphony, is 4.26 minutes. The collection contains more than 279 million notes and 567 million tokens in MMR forms. Our symphony dataset is, to the best of our knowledge, the first worldwide large-scale symbolic symphonic music dataset, which might serve as a foundation for future work in multi-track music production.

6.2 Training Details

In our experiment, the model adopts 4096 as the length of input sequence. We set the embedding size for event tokens, durations, instruments and 3-D positional embedding to 512. The final size of event token vocabulary is assigned to 1000 after running Music BPE algorithm and the vocabulary size of durations, instruments, 3-D positional embeddings are derived from the dataset. The linear transformer decoder contains 12 self-attention layers and each layer consists of 16 attention heads. SymphonyNet is trained with eight 2080 Ti GPU and we use a batch size of 128 and an AdamW [21] optimizer with a learning rate of 3×10^{-4}.

6.3 Music BPE Result

After constructing a vocabulary list of length $1,000$ with Music BPE algorithm, the top-5 merged pairs shown in Fig. 4 with the highest frequency are: ($D4$, $F4$), ($C4$, $E4$),

[1] Our code, demos, dataset and further analysis can be accessed at https://symphonynet.github.io

(b) Trained on Lakh MIDI Dataset

Table 2: Human evaluation results from 25 musicians and 25 non-musicians, with mean opinion scores and 95 percent confidence intervals reported.

($E4$, $G4$), ($D4$, $D5$), and ($G4$, $G5$), which are usual intervals occurring in symphony *divisi* passages. After applying Music BPE on the whole music corpus, the average token length of a $mulpi$ shortens to half (from 2.28 to 1.13), also reducing the burden of modeling ultra-long symphony sequences.

6.4 Ablation Study and Human Evaluations

We train a linear transformer decoder model with the vanilla positional encoding of GPT-3 [18] as a baseline. Then we train another model of the same architecture with the training data processed by the proposed Music BPE algorithm. Finally, we incorporate both 3-D positional embedding and Music BPE algorithm, which achieves the lowest training and validation loss after the same total training steps, as is shown in Fig. 4. The objective metric indicates that our permutation-invariant 3-D positional embedding and Music BPE algorithm could significantly improve model performance and generalization ability.

Also, we perform a human evaluation to compare the quality of generated music excerpts from different models with human composition. Participants include 25 professional musicians and 25 non-musicians. Each participant receives 16 excerpts: four excerpts conditioned on a chord progression, four excerpts conditioned on a given 4-bar prime, and eight unconditioned excerpts. The music excerpts are rated in 5 dimensions: Coherence **(C)**, Diversity **(D)**, Harmoniousness **(H)**, Structureness **(S)**, Orchestration **(O)** and Overall Preference **(P)**, in a 5-point Likert scale. As shown in Table 2a, the model with 3-D positional embedding and Music BPE beats most of the approaches. It is worth noting that excerpts generated by our models surpass the human compositions in the indicator of diversity marked by yellow color.

To further explore the model performance, we retrain SympohyNet on Lakh MIDI Dataset [22] with the same backbone model architecture as MMM [15], and carry out another human evaluation to compare with MMM. Each participant receives 10 excerpts: five generated unconditionally from MMM and the others generated unconditionally from retrained SymphonyNet. The results are presented in Table 2b, which indicate that SymphonyNet surpass MMM in all indicators. Overall, the human hearing test suggests that SymphonyNet can construct coherent, unique, complex, and harmonic symphonies.

7. CONCLUSION

In this work, we illustrate the properties of multi-track and multi-instrument music, like symphony, and propose a novel MMR representation with 3-D positional embedding for modelling it. To tokenize the ultra-long symbolic music sequence at sub-word level, we propose the Music BPE algorithm. Besides, we design a joint task for the model to learn auto-orchestration. Human evaluation results show that our suggested technique produces competitive symphonic music when compared to human compositions. In the future, we will investigate modelling long-term musical structures, since complex music, such as symphonies, often consists of numerous parts or movements.

8. ACKNOWLEDGEMENTS

Thanks for the anonymous reviewers for their valuable comments. This work is supported by High-grade, Precision and Advanced Discipline Construction Project of Beijing Universities, Major Projects of National Social Science Fund of China (Grant No. 21ZD19), and Nation Culture and Tourism Technological Innovation Engineering Project.

ABSTRACT

Music tagging and content-based retrieval systems have traditionally been constructed using pre-defined ontologies covering a rigid set of music attributes or text queries. This paper presents MuLan: a first attempt at a new generation of acoustic models that link music audio directly to unconstrained natural language music descriptions. MuLan takes the form of a two-tower, joint audio-text embedding model trained using 44 million music recordings (370K hours) and weakly-associated, free-form text annotations. Through its compatibility with a wide range of music genres and text styles (including conventional music tags), the resulting audio-text representation subsumes existing ontologies while graduating to true zero-shot functionalities. We demonstrate the versatility of the MuLan embeddings with a range of experiments including transfer learning, zero-shot music tagging, language understanding in the music domain, and cross-modal retrieval applications.

1. INTRODUCTION

Classifiers are generally trained to label examples with predefined and fixed class inventories, which are often manually specified as a structured ontology indicating interclass relationships. Empowered by recent advances in neural language modeling and their demonstrated transfer learning competence, researchers have begun exploring less restrictive natural language interfaces to access the categorical information underlying raw content signals. The majority of this work has been in the visual and audio event domain, where a recent series of studies have demonstrated the utility of jointly embedding media content with natural language captions [1–5]. These joint embeddings have demonstrated strong capabilities in a range of applications, including transfer learning, cross-modal retrieval, automatic captioning, and zero-shot classification.

The success of these efforts strongly depends on large-scale training resources and hefty neural network architectures that are flexible enough to model the complex, non-monotonic relationship between language and other modalities. In particular, the visual domain has greatly benefited from the availability of large amounts of captioned images available across the web [1]. However, in the general environmental audio domain, such large-scale audio-caption pairs are less readily available and related efforts have relied on small captioned datasets [6, 7]. Critically, these datasets do not span the diversity of sound-descriptive language and their success in the more difficult zero-shot setting has been lacking [3, 8, 9].

This paper considers this task of jointly embedding audio and natural language, but focuses specifically on the music domain. Our goal is to produce a flexible language interface with which any musical concept can be linked to related music audio. We face similar training data prerequisites to works listed above. However, while general environmental audio consists of background sounds that are unlikely to elicit unprompted description, music audio is often a central focus. Consequently, text associated with music videos is much more likely to relate to the underlying musical concepts that we aim to model (e.g., genres, artists, moods, structure). Thus, our strategy is to assemble a collection of textual annotations extracted from metadata, comments, and playlist data and map them to a training set of over 44 million internet music videos. As was the case with image-text model training in [1], our text data only truly refers to the musical content in a fraction of cases. Therefore, we also explore text pre-filtering using a text classifier separately trained to identify music descriptions.

We use this large-scale dataset to train MuLan, a new generation of semantically-structured music audio embedding model equipped with a natural language interface. MuLan employs a two-tower parallel encoder architecture, using a contrastive loss objective that elicits a shared embedding space between music audio and text. We demonstrate that MuLan not only leads to state-of-the-art performance in transfer learning for various music information retrieval tasks, but also enables a range of functionalities in cross-modal text-to-music retrieval, zero-shot music tagging, and music-domain language understanding.

2. RELATED WORK

Audio representation learning. Transfer learning using large-scale, task-agnostic pretraining of general-purpose content representations has become a dominant approach

Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

in several fields. Audio representation learning has been no exception, including both general environmental audio [10, 11] and music audio [12–15]. Different pretraining mechanisms have been explored. In supervised pretraining, an Audio Spectrogram Transformer (AST) [10], pretrained on ImageNet [16] and AudioSet [17], achieved state-of-the-art results in various tagging tasks. A strong early baseline for music audio representation learning was provided in [13], using the Million Song Database [18].

In unsupervised and self-supervised pretraining, both discriminative and generative model approaches have been demonstrated to be successful. Discriminative training was explored in [19–22] where the models tried to learn representations that assign higher similarity to audio segments extracted from the same recording compared to segments from different recordings. SSAST [11] explored similar discriminative losses, as well as generative masked spectrogram patch modeling. It was shown in [23] that the intermediate embedding of a generative model also provides a strong audio representation for downstream classification. Various forms of weak supervision, such as user interaction statistics and visual cues, have also been examined in [24–26].

Our work focuses on developing a recipe of cross-modal supervision using an abundance of text annotations that are weakly associated with the music audio. We benchmark the transfer learning capabilities of the learned representations against analogous past work, and also evaluate different audio encoder architectures.

Cross-modal contrastive learning. Spurred by the success of using contrastive learning to align image features and free-form natural language using large-scale data [1, 2], tri-modal architectures were proposed in [27] and [5] where an audio tower was introduced to the image-text model and contrastive learning is used to enforce the cross-modal alignment. Along the same line in the audio domain, [8] used contrastive learning to align the latent representation of audio and associated tags. The tags come from a fixed vocabulary of size 1K from Freesound [28], and the input to the text encoder was the multi-hot encoded tags. Follow up work in [9] uses a pretrained, non-contextual word embedding (Word2Vec) model to support generalization to new terms beyond the 1K tags. However, this still does not support generalization to free-form natural language. Contrastive learning was also explored in [29] for zero-shot audio classification, using AudioSet and ESC-50 [30] data. Our method focuses on mining a much larger scale collection of audio-text pairs specifically for the music domain. Our data scale supports using state-of-the-art Transformer-based audio and contextual language encoders, which led to a truly arbitrary zero-shot music tagging and retrieval for the first time.

Music text joint embedding models. Content-based music information retrieval requires linking the rich semantics expressible to free-form text with both broad and fine-grained musical properties. One approach is to consider a large number of text label classes and try to ground the semantics in music with a multi-label classification task. In [25], a large vocabulary of 100K n-grams was mined from noisy natural language text associated with music videos. Then, a cross entropy loss was employed to train the music audio encoder, where the softmax layer weights served as text label embeddings that were aligned with audio features by construction. The work in [31] explored various training tasks (classification, regression, metric learning) to align free-form text and music audio, relying on pre-existing emotion labels to connect the modalities.

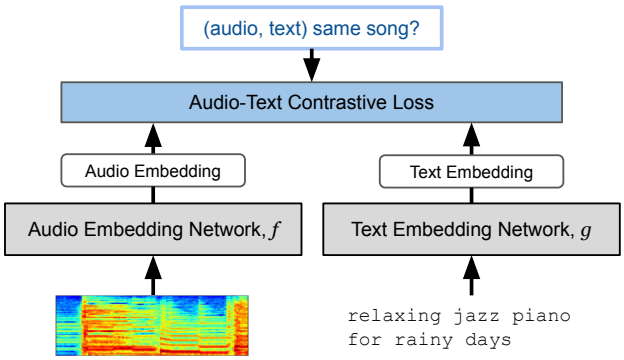

Figure 1. Learning framework diagram.

Closest to our work is MuLaP [32], where 250K audio-caption pairs were mined from a private production music library and used to train a multimodal Transformer with early fusion of the two modalities. Their choice of early fusion, as accomplished with cross-attention layers, restricts the utility of the resulting embeddings to transfer learning applications. Critically, our two-tower parallel encoder approach results in a joint embedding space that provides a natural language interface to arbitrary music audio. This opens up downstream opportunities for cross-modal retrieval, zero-shot tagging, and language understanding.

3. PROPOSED APPROACH

Our goal is to construct a shared embedding space for music audio and free-form natural language text, in which proximity is predictive of shared semantics both within and across modalities. To accomplish this, we rely on cross-modal contrastive learning and a simple two-tower architecture. This is a highly data-intensive endeavor, which we support by mining a large-scale training dataset of (audio, text) pairs. We describe these components in turn below.

3.1 Learning Framework

Figure 1 shows a high-level schematic of the learning framework. Each MuLan model consists of two separate embedding networks for the audio and text input modalities. These networks share no weights, but each terminates in ℓ_2-normalized embedding spaces with the same dimensionality, d. The audio embedding network, $f : \mathbb{R}^{F \times T} \rightarrow \mathbb{R}^d$, takes as input log mel spectrogram context windows with F mel channels and T frames. The text embedding network, $g : \mathcal{A}^n \rightarrow \mathbb{R}^d$ takes as input a null-padded text token sequence of length n over a token vocabulary $\mathcal{A}$.

Given a set of music recordings and the associated text elements for each recording, we construct a cross-modal training dataset of (audio, text) pairs as follows. For each recording, we compute an F-channel log mel spectrogram and extract a collection of T-frame context windows. We null-pad or truncate each associated text element to a fixed length n. Then, each mini-batch $\mathcal{B}$ consists of a set of B target audio-text pairs of the form $\{(\mathbf{x}^{(i)}, \mathbf{t}^{(i)})\}_{i=1}^{B}$. Here, each target pair is sampled by first selecting a random recording and sample a random spectrogram context window $\mathbf{x}^{(i)} \in \mathbb{R}^{F \times T}$ from it. Next, we randomly select one of its associated text elements $\mathbf{t}^{(i)} \in \mathcal{A}^n$. This sampling scheme means that multiple epochs are required to cover the entirety of the training audio and all the associated text. We also experimented with concatenating multiple text annotations for each example, but it did not generally work as well.

We train to minimize a batch-wise Contrastive Multiview Coding loss function [33], which is a cross-modal extension of the popular InfoNCE and NT-Xent losses [34, 35]. For each batch $\mathcal{B}$, this loss $\mathcal{L}(\mathcal{B})$ takes the form

$$\sum_{i=1}^{B} -\log \left[\frac{h[f(\mathbf{x}^{(i)}), g(\mathbf{t}^{(i)})]}{\sum_{j \neq i} h[f(\mathbf{x}^{(i)}), g(\mathbf{t}^{(j)})] + h[f(\mathbf{x}^{(j)}), g(\mathbf{t}^{(i)})]} \right],$$

where h is a critic function given by $h[\mathbf{a}, \mathbf{b}] = \exp(\mathbf{a}^T \mathbf{b}/\tau)$ for $\mathbf{a}, \mathbf{b} \in \mathbb{R}^d$, and $\tau \in (0, 1]$ is a trainable temperature hyperparameter. For our ℓ_2-normalized embedding model outputs, the inner product is effectively cosine similarity. The critic's goal is to produce a large positive value for target audio-text pairs, and a small value close to zero for all non-target pairs constructed within the batch. Temperature values less than one function to increase the output range of h. Previous research [35, 36] demonstrated that a large batch size is beneficial to contrastive loss optimization.

3.2 Audio Embedding Network

For the audio embedding tower, f, we consider two proven audio architectures. Following its introduction to the audio machine learning community [37], the *Resnet-50* architecture has become a common and well-performing option. It is a straightforward adaptation of the original vision architecture: as in [37], we remove the stride of 2 in the first convolutional layer and apply to log mel spectrograms ($F = 64$ mel channels, 25 ms Hanning window, 10 ms step size) treated as grayscale images. Unlike the Resnet-50 model in [37] which operated on 0.96-second context windows, in order to allow the modeling of longer-term musical structure, our implementation takes as input 10-second windows (randomly selected from each training clip), in the form of $(F = 64) \times (T = 1000)$ spectrogram patches. During training, we apply SpecAugment to each spectrogram using the parameters from [10] before passing it into the embedding network. A final mean pooling operation is applied across time and mel channels, followed by a linear fully connected layer with $d = 128$ units, whose output is ℓ_2-normalized. We pretrain all but the final linear transform layer via logistic regression on AudioSet [17], including all 527 classes, and discard the final classifier layer before fine-tuning for our task.

Table 1. Text annotation examples.

Type	Examples
Short-form (SF)	tags like genre, mood, instrument, artist name, song title, album name
Long-form (LF)	'Hip-hop features rap with an electronic backing.' 'The melody is so nostalgic and unforgettable.'
Playlist (PL)	'Feel-good mandopop indie', 'Latin workout' 'Salsa for broken hearts', 'Piano for study'

Audio Spectrogram Transformer (AST) is a port of the successful Vision Transformer (ViT) base architecture and is currently the state-of-the-art in the audio event classification space [10]. AST consists of a stack of 12 Transformer blocks (hidden dimension 768, 12 self-attention heads) that are applied to a sequence of "tokens" corresponding to a flattened set of linear-transformed 16×16 (stride 10 along both axes) time-frequency patches extracted from the $(F = 128) \times (T = 1000)$ log mel spectrogram context windows. We again apply SpecAugment during training. Similar to the Transformer-based language models, trainable positional encodings are added to the sequence of patch tokens, and a `[CLS]` token is prepended to the sequence as a summary of the contextual patch embeddings. We apply a linear fully-connected layer with $d = 128$ units and ℓ_2-normalization to the final 768-dimensional encoding at the `[CLS]` token position, and this forms the output of audio embedding network f. We warm-start training for all but the final linear transform layer using the public AST checkpoint [10].

3.3 Text Embedding Network

For the text embedding model, we consider the commonly-used Bidirectional Encoder Transformer (BERT) with base-uncased architecture [38], which consists of a stack of 12 Transformer blocks (hidden dimension of 768 and 12 self-attention heads). We apply the BERT wordpiece tokenizer to convert a text input string into a sequence of tokens ($n = 512$). The output of the text embedding network is defined to be the `[CLS]` token embedding, linearly transformed to the shared audio-text embedding space of dimension $d = 128$ and subsequently ℓ_2-normalized. We warm-start our text embedding network using the publicly available checkpoint [39].

3.4 Training Dataset Mining

To assemble a large-scale collection of (audio, text) pairs needed to train our MuLan embedding models, we start with a collection of 50 million internet music videos. From the soundtrack of each video, we extract a 30-second clip starting at the 30 second mark. We then apply a pre-existing music audio detector and discard any clip that is less than half music content. After this filtering, we are left with approximately 44 million 30-second clips, which amounts to nearly 370K hours of audio.

Table 2. Statistics for text data sources. Tokens counts (in billions) are across all 44M videos. APV is the average number of text annotations (i.e. separate free-form strings) per video, including those with none.

	Pre-filter		**Post-filter**	
Type	Tokens (B)	APV	Tokens (B)	APV
Short-form	31.2	42.9	5.4	29.6
Long-form	30.7	70.7	0.2	0.4
Playlists	2.5	24.3	-	-

For each music video, we consider 3 sources of noisy text data: (i) *short-form* (SF) text including video titles and tags; (ii) *long-form* (LF) text including video descriptions and comments; and (iii) titles of 171 million *playlists* (PL) that are linked to the internet music videos in our dataset. None of these text sources is guaranteed to be referring to the musical properties of the soundtrack. In particular, comments data contains the most noise, and can be subjective or less directly related to the music content. In Table 1, we show examples that are indeed music-related to give the readers a flavor of each type of text annotation.

In observance of the highly noisy text, we experimented with training MuLan with the SF and LF text data filtered to a cleaner set of music-descriptive annotations (PL is used unfiltered). For this, we fine-tune a pre-trained BERT model with a binary classification task on a small curated set of 700 sentences, which are manually labeled to be music-descriptive or not. We then apply this text classifier to filter the sentences in the LF annotations. Separately, we apply a set of rule-based filtering heuristics to clean up the SF annotations. Table 2 shows the size and coverage of each of these text sources, both before and after filtering. Note that playlist titles and filtered long-form annotations are only available for a minority of recordings in the dataset (18M and 6.8M out of the total 44M, respectively).

We also convert AudioSet into a set of audio-text pairs, denoted below as ASET. Specifically, we include all examples for all 527 classes, using each label string attached to an example as an associated text annotation. This results in a set of approximately 2 million 10-second clips for training, each with 1.8 label annotations on average. Given the great scale imbalance of these four different data sources, which is often at odds with their linguistic richness and quality, we construct each mini-batch with a prescribed set of proportions that were chosen without any optimization: 2:2:1:1 for SF:LF:PL:ASET. This means that despite its small scale, the (e.g.) filtered LF annotations still comprise 1/3 of each mini-batch.

4. EXPERIMENTS

We evaluate MuLan using both the Resnet-50 audio encoder (M-Resnet-50) and AST audio encoder (M-AST). In both cases we use the BERT-base-uncased architecture as the text encoder. We train all models for 14 epochs on the collection of audio-text pairs mined from the 44M music recordings and the processed text labels in all categories: AudioSet (ASET), short-form tags (SF), long-form sentences (LF), playlist information (PL). We use the Adam optimizer with a step decay learning rate schedule using a decay factor 0.9 applied every 40K steps and initial values of 5×10^{-5} for M-Resnet-50 and 4×10^{-5} for M-AST. The temperature parameter is initialized to $\tau = 0.1$ for all models. M-Resnet-50 is trained with a batch size of $B = 6144$ pairs, while $B = 5120$ pairs were used for M-AST due to memory limitations. Since M-AST and M-Resnet-50 show roughly similar performance in the evaluation tasks considered, we use M-Resnet-50 throughout the text ablation study for its better training efficiency.

4.1 Evaluation Tasks

4.1.1 Zero-shot Music Tagging

Given a music clip and a set of candidate text label tags, we define each prediction score as the cosine similarity between the audio embedding of the music clip and the text embedding of each tag string. The generalization ability of the proposed method to potentially unseen target labels is achieved through (i) the use of a contextual text encoder, which provides a flexible prediction space, and (ii) the use of cross-modal contrastive learning to anchor the language semantics to an audio representation.

We conduct this evaluation with two music tagging benchmarks: MagnaTagATune (MTAT) [40] and the music related portion of AudioSet [17]. For MagnaTagATune, we consider both the well-exercised top-50 tag set, as well as the full 188 tag set. We use standard train/validation/test partitions (note that zero-shot experiments do not use train/validation) and report class-balanced area under the receiver operating characteristic curve (AUC-ROC) on the test set. The audio clips in MagnaTagATune are 29 seconds long, so we split each into 3 non-overlapping 10-second segments and average the segment-level embeddings to get the clip-level embedding. For AudioSet, we consider a 25-way genre tagging task (Gen-25) as studied in [25], and a richer 141-way tagging task (Mu-141) that includes the entire music subtree of AudioSet ontology.

It is important to note that AudioSet is included in contrastive training, and a fraction of MTAT classes overlap with the AudioSet ontology. As a result, AudioSet and (to lesser extent) MTAT evaluations are not strictly zero-shot from a label exposure perspective. However, the explicit, matched AudioSet supervision is diluted by the abundance of free-form language supervision during MuLan training. Therefore, by comparing MuLan models and conventional AudioSet classifiers, we can measure the cost of moving to a flexible natural language interface that additionally supports classes outside the AudioSet ontology.

4.1.2 Transfer Learning with Linear Probes

In addition to the zero-shot experiments introduced above, we also evaluate the audio encoder as a general purpose feature extractor for downstream tagging tasks. We again consider the two benchmarks of MagnaTagATune and AudioSet, and use the training datasets to train an independent per-class logistic regression layer on top of the frozen 128-dimensional audio embeddings. We follow the same eval-

Table 3. Text triplet evaluation examples.

Eval Set	Anchor / Positive / Negative
Ontology	Steelpan / Sounds of a tuned percussion instrument originally constructed from steel oil drums by hammering out small patches on the head to produce separate pitches. / The sound of a musical instrument that produces sound by vibration of air in a tubular resonator in sympathy with the vibration of the player's lips.
Playlist	Relaxing Korean Pop / Lets make your chill mood with a collection of easy-going sounds from Korean artists. / These fun and upbeat songs from the alternative side of the pop music spectrum will keep you energized while you exercise.

uation protocol of past transfer learning studies using these datasets, allowing for a direct comparison of performance.

4.1.3 Music Retrieval from Text Queries

Given a music search collection and a text query, MuLan provides the ability to retrieve the music clips that are closest to the query in the embedding space. This evaluation is relevant to music retrieval applications, where content features can offer finer-grained and more complete similarity information when compared with metadata-based methods [41]. We consider a proprietary collection of 7,000 expert-curated playlists, which do not overlap with the playlist information used in training. Each expert-curated playlist has a title and a description, and consists of 10-100 music recordings. The playlist titles are usually short phrases, including a mixture of genres, sub-genres, moods, activities, artist names, and compositional elements (e.g. *'Indie Pop Workout'*, *'Relaxing Korean Pop'*). Playlist descriptions consist of one or more complete sentences (see pos/neg entries of "Playlist" row of Table 3 for examples). The playlist evaluation includes approximately 100K unique recordings.

We construct two cross-modal retrieval evaluation sets from the expert-curated playlist data, one using titles as queries and the other using descriptions. For each dataset, we use the recordings belonging to the corresponding playlist as the ground truth retrieval targets, and all the 100K recordings as the pool of candidates. We report both AUC-ROC and mean average precision (mAP). We use the same embedding averaging and cosine similarity-based scoring mechanism as in the zero-shot tagging case. However, the playlist information is of substantially different nature compared to the tags involved in the music tagging benchmarks. Instead of a small vocabulary of mostly basic genres and instruments, the playlist titles and descriptions have much finer-grained information and are similar to queries that are presented to music search engines.

4.1.4 Text Triplet Classification

Compared to the conventional pre-trained BERT model, our text encoder is fine-tuned using in-domain music data and cross-modal contrastive loss. Note that there are no text-only training objectives. To measure whether our proposed method deepens the text encoder's understanding of music related text, we directly evaluate the text embeddings with a triplet classification task. Each triplet consists of 3 text strings of the form of (*anchor*, *pos*, *neg*), and it is considered correct if *pos* is closer than *neg* to *anchor* in the text embedding space. We derive two such text triplet evaluation sets. The first uses the AudioSet ontology [17]: for each of the 141 music related classes, we use its label string as the anchor text, its long-form description as the positive text, and sample 5 random class's long-form description as the negative text to construct 5 triplets. For the second set, we sample 1,000 triplets from the expert-curated playlist data in a similar fashion: we first sample a playlist, set the anchor and positive text to be its title and description, respectively, and then set the negative text to be the description of another randomly sampled playlist. Examples of both sets are shown in Table 3.

4.2 Results and Discussion

4.2.1 Music Tagging

Table 4(a) shows the zero-shot tagging metrics, where M-Resnet-50 and M-AST obtain comparable performance. Note that there can be a significant misalignment between the word sense of a label in the tagging evaluation compared to that in our training text. This can lead to a degradation in performance relative to the explicitly supervised linear probe setting where the task-expected tag semantics can be learned. The MTAT gap is substantially larger than AudioSet's, driven by particularly bad performance for (i) MTAT tags with nonspecific meaning or multiple senses, e.g. "weird" and "beats"; and (ii) MTAT tags involving simple negation (e.g. "not rock", "no piano"). This is a result of the text encoder not adequarely modeling the meaning of these negated concepts, which is a well known problem with BERT [43, 44] (the text embedding of "not rock" is similar to "rock" and performance suffers).

Table 4(b) shows the results of the text ablation study,

Table 5. Text query music retrieval evaluation results. Text ablation/unfiltered models use M-Resnet-50.

	Title		Description	
Model	AUC	mAP	AUC	mAP
M-AST	**0.933**	0.110	**0.903**	**0.090**

which aims to understand the benefits of different sources of text labels. Note that as we remove each dataset we maintain the same proportions described in Section 3.4. Unsurprisingly, training with AudioSet alone gets the highest AUC in AudioSet evaluation, with the text encoder learning the exact label semantics reflected in the test data. On the other hand, including more data sources in general improves performance on all other downstream tasks (MTAT, retrieval/text triplet evaluations in Tables 5 and 6) and the loss on AudioSet AUC is relatively minor. We observe that for the music tagging tasks considered, training with unfiltered data actually achieves comparable performance compared to the filtered version. That the model learns similarly useful associations without being overwhelmed by the sheer amount of noise in the raw text data came as a surprise. We speculate that our text filtering was too aggressive, having removed annotations that were not obviously music-related, but semantically important nonetheless. Since contrastive learning is highly noise tolerant, the gain from restricting to more strongly aligned audio-text pairs may have been offset by the loss of a large set of additional useful pairs.

Table 4(c) shows that when applying linear probes on MuLan audio embeddings, we achieve SOTA transfer learning performance on all tagging tasks. This demonstrates that MuLan's pretrained audio encoder continues to produce high quality general-purpose music audio embeddings, while also supporting new natural language applications. Finally, Table 4(d) lists end-to-end training baselines for 3 of these tasks. Our linear probe results exceed 2 of 3, and only slightly trails a SOTA AST AudioSet classifier.

4.2.2 Music Retrieval from Text Queries

In Table 5, we evaluate MuLan models (including with text/filter ablation) on the query retrieval evaluation tasks introduced in Section 4.1.3. Even though we start with a BERT checkpoint pretrained with massive language resources, training MuLan with only AudioSet clips and label annotations provides very limited ability to ground in-domain natural language to music. Such limited cross-modal supervision does not generalize to the rich semantics that appear in the playlist titles and descriptions, which are more in line with the complex queries that are presented to real-world music search engines. We observe significant gain after including the large-scale short-form tags mined from the internet, which helps the model learn to ground more fine-grained music concepts. There is additional gain when including comments and playlist data, where the complete sentences are helpful for grounding the more complex queries, including multi-term queries (e.g.*'instrumental action movie soundtrack'*), compositional queries (e.g. *'classical music with middle eastern influence'*), and even queries with negation (e.g. *'hard rock without vocals'*). Again, we find that training is surprisingly robust to annotation noise, achieving similar performance using unfiltered training text.

4.2.3 Text Triplet Classification

Table 6 lists triplet classification accuracy on evaluations introduced in Section 4.1.4. We compare MuLan text embedding against the following baselines: Sentence Transformer [46], SimCSE [45], Universal Sentence Embedding [47], and the average token embedding of BERT-base-uncased (this outperforms the `[CLS]` encoding by a large margin). All baselines are Transformer-based models with similar size to ours. The first three were trained with sentence-level contrastive loss, while BERT is trained with masked language prediction. We warmstart the MuLan text encoder using this same BERT baseline, but it is subsequently only trained with the cross-modal loss. We find that when including our long-form text annotations, the resulting text embedding model, which is now specialized to the music domain, outperforms the generic sentence embedding models. While it is not surprising in-domain text is helpful, it is remarkable that successful specialization is accomplished without using any text-only fine-tuning loss.

5. CONCLUSIONS

We presented a music audio and natural language joint embedding model trained with an unprecedented scale of weakly paired text and audio data. Our experiments demonstrate the versatility of the natural language interface in a range of applications. The pretrained audio embeddings also achieve SOTA transfer learning performance on music tagging benchmarks. This is a first attempt at building a free-form natural language interface for music audio and there is plenty of room for improvement. Specifically, we believe improved text filtering methods that better distinguish weak signal from absolute noise will result in better handling of rare and subtle language constructs.

ABSTRACT

Human usually composes music by organizing elements according to the musical form to express music ideas. However, for neural network-based music generation, it is difficult to do so due to the lack of labelled data on musical form. In this paper, we develop MeloForm, a system that generates melody with musical form using expert systems and neural networks. Specifically, 1) we design an expert system to generate a melody by developing musical elements from motifs to phrases then to sections with repetitions and variations according to pre-given musical form; 2) considering the generated melody is lack of musical richness, we design a Transformer based refinement model to improve the melody without changing its musical form. MeloForm enjoys the advantages of precise musical form control by expert systems and musical richness learning via neural models. Both subjective and objective experimental evaluations demonstrate that MeloForm generates melodies with precise musical form control with 97.79% accuracy, and outperforms baseline systems in terms of subjective evaluation score by 0.75, 0.50, 0.86 and 0.89 in structure, thematic, richness and overall quality, without any labelled musical form data. Besides, MeloForm can support various kinds of forms, such as verse and chorus form, rondo form, variational form, sonata form, etc. Music samples generated by MeloForm are available via this link [1], and our code is available via this link [2].

1. INTRODUCTION

Melody is often composed of hierarchical motifs, phrases and sections with repetitions and variations given musical form [1]. This organized structure provided by musical form can help better express music ideas. For example, verse and chorus form is widely used in popular music. The repetition of verse and chorus sections helps emphasize music ideas, while the contrast between verse and chorus can create more emotional intensity. Automatic melody generation with pre-given musical form based on purely data driven technology is difficult due to the lack of labelled data on musical form. Previous work attempt to generate melody with structure information, but still suffers from the following issues: 1) They generate melodies with repetitive patterns implicitly either by learning long-term dependency [2–4] or representing the repetition structure with same harmony, rhythm patterns, etc [5–7]. However, repetitive patterns are far from the exact musical form. 2) They generate melodies with bar-level structure explicitly by learning the relationship between bars [8, 9], but bar-level structure is still not the exact musical form. 3) They generate melodies with repetitive phrases and sections either by detecting phrase labels with rules and algorithms [10] or using human labelling [11]. But it is hard for rules or algorithms to detect precise musical form, and it costs much for hiring people to label this musical form data. Furthermore, all of these work aim to generate melodies with some kind of repetitive patterns, but musical form is constructed to express music ideas by developing the hierarchical structural units (i.e., motifs, phrases and sections) with repetitions and variations. Simply repeating some fragments, or even phrases and sections, without considering the relationships among these hierarchical structures, is superficial.

Although it is difficult to collect labeled musical form data through detection algorithm or human labeling, it is much easier for expert systems to generate melodies with musical form. However, experts systems may suffer from monotonous musicality because of handcraft rules. On the other hand, neural networks are capable of creating melodies with rich expressions by learning the data distribution, but it is hard to precisely control the musical form. Considering the complementary characteristics of these two systems, we come up with a method that can leverage the advantages and make up for the shortcomings.

Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

In this paper, we develop MeloForm, a system that generates melody with musical form using expert systems and neural networks. The expert system is designed to generate synthetic melodies with precise musical form. It develops the motifs to phrases then to sections, which are arranged by repetitions and variations according to the pre-given musical form. The encoder-attention-decoder Transformer based neural network is introduced to refine melodies generated by expert systems. To improve musical richness without changing musical form, we propose the refinement strategy in phrase level, the conditioning on rhythm and harmony, and the methods for differentiating sections.

MeloForm enjoys the advantages of expert systems and neural models and avoids their limitations as following: 1) Comparing with expert systems, we can generate melodies with better musical richness. 2) Comparing with the models that implicitly learn the repetitive patterns, we can generate melodies explicitly with precise musical form control. 3) Comparing with the models that depend on bar-level structures, we construct higher-level phrases and sections structures. 4) Comparing with the models using detected phrases labels or human labels, we have the labeled musical form data naturally from expert systems with zero cost and precise accuracy.

The main contributions of this work are as follows:

- We develop MeloForm, a system that generates melody with musical form using expert systems and neural networks. This system combines the best of white-box expert system and black-box neural networks for generating melodies with precise musical form and rich melodic expression without any labeled data.
- Experimental results demonstrate that MeloForm achieves precise musical form control with 97.79% accuracy without any labeled data, and outperforms baseline systems by 0.75, 0.50, 0.86 and 0.89 averagely in structure, thematic, richness and overall quality in subjective evaluation.
- MeloForm can generate melodies with various kinds of forms, such as verse and chorus form, rondo form, variational form, sonata form, etc.

2. RELATED WORK

Automatic melody generation evolves from grammar or statistical based generation [12–17] to deep learning empowered generation [2, 3, 6, 8–10, 18–31]. In this section, we introduce existing neural networks and expert systems for melody generation with musical structure.

2.1 Neural Networks for Melody Generation

Generating structured melody has attracted more attention when modeling long music sequence. Previous work address this problem as following: 1) They implicitly learn the long-term dependency or represent repetitive structure with same musical elements to generate melodies with repetitive patterns. Music Transformer [3] introduces a relative attention mechanism to capture long-term dependency. Theme Transformer [4] proposes a novel gated parallel attention module for generation with theme-based conditioning. Another work [2] presents a hierarchical recurrent neural network to model the note-beat-bar structure. Other methods [5–7] condition the model with same musical features (e.g., harmony and rhythm patterns) to represent the repetitive structure. 2) They explicitly model the bar-level structure for generating melodies one bar after another. In [9, 32], the authors leverage the bar related self-similarity matrix to model the relationship between bars for guiding the melody generation. MELONS [8] constructs a bar-level structure graph for generating melodies with clear bar-level structures. 3) They collect labeled musical data by detection algorithms for generating repetitions for melodies. Repetitive patterns from melodies are detected by music analysis algorithms in [33], while the boundaries of repetitive phrases are recognized in [10]. All of these works can help realize repetitive patterns for melody in some degree, but they still cannot model precise musical form.

2.2 Expert Systems for Melody Generation

Back to 18th century, a system called music dice game is developed for randomly generating music from precomposed options [34]. Recently, much work still investigate rule-based algorithm compositions for specific purpose. The author in [35] comes up with a rule-based algorithm to generate melody note sequence, which is constructed for comparison with the machine learning based compositions. dMelodies [36] combines the designed latent factors to create 2-bar melodies for improving data diversity in disentanglement learning. However, none of them consider the rules for generating melodies with musical form. Computoser [37] proposes a hybrid probability/rule based algorithm for music composition, which based on rules about structure, rhythm, repetition, variations, endings, etc. But it did not provide the methods about how to arrange these elements with musical form. And the method for constructing a phrase by multiple different motifs may brings about divergence from music ideas. In [38], repetition of phrases is also considered at a rhythmical level and concerning pitch intervals, but the melody in each phrase is generated one note at a time, which is different from a common composition process by developing a phrase from a motif. Comparing with these systems, the expert system in MeloForm generates melodies by considering the musical form as the hierarchical structure of motifs, phrases and sections with repetitions and variations, which can better express music ideas.

3. METHOD

To combine the advantages of precise musical form control by expert systems and musical richness learning by neural networks, we develop MeloForm that is shown in Figure 2(a), which contains two modules: 1) expert systems for generating synthetic melodies with musical forms; 2)

Figure 1. The score of the melody part from "*Minuet in G Major*" by the composer Christian Petzold. This is an example of a melody with musical form as $A(a_1, a_1)B(b_1, b_2)$. We use capital letters (e.g., A, B) to label sections, while using lowercase (e.g., a_1, b_1, b_2) for representing phrases. Different phrases in the same section are labeled with different numbers.

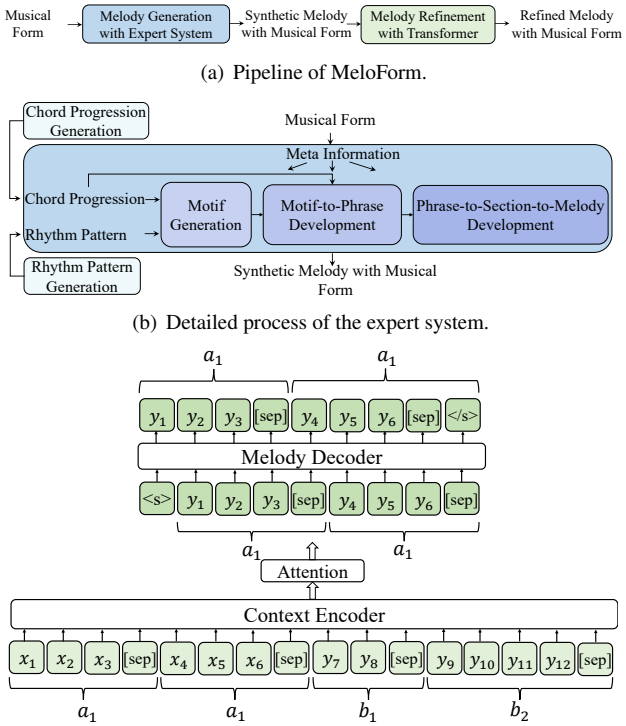
Transformer based neural networks for refining the generated melodies from expert systems.

3.1 Melody Generation with Expert System

The designed expert system with purely handcraft rules is inspired by music theory [1], and is shown in Figure 2(b). Given the musical form with hierarchical structure of sections and phrases, the expert system firstly generates the motifs based on chord progression and rhythm patterns, then develops the generated motifs to phrases. In the phrase-to-section-to-melody development module, we arrange the phrases in sections and sections in melody with repetitions and variations according to the given musical form to generate the synthetic melody with musical form. For example in Figure 1, given the musical form $A(a_1, a_1)B(b_1, b_2)$, a 2-bar motif in the blue box is developed into 8-bar phrase a_1. Section A is formed by placing repeated phrase a_1 sequentially with some variations. The similar process is implemented to form section B, in which different phrases b_1 and b_2 are developed from different motifs. Then section A and section B are placed sequentially for getting the final composition.

3.1.1 Motif Generation

Motif is the smallest structural unit for identifying music theme, so we create an initial melody in a few bars (i.e., usually 1-2 bars) to construct the motif. Before the generation process, we should define the meta information (i.e., scale, pitch range, tempo and meter) for guiding the whole generation procedure. Considering note sequences are composed of pitches and rhythm patterns, we come up with rule-based algorithms for chord progression generation to guide pitch selection and for rhythm pattern generation to create rhythm patterns for the note sequence in motif. Specifically, the initial pitch of notes is selected from tones in corresponding chords. Then we add some embellishing tones [3] to decorate the motif melody. Besides, the interval between adjacent note pitches is constrained to be not greater than seven semitones to ensure pitch consistency. The detailed algorithms of chord progression generation and rhythm pattern generation can be referred in Supplementary Materials Section 1 and 2.



(a) Pipeline of MeloForm.

(b) Detailed process of the expert system.

(c) Architecture of melody refinement neural networks. The input contains four phrases from a melody with musical form as $A(a_1, a_1)B(b_1, b_2)$. In each phrase, x represents the conditioning information (i.e., rhythm, chord and cadence) for each note, while y represents the melody information (i.e., rhythm and pitch) for each note. [sep] indicates the boundaries between phrases, while <s> and </s> indicates the beginning and end of phrases.

Figure 2. Architecture of MeloForm.

3.1.2 Motif-to-Phrase Development

A motif is a unit for identifying the music theme, but it is not a complete music expression. Thus, we need to develop it into a phrase, which is the smallest structural unit for expressing complete music ideas. In order to develop motif into phrase, we introduce three basic categories of development strategies: sequence [4], transformation and ending. These basic development strategies can be combined with each other to create compound development strategies. For example, in Figure 1, the 2-bar motif in the blue box is developed by sequence (i.e., 3-4 bars), transformation (i.e., 5-6 bars) and ending (i.e., 7-8 bars) to form 8-bar phrase a_1. The detailed description of each development strategy can be referred in Supplementary Materials Sections 3.

There may exist multiple different phrases in each section, each of which has its own motif. Too much different motifs in each section may distract listeners from the main ideas. Thus, we present another way to generate a new motif similar to already generated one for a new phrase. Specifically, we can either directly copy the already generated motif or borrow its rhythm patterns to create a new motif, which can help build some relationships between

[3] http://openmusictheory.com/embellishingTones.html

[4] https://en.wikipedia.org/wiki/Sequence_(music)

phrases in the same section. For example, in Figure 1, the rhythm patterns from the motif in the orange box of phrase b_2 is borrowed from the motif in the pink box of phrase b_1 with a few variations.

3.1.3 Phrase-to-Section-to-Melody Development

After generating all phrases, we need to arrange them with repetitions and variations to form sections, which are higher-level structural units. And sections are then ordered sequentially to finish the composition. As shown in Figure 1, given musical form as $A(a_1, a_1)B(b_1, b_2)$, repeated phrases a_1 with variations are placed in order to form section A. Phrase b_1 and b_2 are placed in order to form section B. At last, section A and section B are arranged sequentially to get the final composition.

Directly generating new motifs when building different sections is not always musically expressive, so we introduce another method for establishing not only similar but also contrastive motifs. To establish the similarity, we can borrow one of the random fragment from phrases in other sections. To form a contrast, we can adjust the rhythm patterns and pitch selection in desired section to change the tension. For example, in Figure 1, the rhythm patterns of the motif in the pink box from phrase b_1 is borrowed from that of the third bar from phrase a_1, which is not the exact motif for phrase a_1. And to form a contrast, the pitch is selected from higher range for more tension.

3.2 Melody Refinement with Transformer

Melodies generated by the expert system are guaranteed to have precise musical form, but are lack of musical richness since they are generated by handcraft rules. Thus, in this section, we introduce an encoder-attention-decoder Transformer that takes the synthetic melodies as input and outputs refined melodies with better musical richness. However, the refinement is challenging since it needs to keep the musical form unchanged while improving the musical richness. Due to the lack of controllability of neural networks, directly refining the whole melody without any constraints is easy to lose musical form information. To address this challenge, we describe several design principles in our Transformer model for refinement:

- *Refining melody phrases by phrases.* Since musical phrase is the smallest structural unit for a complete musical expression, it is better to refine the melody phrase by phrase in an iterative process, instead of refining the whole melody in a single time that fails to maintain the musical form from the expert system. However, only refining one phrase at a time is hard to model the repetitive patterns from similar phrases. Therefore, we should refine similar phrases at each iteration step.

- *Refining phrases by conditioning on rhythm and harmony.* Directly generating the refined musical phrases from scratch may lose bottom-level music structure determined by rhythm patterns and harmony. Thus, we should provide explicit condition and control with rhythm and harmony to guide the refine process.

- *Refining phrases by considering their differentiations among different sections.* When composers need to distinguish different sections (e.g., verse and chorus) in melodies, they usually change pitch distribution or rhythms patterns for building up contrasted tension. Accordingly, to maintain such contrast between sections, we need to consider these differentiations in the refinement process.

Based on these design principles, our model architecture is shown in Figure 2(c). We introduce the implementations corresponding to each design principle as follows.

3.2.1 Iterative Phrase Refinement

According to the first design principle, we refine the similar phrases in each iterative step. To train the Transformer model with iterative refinement capability, we first mask similar phrases of the melody in the training data and take the masked melody as the input of the encoder, and generate original phrases corresponding to the masked positions with the decoder, like the masked sequence to sequence (MASS) task in [39]. After model training, the Transformer model is used to refine the similar phrases in synthetic melodies from expert systems in an iterative way. Specifically, if we want to refine the melody with musical form as $A(a_1, a_1)B(b_1, b_2)$, we can refine phrases a_1 for the first iteration and replace the two original phrases with the refined versions, and then refine the phrase b_2 based on the refined melody. This iteration step is finished until all phrases are refined.

3.2.2 Condition with Rhythm and Harmony

The phrases are developed from motif by sequence strategy that results in similar rhythm patterns within some bars. Besides, harmony plays an important role to control pitch distribution in phrase development. Thus, to maintain these music structures in refinement, we condition the model with rhythm patterns, chord progression and cadence to encourage the model to only refine the pitch of the phrase. Specifically, instead of replacing the masked phrases with masked symbols in MASS [39], we replace them with the corresponding rhythm, chord and cadence symbols, shown as x in Figure 2(c).

3.2.3 Differentiation between Sections

We differentiate the phrases in different sections into aspects: 1) Controlling rhythm patterns in the expert system. Rhythm patterns can be adjusted directly in expert system by increasing/decreasing note density, prolong/shrink note length, etc. It is common that larger note density or faster tempo can bring about more intensity. 2) Controlling the pitch distribution in the Transformer model. Although expert systems can control the pitch distribution by selecting pitch from different ranges, it is hard for neural networks to control in the same way. Thus, we insert an "AVG-PITCH" token at the beginning of the condition from each target phrase to represent the average pitch of this phrase, and another "SPAN" token to indicate the pitch span (i.e., the difference between the maximum pitch with minimum

pitch). Higher average pitch and more pitch span can build up much more tension.

4. EXPERIMENTAL RESULTS

In this section, we first describe the dataset and system configurations. Next, we show the main results compared with baseline systems. Then we implement some method analysis to further validate the effectiveness of each design. Finally we implement some extensions to demonstrate the scalability of this system. Music samples generated by MeloForm are available via this link [1] . Our code and Supplementary materials are available via this link [2] .

4.1 Experiment Setup

Dataset. We utilize the LMD-matched MIDI dataset [40] in the training stage of the Transformer based neural networks for melody refinement. We select melodies in 4/4 time signature, and normalize them to the tonality of "C major" or "A minor". At last, we obtain 30,218 MIDI samples. This dataset contains 471,058 phrases, in which there exists 100,948 distinct set of similar phrases based on our phrase boundary detection and similarity calculation, of which the detailed algorithm can be found in Supplementary Materials Section 4.

System Configurations. The encoder-attention-decoder Transformer has 4 encoder and decoder layers, both of which contains 4 attention heads. The hidden size is set as 256. We use Adam optimizer [42] with the learning rate is 0.0005. The dropout rate is set as 0.2 during training. There contains maximum of 4,096 tokens in each batch. The dataset is randomly splitted into training/valid/test set with the ratio of 0.8, 0.1, and 0.1, respectively. We use nucleus sampling [43] with the p set as 0.9.

Subjective Evaluation Metrics. For subjective listening, we invite 10 participants to evaluate 30 samples. There are five randomly selected samples from MeloForm and baselines described in Section 4.2. For each listener, they are randomly ordered to avoid perceptual bias and habituation effect. The rating is based on five-point scale. We define the following four metrics: 1) Structure: Does this melody have complete structure with repetitions and variations? 2) Thematic: Can you figure out the musical theme? 3) Richness: Is the melody similarly melodious as human compositions? 4) Overall: Is the overall quality of the melody the same as human compositions?

4.2 Main Results

We compare MeloForm with the following baselines: 1) Music Transformer [3], an end-to-end neural network solution which introduces the relative attention to learn long-term repetitive patterns; 2) MELONS [8], a Linear Transformer and structure graph based framework for generating melody with bar-level structure; 3) POP909_lm, a language model implemented by ourself for leveraging the phrase labels in POP909 [41] to generate melodies given musical form, whose details can be found in Supplementary section 6. These baselines share the same system configurations with MeloForm for fair comparison.

Table 1 shows the subjective evaluation results in the mean opinion scores (MOS) and 95% confidence interval for these four metrics over all experimental groups. Comparing with baseline systems, MeloForm outperforms all of them in thematicness, structureness, richness and overall quality. We calculate the controlling accuracy of phrase labels for POP909_lm to verify if same phrase labels results in similar melodies. The high accuracy of 100% demonstrates it is capable of generating corresponding repetitive melodies for same phrase labels. It is worth noticing that although POP909_lm can realize the repetitions of phrases, it still fails to provide good listening experience comparing with MeloForm. This demonstrate simply repeating phrases is still deficient. Besides, the less 95% confidence interval of MeloForm provides more confidence for its better performance. We also compare MeloForm with human composed data from the LMD-matched MIDI dataset and POP909. MeloForm shows better performance compared with LMD-matched MIDI dataset, since the samples from LMD-matched MIDI dataset are collected from various kinds of publicly-available sources on the internet, which is hard to guarantee the production quality. In contrast, POP909 is constructed by hiring professional musicians for creating the samples and reviewing the whole generation process, which ensures the quality to be the same as realistic compositions. The comparing results with POP909 reveal that there still exist gaps between melodies generated by MeloForm with the human composed ones.

4.3 Method Analysis

Controllability Study. We calculate the controlling accuracy of musical form by calculating the similarity score between generated melodies from same phrases. The accu-

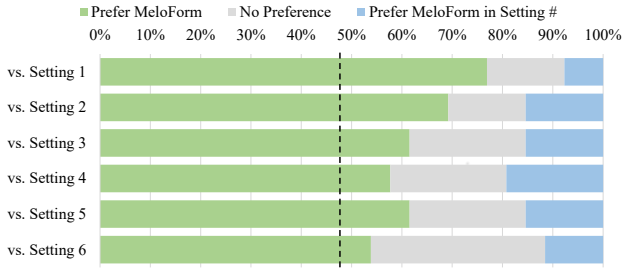

Figure 3. Preference distribution for ablation study, which compares the melodies generated by MeloForm with that from modified system (i.e., MeloForm in Setting #).

racy of 97.79% indicates MeloForm can generate melodies with precise musical form control. We also calculate the accuracy to verify if the pitch distribution is well controlled by average pitch and pitch span. The accuracy of 92.5% in average pitch controlling and 99.71% in pitch span controlling demonstrate its controllability to differentiate sections in pitch dimension.

Ablation Study. We conduct preference tests to verify the contribution of the components in MeloForm with the following settings: 1) Setting 1: w/o development strategies from expert systems. Notes are randomly arranged in expert systems without any development strategies. 2) Setting 2: w/o expert systems. Melodies are first generated for each phrase by neural networks, and then got copied directly with the given musical form for repetition in the same phrase. 3) Setting 3: w/o neural networks. We remove melody refinement neural networks. 4) Setting 4: w/o fine-grained rhythm pattern condition. The condition of rhythm patterns changed from fine-grained level to coarse-grained level. 5) Setting 5: w/o refinement strategy. We directly copy the generate melodies from each phrase to the following same phrases. 6) Setting 6: w/o section differentiation. The "AVGPITCH" and "SPAN" tokens are removed from the beginning of each phrase. The participants are required to compare the samples from MeloForm and these settings and give their preference score.

The preference distribution for the above settings is shown in Figure 3. We derived some observations in the following: 1) More preferences over setting 1 and 2 demonstrate the effectiveness of the whole expert system and the development strategies for building up phrases. 2) More preferences over setting 3, 4, 5, and 6 validate the efficacy of the whole neural refinement model, the rhythm pattern condition, the iterative refinement strategy, and the section differentiation method.

4.4 Extensions to More Musical Forms

In this section, we illustrate the principles to generate melodies with four different musical forms (i.e., Verse and Chorus, Rondo, Variational and Sonata form) based on MeloForm. The examples from these extensions are shown in the demo page.

Verse and Chorus Form is widely used in popular music. It contains two contrasting sections: verse section (i.e., A) and chorus section (i.e., B), which can be arranged in various kinds of ways, such as $AABAAB$, ABA, or $AABB$. Users can follow the method in Section 3.1 to build the verse and chorus sections, and leverage the section differentiation in Section 3.2.3 to change the tension. For example, Chorus tends to have more intensive emotional expression. To achieve this, we can control the average pitch to higher level or increase the pitch span for this section.

Rondo Form is a musical form where the refrained section alternates with contrasting sections, such as $ABACADA$. Melody of Rondo Form can be generated by leveraging the method in Section 3.1 to construct the refrained section and contrasting sections, and arrange them sequentially based on the given Rondo Form.

Variational Form is a musical form where the main section is followed by its variations. We represent Variational Form as $AA'A''$ to describe the main section and its variations. To address the challenge of deriving variations from the main section, we can treat the main section as a motif, and use the development strategies in 3.1.2 to develop this longer motif into another higher-level section. Another way is to generate melodies with same sections like AAA by expert systems, and predict the melodies from each section in different iteration steps. There are many other ways for creating the Variational Form, so users are encouraged to provide their own creative design.

Sonata Form is generally consisted of three sections: an exposition, a development, and a recapitulation, which can be represented as ABA' in our system. For the exposition, we generate two phrases with contrasting motifs, where the second phrase is a transposition of the first one by controlling the tonality token when refining the second phrase. The development section is a variation of the exposition, which can be generated by leveraging the methods for constructing variational form. The recapitulation is a repetition of the exposition, in which the second phrase should go back to the tonic key by controlling the tonality token in condition from neural networks.

5. CONCLUSIONS

In this paper, we propose MeloForm, a system to generate melody with musical form based on expert systems and neural networks. It combines the advantages from expert systems to precisely control musical form and neural networks to refine melody for better musical richness without changing musical form. Experimental results demonstrate MeloForm achieves 97.79% accuracy in musical form control, and outperforms baseline systems in structure, thematic,richness and overall quality in terms of subjective evaluation. We will release the dataset of the synthetic melodies generated by our expert system and the refined version from our Transformer model to facilitate the future research on music form modeling. Furthermore, we will explore the generation of intro, outro and bridge, and investigate the arrangement generation with musical form to accomplish a complete music composition.

ABSTRACT

Nowadays, commercial music has extreme loudness and heavily compressed dynamic range compared to the past. Yet, in music source separation, these characteristics have not been thoroughly considered, resulting in the domain mismatch between the laboratory and the real world. In this paper, we confirmed that this domain mismatch negatively affect the performance of the music source separation networks. To this end, we first created the out-of-domain evaluation datasets, *musdb-L* and *XL*, by mimicking the music mastering process. Then, we quantitatively verify that the performance of the state-of-the-art algorithms significantly deteriorated in our datasets. Lastly, we proposed *LimitAug* data augmentation method to reduce the domain mismatch, which utilizes an online limiter during the training data sampling process. We confirmed that it not only alleviates the performance degradation on our out-of-domain datasets, but also results in higher performance on in-domain data.

1. INTRODUCTION

Recent commercial music has extreme loudness compared to the past [1, 2]. Since many artists and producers want their music to be perceptually louder, it has become so trendy that it rather harms the quality of music [3] and even there exists the expression 'loudness war' [4].

A dynamic range compressor [5] is used to increase the loudness of music while keeping the digital level under 0 decibels relative to full scale (dBFS), which is the maximum possible level in the digital domain. It is a time-varying non-linear processor that adjusts the level of the signal when the level exceeds the threshold. Especially, a limiter refers to a dynamic range compressor that strongly compresses the signal with a high ratio parameter above 1:10 and increases the gain of the signal by the headroom obtained through compression.

In the last stage of music production, so-called mastering, engineers are often asked to increase the overall loudness of music. A limiter is a core tool for achieving it; it is used to make small parts of music to be louder and loud parts of music fit under 0 dBFS [7, 8]. In this process, original signals are distorted and become louder. The example of a limiter usage is depicted in Figure 1.

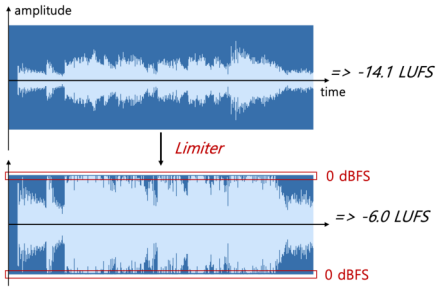

Figure 1. The short example of a limiter applied music source in our *musdb-XL* dataset. Recent commercial music has this loud volume and distorted signal characteristics.

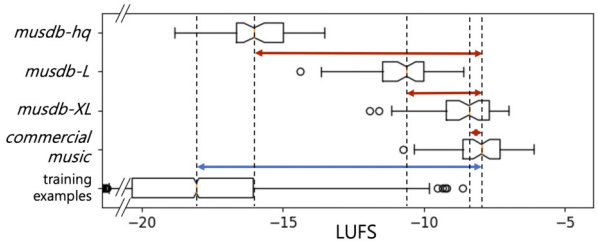

Figure 2. The boxplot representing the loudness distributions of different evaluation datasets, recent commercial music, and training examples generated from the official implementation of *Open-unmix* [6].

However, these characteristics have not yet been thoroughly considered in the music source separation. Although many data augmentation techniques have been proposed, such as random gain scaling and mixing of different instrumental stem sources [9, 10], the training examples have small overall loudness that is far from real-world commercial music [1], as can be seen in the blue line of Figure 2. This causes a huge domain shift between train and real-world domains. The term LUFS in Figure 2 is an abbreviate for loudness unit relative to full scale, which is a

Lee, "Towards robust music source separation on loud commercial music", in *Proc. of the 23rd Int. Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

[1] Based on the investigation of 50 songs in *'Pop Life playlist'* created by Tidal, May. 2022.

measure of music loudness [11, 12].

Furthermore, since the standard benchmark datasets for music source separation, *musdb* [13] and *musdb-hq* [14], do not reflect the characteristics of loud commercial music as shown in the red lines of Figure 2, they are unable to show performance degradation comes from the domain shift. Therefore, we conjecture that even good-performing networks based on *musdb* test subset may exhibit worse performance on real world. This problem is no exception to other datasets [15–17] for music source separation, since they do not consider the music mastering process.

Based on this question, we investigated how heavily compressed music and its loudness affect the degradation of music source separation networks. To this end, we manually built new evaluation datasets by applying a limiter to the *musdb-hq* test subset [14] to get loud and compressed music imitating the modern music mastering process. One is the *musdb-L* dataset, with increased loudness to an appropriate degree for pleasant sound following [3]. The other is the *musdb-XL* dataset, which raised the loudness to an excessive degree, as often found in recent popular music. Using our datasets, we confirmed that more dynamic range compression in test domains results in more performance degradation of the networks.

Moreover, we conducted various experiments on the training data creating methods to reduce the domain shift between train and real world data from the perspective of music loudness and heavy compression. We trained music source separation networks using the training examples constructed by *(1)* linear gain increasing, *(2)* the proposed *LimitAug* method which utilizes an online limiter during the sampling process of training examples, *(3)* simple input loudness normalization, and *(4)* the loudness normalization after applying the *LimitAug*. We confirmed that all of the methods not only showed robust performance on out-of-domain *musdb-L* and *musdb-XL* data, but also showed better performance on in-domain *musdb-hq* test dataset than the baseline.

To summarize, our contributions are three-fold.

- We built *musdb-L* and *XL* datasets [2], which have comparable overall loudness to commercial music, for evaluation of music source separation algorithms.
- Using *musdb-L* and *XL*, we quantitatively confirmed that the domain shift causes performance degradation of the state-of-the-art networks that were trained without considering loud and compressed music characteristics.
- We proposed *LimitAug* [3] data augmentation method and experimentally confirmed that it is beneficial to alleviate the domain shift between train data and the *musdb-L* or *XL*.

[3] https://github.com/jeonchangbin49/LimitAug

dataset	Loudness [LUFS]			
	min	max	median	mean (std)
musdb-hq	-18.84	-13.52	-16.02	-15.92 (1.27)
musdb-L	-14.39	-8.61	-10.61	-10.89 (1.19)
musdb-XL	-11.93	-6.99	-8.41	-8.61 (1.17)
commercial	**-10.75**	**-6.10**	**-7.96**	**-8.05 (1.06)**

Table 1. Loudness statistics of *musdb-hq*, *musdb-L*, *musdb-XL* datasets, and the investigated commercial music.

2. MUSDB-L AND MUSDB-XL

musdb [13] and *musdb-hq* [14] have been the standard benchmark datasets on music source separation since their presentation in Signal Separation and Evaluation Challenge (SiSEC) 2018 [18]. They consist of various genres of 150 professionally produced songs — 100 songs for train, 50 songs for test — from folk, indie to electronic, rock genres. Each song has its constituting 4 stems, *vocals*, *drums*, *bass*, and the remaining as *other*. The *musdb-hq* dataset is the uncompressed version of *musdb* with the extended frequency bandwidth from 16kHz to 22.05kHz, which is a full bandwidth of 44.1kHz sample rate. We used *musdb-hq* for high-quality dataset construction.

Since the test subset of *musdb-hq* has small overall loudness compared to commercial mastering-finished music, we conjectured that it could not fully reflect the performance degradation related to heavy dynamic range compression, which prevails in recent commercial music. In addition, to the best of our knowledge, there is no dataset for music source separation that reflects these characteristics or considers the music mastering process. Therefore, we built *musdb-L* and *musdb-XL* datasets, which have loud and compressed characteristics similar to commercial music. *L* and *XL* each stands for *Loud* and *eXtremely Loud*.

2.1 Dataset construction

To reflect the characteristics of commercial music, we created datasets by imitating the music mastering process. Both datasets were made by manually applying the commercial digital limiter, iZotope Ozone 9 Maximizer [4], to the *musdb-hq* test subset. For each *musdb-L* and *musdb-XL*, we controlled the threshold parameter of a limiter so that compression is applied about 3-4 dB and 6-7 dB in loud parts of *mixture* tracks of the *musdb-hq*. As shown in Table 1, *musdb-L* and *musdb-XL* are about 5 and 7 LUFS louder than the original *musdb-hq* dataset on average, respectively. *musdb-L* has insufficient loudness compared to loud commercial music but less distorted sources. *musdb-XL* has comparable loudness to commercial music and more distorted sound than *musdb-L*.

To make the ground truth stem tracks of each mixture, we calculated the sample-wise ratio between the limiter applied mixture and the original mixture, then multiply it to the individual stems to make the ground truth stems for *musdb-L* and *XL*.

3. METHODS

In general, a limiter is used as the last signal processor in music mastering of commercial music [7, 8]. Since it tends to be used excessively in modern commercial music [1, 2, 4], it should be considered in music source separation for the development of robust application.

We assumed that the key differences between the real-world mastering-finished music, i.e. a limiter applied music, and the standard training examples for music source separation are *i)* the overall amplitude scale, and *ii)* the signal distortion caused by a limiter.

Here we introduce two ways to avoid each domain mismatch problem.

3.1 Input loudness normalization

First of all, the simple loudness normalization, which is a linear gain adjustment of network inputs to the pre-defined reference level, is the easiest technique to avoid the domain shift caused by *i)* overall amplitude scale mismatch. This can be categorized into two, *(i)* input loudness normalization during both the training and evaluation stages of networks, and *(ii)* normalization only at the evaluation stage.

The method *(i)* is already used in various studies with different ways. For example, the network such as *Demucs v3* [19], uses input standardization in time domain based on the mean and standard deviation of the training data. In *Open-unmix* [6], the network implicitly normalizes the input by utilizing trainable input scaling parameters that works in time-frequency domain. However, we assumed that explicitly adjusting the gain of the inputs based on the waveform, thereby minimizing the overall amplitude scale mismatch between train and test domain, can greatly reduce the performance degradation comes from the domain shift.

The method *(ii)*, normalization only at the evaluation stage, can be considered as a readily applicable workaround for the models that were trained without considering music loudness. This method is a simple idea to reduce the overall amplitude scale difference between train and real-world domain. Since the music source separation networks are non-linear systems, we hypothesized that linear scale difference of the inputs might affect the quality of final outputs. That is, input normalization only at the evaluation stage can be a simple, yet effective trick for models that were already trained without considering the domain mismatch.

Though these methods can mitigate the domain mismatch related to *i)* amplitude scale, there needs to be another strategies that can reflect *ii)* the signal distortion caused by a limiter.

3.2 *LimitAug*

The best way to consider the characteristics of the limiter applied source is simply using the limiter during the network training. Therefore, we propose the *LimitAug* data augmentation method, which utilizes an online limiter during the training examples construction process, to reduce the domain shift between the training examples and real-world commercial music. The *LimitAug* can be considered as creating train examples that forcibly reflect the distortion that comes from a limiter, which cannot be reflected by the simple input loudness normalization technique.

```

Figure 3. `numpy`-like pseudocode of the proposed *LimitAug* method.

The pseudocode for *LimitAug* is shown in Figure 3. First, calculate the LUFS of the mixture created by the data sampling process. Second, adjust the gain of the input mixture source targeting the randomly sampled LUFS value. Then, it is followed by the online limiter to fit the waveform under 0 dBFS. Lastly, calculate the sample-wise (A sample refers to an each waveform value) ratio between the limiter applied mixture source and the original mixture source, then multiply the ratio to the original target source to get the ground truth target signal of the limiter applied mixture source.

When adjusting the gain and applying the limiter to the input mixture, for example, if the input mixture had -15 LUFS and the randomly sampled target LUFS was -10, note that the gain-scaled mixture by +5 dB does not have exact -10 LUFS due to the compression of a limiter and the nature of LUFS calculation, which considers frequency weighting [11, 12].

The proposed *LimitAug* can be used with other data augmentation methods; in our study, random gain scaling, channel swap and mixing of different instrumental stem sources [9, 10] were used. Also, additional loudness normalization can be applied after the *LimitAug* as depicted in conditional statement of Figure 3, so that the overall amplitude scale mismatch between training and evaluation stages be minimized.

4. EXPERIMENTS

Here we briefly summarize our following experiments.

In Section 5.1, we quantitatively evaluated various music source separation networks that were trained without considering the loudness and heavy dynamic range compression, and confirmed the performance degradation on *musdb-L* and *musdb-XL*, compared to the origianl *musdb-hq* evaluation dataset.

Table 2. Performance of various music source separation networks trained with *musdb-hq* [14] on the test using *musdb-hq*, *musdb-L* and *musdb-XL*.

In Section 5.2, we simply normalized the network inputs in the evaluation stage, to observe the performance degradation caused by the signal distortion caused by a limiter, not an overall amplitude mismatch between the training and the evaluation data. Then, we carefully analyzed the results on *Demucs v3* [19], which took the 1st place in the 2021 Sony Music Demixing (MDX) Challenge leaderboard A and the 2nd place in the leaderboard B [22]. The leaderboard A was the competition that only allowed training on the only *musdb-hq* train subset, and the leaderboard B allowed the extra training data.

In Section 5.3, we conducted a comparative study on various training data construction strategies. Unfortunately, we were unable to train the current state-of-the-art *Demucs v3*, due to the constraint of our GPU experimental environments. Considering the training efficiency and reasonable performance, we used *TFC-TDF-U-Net* [20] — a backbone architecture of KUIELab-MDX-Net [23] with slight modifications, which took the 2nd place in the 2021 MDX Challenge leaderboard A — in this experiment.

4.1 Training

In Section 5.1 and Table 2, we used official pre-trained weights of each model except *TFC-TDF-U-Net* since there were no official weights for the 4 stems of *musdb-hq*. For fair comparison in Section 5.3, we trained *TFC-TDF-U-Net* for 300 epochs with early stopping, based on official training framework of *Open-unmix* [6] and official network implementation of *TFC-TDF-U-net*. We used default network hyper-parameters introduced in its webpage [5] .

For the *LimitAug*, we used the limiter implemented in `pedalboard` [24]. The threshold parameter was set to 0 dBFS, and the release parameter was randomly sampled from uniform distribution of (30, 200) millisecond in data sampling process. Also, we used `pyloudnorm` [25] for loudness calculation.

[5] https://github.com/ws-choi/ISMIR2020_U_Nets_SVS

4.2 Evaluation

In all of the evaluations, Signal-to-Distortion Ratio (SDR) [26] was calculated using `museval` python library [18]. Also, in following experimental results, both *median* and *mean* SDR scores were presented for the detailed comparison. Note that we only used the *musdb-hq* train subset for training the networks. *musdb-L* and *XL* are only for evaluation.

In the original *musdb-hq* test subset, as stated in the official webpage [6] , 'PR - Oh No' track's mixture signal is panned to the right channel, which causes the inconsistency between linear summation of stems and mixture source. Since this causes the limiter to be operated in unmusical way while the construction of *musdb-L* and *XL*, which also can be hardly found in popular music, we used the linear summation of stems as a mixture only for this track. This may results in the slight difference of SDR scores between the Table 2 and the official scores of each network.

5. RESULTS

5.1 Performance degradation on *musdb-L* and *XL*

Here we quantitatively evaluated the performance of state-of-the-art networks on *musdb-hq* [14], *L* and *XL* datasets and confirmed that the domain shift in perspective of music loudness and compression negatively affect the performance, indeed. As shown in the Table 2, all networks showed significant performance degradation on the evaluations with *musdb-L* and *musdb-XL* datasets. The amount of decrease on *Demucs v3* [19] was slightly larger than the others. Overall, we concluded that every networks are somewhat overfitted to the *musdb-hq* data, making the networks vulnerable to loud and heavily compressed music. Therefore, it is highly required to consider these characteristics for the robust music source separation. Note that

Table 4. Performance of networks with loudness normalized input at the evaluation stage. Each score represents the average score across the 4 stems. Note that the networks were trained without considering music loudness or dynamic range compression explicitly.

we stated the scores on different test datasets in each block to emphasize the performance degradation between the domains.

5.1.1 Extra training data

Though the extra training data was of help, it did not work as the fundamental solution to the domain shift. *Open-unmix* [6] with extra training data showed more robust performance than that of the network without extra data, but performance degradation on *Demucs v3-B* was more significant than that of *Demucs v3-A*. Since *Demucs v3-B* was trained with extra training data including *musdb-hq* test subset, it is reasonable to guess that the network is highly overfitted to the *musdb-hq* data. Nevertheless, the amount of performance decrease especially on *drums* comparing the scores between *musdb-hq* and *XL*, 2.5 dB, is somewhat high. Considering *Demucs v3* uses an input standardization technique based on mean and standard deviation of waveform values both at training and evaluation stages, this implies that there needs to be another solution for the robust music source separation.

5.1.2 Performance degradation on drums and vocals

It is noteworthy that the degradation on *drums* and *vocals* were more significant than the others. Due to the percussive nature of *drums*, in general, they have the biggest momentary energy in music. Also, since *vocals* are important ingredients in modern commercial music, they usually consist of not only a single singing voice but also doubling, harmony and chorus. Therefore, we assumed *drums* and *vocals* are most affected by the limiter, which is activated when loud input sources that are above the threshold are given. To quantitatively confirm the signal distortion by the limiter, we calculated Scale-invariant Signal-to-Distortion Ratio (SI-SDR) [27] between *musdb-hq* and *musdb-XL* for each stem. As a result, *drums* and *vocals* scored each 19.97 and 23.69 dB, on the other hand, *bass* and *other* scored each 25.12 and 25.48 dB on average. That is, the signal distortion caused by a limiter is more significant on *drums* and *vocals*.

Unfortunately, since the networks in the Table 2 have never seen these kinds of distorted *drums* or *vocals* as training examples, we assumed that the degradation on *drums* and *vocals* were significant compared to the rest. This result strongly supports the necessity of considering the heavy dynamic range compression from the training stage, i.e. the *LimitAug*, which forcibly makes the distorted and compressed training examples for training purposes, thereby minimizing the domain shift.

5.2 Analysis on the input normalization at the evaluation stage

If the key differences between the real-world music and the training examples of music source separation networks are *i)* overall amplitude scale, and *ii)* the signal distortion caused by a limiter, as stated in Section 3, then what if we give the loudness normalized *musdb-L* or *XL* data as inputs to the networks in Table 2? Due to the non-linear nature of deep neural networks, we assumed that simply normalizing the amplitude scale of the networks on the evaluation stage may affect the performance.

The inference was conducted with following procedures, *(i)* reducing the loudness of *musdb-L* or *XL* input so that its loudness becomes same with that of the corresponding original *musdb-hq* data, *(ii)* inference with loudness normalized input, and *(iii)* increasing the scale of output as much as reduced in step *(i)*.

Comparing the scores between Table 2 and Table 4, we confirmed that the performance degradation was greatly alleviated by just the simple loudness normalization of the inputs only at the evaluation stage. Note that the networks were not trained with loudness normalized inputs. This result shows that the input loudness normalization at the evaluation stage can be a quick and easy solution to get robust results from the pre-trained music source separation networks.

Especially, on *drums* of *Demucs v3-B*, it should be noted that the amount of decrease on *median* SDR score between the test using *musdb-hq* and *XL* was sharply reduced from 2.5 dB in Table 2 to 0.4 dB in Table 3. This implies that the network is overfitted not only to the contents of the signal, but also to the scale or loudness, especially

Table 6. Stem-wise performance of *TFC-TDF-U-Net* [20] trained with the method *(3)* input loudness normalization, and *(4)* input loudness normalization after the proposed *LimitAug*.

on *drums*. Note that there was no distinction between the given input sources to the networks except the linear gain difference.

Although the performance degradation was reduced by the input loudness normalization, still there exists the performance degradation due to the signal distortion caused by a limiter. Similar to Section 5.1.2, this result also supports the necessity of the *LimitAug* for robust music source separation.

5.3 Analysis on various training strategies

In this section, we trained the *TFC-TDF-U-net* [20] with various training data creating methods; *(1)* linear gain increasing, *(2)* the proposed *LimitAug*, *(3)* input loudness normalization, and *(4)* input loudness normalization after the *LimitAug*. Of course, the methods *(3)* and *(4)* includes the input loudness normalization at the evaluation stage for the consistency between train and test domains. We compared the results to check which one is the most powerful way for training robust music source separation networks. For the input normalization, we chose the target reference LUFS value as -14.

In Table 5, we confirmed that all of the methods were effective for robust music source separation; every methods showed relatively robust performance on *musdb-L* and *XL*, compared to the baseline. Especially, except the method *(1)* targeting LUFS of a normal distribution following statistics of *musdb-XL*, $\mathcal{N}(\mu_{XL}, \sigma_{XL}^2)$, all methods showed greater performance on *musdb-hq* than the baseline. This result implies that these methods are useful not only for the domain shift, but also for the standard benchmark data.

Furthermore, the methods *(3)* and *(4)*, which prevent the domain shift caused by overall amplitude scale mismatch by input loudness normalization, showed slightly better performances than others. In the stem-wise analysis as presented in Table 6, though we expected that the *LimitAug* would be of help for *vocals* and *drums*, the method *(4)* was better at *vocals* and *other* than the method *(3)*.

Overall, it seems obvious that considering the music loudness and heavy dynamic range compression from the training stage is beneficial for robust music source separation. For real world applications, it is highly recommended that not just using the single method we experimented, but using various training methods on different stems or using a bag of models trained with various methods.

6. CONCLUSIONS

In this study, we questioned the domain shift between the research and the real-world data for music source separation, from the viewpoint of music loudness and heavy dynamic range compression. To answer this, We first built new evaluation datasets, *musdb-L* and *musdb-XL*, which reflect dynamic range compressed music characteristics and heavy loudness. Then, we confirmed the significant performance degradation of state-of-the-art networks on our datasets. To alleviate this, we conducted various experiments on training data construction strategies, including the proposed *LimitAug* method, and confirmed that the methods using the input loudness normalization only or with the *LimitAug* greatly improved the robustness. We hope that our proposed methods and evaluation datasets could contribute to future music source separation research and application.

7. ACKNOWLEDGEMENTS

We appreciate Zafar Rafii, the author of *musdb*, for allowing us to reprocess the original musdb data. We thank Antoine Liutkus, also the author of *musdb*, for giving the creative suggestion on the distribution of our proposed datasets. We are grateful to Ben Sangbae Chon, Keunwoo Choi, and Hyeongi Moon from GaudioLab for their fruitful discussions on our proposed methods. Last but not least, we thank Donmoon Lee, Juheon Lee, Jaejun Lee, Junghyun Koo, and Sungho Lee for helpful feedbacks.

ABSTRACT

There are many benefits for a community when there is a vibrant local music scene (e.g., increased mental & physical well-being, increased economic activity) and there are many factors that contribute to an environment in which a live music scene can thrive (e.g., available performance spaces, helpful government policies). In this paper, we explore using an estimate of the *live music event rate* (LMER) as a rough indicator to measure the strength of a local music scene. We define LMER as the number of music shows per 100,000 people per year and then explore how this indicator is (or is not) correlated with 28 other socioeconomic indicators. To do this, we analyze a set of 308,051 music events from 2019 across 1,139 cities in the United States. Our findings reveal that factors related to transportation (e.g., high walkability), population (high density), economics (high employment rate), age (high proportion of individuals age 20-29), and education (bachelor's degree or higher) are strongly correlated with having a high number of live music events. Conversely, we did not find statistically significant evidence that other indicators (e.g., racial diversity) are correlated.

1. INTRODUCTION

Certain American cities such as Los Angeles and New York City are famous for having great music scenes. However, there are hundreds of small, medium, and large cities around the country that support vibrant music scenes. These cities often have well-known venues like the Grand Ole Opry in Nashville, TN, or put on large music festivals such as SXSW in Austin, TX. They can be associated with artists who obtain some level of regional, national, or international fame such as Minneapolis, MN with Prince and Asbury Park, NJ with Bruce Springsteen. They sometimes become historically connected with specific genres as in New Orleans, LA with jazz, Seattle, WA with grunge, and Asheville, NC with bluegrass.

There have been many studies that detail the ways in which music scenes can benefit their communities by enhancing social bonding, improving emotional well-being [1,2], and increased economic activity [3–15]. Researchers have also studied factors that can help foster an environment in which a local music scene can develop and thrive [4, 5, 8, 9, 11, 12, 16–22]. These factors include having a rich music history, having strong support for music education, and government regulations that are favorable for live performance (see Section 2 for details).

Investment by government and non-government organizations (e.g., Chambers of Commerce, Arts Councils) are associated with strong music scenes ("music havens") to both further develop these havens as well as help cities with underdeveloped music scenes ("music deserts") [11]. Many organizations have produced extensive reports [19] about "music cities" based on interviews and surveys of cities around the world (e.g., Austin, USA [3], London, UK [23], Victoria, AU [24]). While these reports produce valuable and transferable knowledge, they tend to be narrow in their geographic focus (i.e., one city or region). To complement this body of work, we propose a quantitative approach that uses the live music event rate (LMER) to estimate the *relative* strength of a local music scene. We argue that this simple statistic is straightforward to calculate, easy to interpret, and useful.

In this work, we introduce a music event dataset that contains information for 308,051 live music events that took place in 1,139 American cities during 2019. Here we consider an event as a live performance by one or more artists at a venue (e.g., bar, concert hall, festival) on a given date. This dataset was collected for music event recommendation application and combines event information that was collected from BandsInTown [1] and Facebook [2]. While this dataset has a number of limitations (e.g., only music events with a digital footprint, data collected using snowball sampling), it allows us to calculate a rough estimate of LMER for each city to enable comparison.

In this paper, we explore how our estimated LMER is (or is not) correlated with 28 socioeconomic indicators across 6 different categories: transportation, population, economics, age, education, and race. These indicators are closely related to some of the factors (e.g., transportation convenience, population density) that other researchers have suggested are important factors for fostering healthy music scenes.

In Section 2, we explore existing research on the ben-

Benefits of Music Communities	Factors that Create a Strong Music Community
Job creation [3, 4, 11, 12]	Availability of performance spaces and venues [11]
Increased consumer spending [6, 8, 9]	Financial affordability [11, 20]
Patronages & sponsorships [5, 11, 12]	Music tourism [8, 9, 11]
Increased financial investments [3, 11]	Music education resources [11, 12, 22]
Lower poverty rates [25]	Music heritage and history [4, 11]
Strengthening social bonding [11]	Demographics (e.g. student populations) [4, 11, 12, 17]
Improved mental/physical health [1, 2]	Government support/regulation [5, 11, 12, 16]
Lower crime rates [7, 13, 15]	Transportation convenience [11, 20]
Better community reputation [3, 11]	Population density [19]
	Population growth [18, 21]

Table 1: Table summarizing the benefits of a music community and factors that stimulate a music community.

efits of and factors that support a strong music scene. In Section 3, we introduce our dataset of music event information and describe how we estimate LMER. Section 4 explores how LMER is correlated with different socioeconomic indicators some of which have been identified as being important factors in healthy music scenes. We then conclude in Section 5 with a discussion of how LMER can be useful for identifying potential music deserts.

2. RELATED WORK

In this section, we review both academic and music industry research that focuses on the following two questions:

1. What are the benefits of having a strong music scene?
2. What factors help foster a strong music scene?

A summary of our review is provided in Table 1.

2.1 Benefits of a Strong Music Community

Vibrant music scenes support local economies [3,4,11,12]. A live music event involves working musicians, booking and ticketing agents, sound and lighting technicians, bartenders, security guards, etc. Consumers spend money [6, 8, 9] on concert tickets, food and beverages, and artist merchandise. If a music community is strong enough, it also attracts tourism, where people from outside the community generate revenue for the local economy [8, 9, 11] through hotel stays and other local attractions (museums, parks, etc.). Live music scenes include many small businesses (music and record stores, recording studios, and private music teachers) and large institutions (music conservatories, theaters, and academic institutions). Finally, a vibrant music scene can generate economic knock-on benefits through patronage, sponsorship, cross-promotion, and cross-pollination relationships with other economic sectors [3, 5, 11, 12]. Such cultural-economic interactions can enhance a location's reputation and quality of life, attracting new residents and new participants to a scene.

The social and individual benefits of music are also well-studied. Music strengthens the social fabric of a community by "building bridges between cultures and languages, connecting people within a city, a region and across borders," as music "touches human beings" and "engages people" [11]. Vibrant music scenes are a component of the "social infrastructure" of healthy communities [26], spaces in which community members of various backgrounds can engage and interact with one another. They are physical spaces that afford and encourage face-to-face social interaction, the development of dense social networks, and the cultivation of shared values.

Many of these spaces gather together people across the social divisions of class, race, ethnicity, and faith. They are contexts in which people of different backgrounds can encounter one another in a common and often public space. According to the sociologist Robert Putnam, in the context of large pluralistic societies such as the USA, social activities such as music cultivate "bridging social capital." These are contexts in which we connect to people potentially unlike ourselves and through this cultivate a sense of "civic virtue" that widens "our awareness of the many ways in which our fates are linked" [27].

Empirical analyses of large social datasets suggest that engagement in arts events is associated with increased happiness and satisfaction measures [2]. Ethnographic case studies of particular music scenes suggest that participation in vibrant scenes is associated with subjective well-being [1, 11]. Industry analyses and censuses associate strong scenes with enhanced civic pride and cultural reputation [3, 11]. Our ongoing work will explore possible correlations between live, public music events across America and a wide range of well-being indicators, including political participation and the experience of belonging, trust, and reciprocity.

2.2 Factors that Create a Strong Music Community

Terrill et al. [11] identifies five essential elements of strong music scenes: a large number of active musicians, a community that supports diverse musical offerings, a variety of spaces for rehearsing, recording, and performance, along with a receptive and engaged audience, and a variety of music-related business. Other helpful factors include multi-level government support [5, 12, 16] (e.g., cultural zones, and accommodating noise ordinances and liquor laws [28]), city infrastructure (transportation, affordable housing), and music education [12, 22] from public school

music programs, to private lessons, to music conservatories [29]. A vibrant music scene also requires equitable access to funding, the fair enforcement of city ordinances, and the cultivation of shared social spaces [28]. Are the small business loans needed to support music infrastructure equitably available across demographic sectors? Are noise ordinances and venue regulations enforced and policed evenly across neighborhoods? Does the local government sponsor arts festivals and programs available to and welcoming of all citizens?

Demographics play a key role in establishing and invigorating a music community; for example, young people such as university students are more likely to go out to music events [4, 11, 12]. Denser populations often mean stronger social networking, associated with vibrant music scenes [19]. Lastly, as the population increases, the demand for live music also often increases, which can strengthen a music community [18, 21].

3. MUSIC EVENT DATA

To obtain a rough estimate of the strength of a city's music scene, we calculated its *live music event rate* (LMER). Specifically, we calculate the number of music events per year per 100,000 residents in a given geographic area.

We compiled the LocalifyMusicEvents-USA-2019 dataset [3] that consists of information for 308,051 music events from 1,139 cities in the United States, each with a population of 10,000 or more residents. The music event information was collected using custom web scrapers in late 2018 and all of 2019. We developed two web scrapers, one for BandsInTown, a comprehensive music event website, and one for Facebook, a popular social network. The BandsInTown scraper relied on snowball sampling [30] to build growing lists of artist and venue pages. Each page was scraped for events every 30 days. New artists and venues were continually added based on similarities between artists, artists playing at different venues, and artists playing events with other artists. By contrast, our Facebook scraper collected music event information by cycling repeatedly over a large list of cities continually.

To calculate LMER, we first count the total number of music events listed in the city during 2019 by matching the city and state names. We then divided by the city population according to the US Census population estimates for 2019.

Our dataset also contains 28 city-level socioeconomic indicators obtained from three different websites: Census Reporter [4], DataUSA [5], and Census Quickfacts [6]. These indicators are partitioned into six groups (transportation, population, economics, age, education, race) and are summarized in Table 2.

[3] Data can be found at `https://github.com/JimiLab/LocalifyMusicEventData`.

3.1 Music Havens

We divide the cities into three subsets grouped by population: small (pop. 10K-100K), medium (pop. 100K-500K), and large (pop. 500K or more). For each subset, the top ten "music havens" (cities with the largest LMER) are shown in Table 3.

Size	Principal City	Pop.	LMER
Small	South Burlington, VT	19162	0.036
	Steamboat Springs, CO	12928	0.020
	Asheville, NC	92859	0.019
	Santa Cruz, CA	64605	0.019
	Key West, FL	24843	0.017
	Burlington, VT	42545	0.017
	Ithaca, NY	30569	0.016
	Fredericksburg, TX	11245	0.016
	Lahaina, HI	12776	0.014
	Rutland, VT	15398	0.013
Medium	Salt Lake City, UT	200546	0.023
	Berkeley, CA	121353	0.016
	New Orleans, LA	390144	0.015
	Richmond, VA	230436	0.015
	Cambridge, MA	118925	0.013
	Boulder, CO	105670	0.010
	Orlando, FL	287435	0.009
	Fort Collins, CO	170245	0.009
	Minneapolis, MN	429605	0.009
	Charleston, SC	143151	0.008
Large	Denver, CO	727211	0.016
	Washington, DC	705749	0.011
	Austin, TX	979263	0.011
	Atlanta, GA	506804	0.010
	Seattle, WA	753655	0.010
	Portland, OR	653467	0.009
	Las Vegas, NV	651297	0.008
	San Francisco, CA	881549	0.007
	Philadelphia, PA	1584064	0.005
	Dallas, TX	1343565	0.005

Table 3: Top 10 "Music Havens" for Small (pop. 10K-100K), Medium (pop. 100K-500K), and Large Cities (pop. 500K+) ranked by Live Music Evert Rate (LMER)

In these three lists, we find several popular tourist towns, e.g., Steamboat Springs, CO, Key West, FL, Las Vegas, NV, as well as college towns, e.g., Burlington & South Burlington, VT (U. of Vermont), Ithaca, NY (Cornell U.), Berkeley, CA (U. of California). We also find several cities, like Austin, TX, Asheville, NC, Atlanta, GA, and New Orleans, LA which all frequently appear on lists of top destinations for "music tourism" in the United States. [7]

Many of the medium and large cities that we identify as music havens also appear on a list of American cities with the most concerts per capita based on data from Seat-

Table 2: A list of all 28 city-level socioeconomic indicators used and their corresponding descriptions.

Geek [8], a large ticket reselling site [31]. Their top cities include Las Vegas, NV, Nashville, TN, Austin, TX, and Denver, CO. This overlap gives us some confidence in our approach but it should be noted that the SeatGeek reports only examines large events from the top 100 grossing artists in the top 100 market areas (i.e., cities).

3.2 Music Deserts

There were 87 cities (7.6% of 1,139 cities) for which there were no events in the LocalifyMusicEvents-USA-2019 dataset. The three "music desert" cities with the largest populations were Renton, WA (pop. 101,747), Deltona, FL (pop. 92,752), and Newton, MA (pop. 88,411). When we examine all three using simple Google web searches, it is clear that there are music events taking place in these cities, as they are listed on their corresponding local websites [9] but not found when we scraped event information from our two data sources (BandsInTown, Facebook). This suggests that our dataset is incomplete due to the imperfect nature of our scraping procedure and our limited set of data sources. We will further discuss these limitations in Section 5.1.

4. CORRELATION WITH SOCIOECONOMIC INDICATORS

In this section, we explore correlations between LMER and the 28 different socioeconomic indicators using statistical testing. If we assume that LMER is a rough indicator of the strength of a local music scene, we can use it to study how music scenes are related to other aspects of our society. We have grouped the 28 socioeconomic indicators into six categories: Transportation, Population, Economics, Age, and Education & Race. The 28 indicators we sampled, as well as the sources they were collected from, are shown in Table 2.

We use a Bonferroni correction when determining statistical significance since we are conducting multiple hypothesis statistical tests [32]. Usually, in significance testing, we perform one statistical test, and obtain the correlations r and p-values p; an indicator is deemed significant if $p < \alpha$, where α is the p-value threshold. The Bonferroni correction, however, deems an indicator significant if $p < \alpha/I$, where I is the number of statistical tests (i.e., one per indicator). In our experiment, there are $I = 28$ indicators and we set α to 0.05; thus, a correlation is significant if the p-value is less than $\alpha/I = 1.8\text{e-}3$.

Table 4 shows the correlation coefficients (or r-values) and the probability of observing the data assuming no correlation (p-value) for each of these indicators grouped in their categories, with the p-values (p) ranked from smallest (most significant) to largest (least significant) for each category.

4.1 Transportation

As shown in Table 4, we find that there is a strong positive correlation between LMER and the first four transportation-based indicators (percentage of people who bike, take public transit, walk, or all three together). Good public transportation reduces the overall cost of attending a show [20] and enables more people to drink alcohol (more safely) at night, which is very often associated with live music events. This finding supports the claim by Terrill et al. [11] that supportive urban infrastructure is an important factor for a strong local music scene. We also considered the mean travel time to work, but did not find it to have a statically significant correlation.

4.2 Population

We observe that population density as well as one-year and ten-year population growth are all positively correlated with LMER. Van der Hoeven and Hitters [19] argue that "density and diversity provide the critical mass of participants that alternative [music] scenes need to thrive." When people are clustered together, it is easier to engage and interact with one another. This idea also relates to population growth; as people with diverse backgrounds immigrate to the city, there is an increase in opportunities for musicians to influence one another in novel ways [18].

4.3 Economics

As we discussed in Section 2.2, many researchers have suggested that having a strong local music scene is good for the local economy [6, 8, 9, 11]. This is consistent with our findings that employment rate, housing cost, per capita income, and median property values are all positively correlated with LMER. We found it interesting that the owner-occupied housing rate is negatively correlated which suggests that there are more live music events when there is a higher proportion of renters relative to homeowners. This is consistent with the observation that home affordability has dropped in the United States, making it harder for young people to own their homes [33], and as we observe in the next subsection, having a larger percentage of younger adults is positively correlated with LMER.

Concerning poverty, Harrison [25] examines how "music projects develop the skills, education levels, incomes, or occupational possibilities of participants living in material poverty, which in turn can enhance their socio-economic status." Accordingly, we might expect a lower poverty rate where there was more live music but we did not find a statistically significant correlation between poverty rate and LMER. We assume therefore that the dynamic between poverty and music is too complex to be measured in a simple quantitative analysis.

4.4 Age

Our results show that cities with a high proportion of young people between the ages of 18 and 29 tend to have a large live music event rate. Conversely, cities with a large population of people under 18 are negatively correlated with LMER. This may be because many music venues (i.e., bars) tend to have 18-and-up and 21-and-up policies due to laws related to serving alcohol. These two results, along with the fact that neither median age nor the percentage of the population under 30 is correlated with LMER, suggest that cities with many young adults (college students, young professionals, aspiring young artists) are places where we expect to have many live music events. Conversely, cities with a relatively large percentage of families are less likely to have a high rate of music events. As mentioned in the previous subsection, age is also positively correlated to home ownership, as decreasing home affordability in the United States has caused fewer young people to own a home; this entails a negative correlation between owner-occupied housing rate and LMER, as higher housing ownership rates means fewer young people, an indicator of a lower LMER.

4.5 Education

Terrill et al. [11] suggests that "cities such as Toronto, Adelaide, Austin, and Berlin point to their large student populations as helpful factors in generating engaged audiences." Our results support this in that we find a positive correlation between LMER and cities with a high proportion of people with undergraduate or graduate degrees. This is also reflected by the fact that many of the top Music Havens in Table 3 are college towns as was discussed in Section 3.1.

4.6 Race

We did not find a significant correlation between our racial diversity index and the LMER. This might be surprising considering the associations suggested between healthy music scenes and demographic diversity [34]. In that, we only explore one indicator that explicitly relates to race, a more thorough analysis is required to explore the complex relationship between race and the strength of music scenes.

5. DISCUSSION

In this paper, we explore how using the live music event rate (LMER) is straightforward to estimate, easy to interpret, and correlated with a large and diverse set of socio-economic indicators. We found a strong positive correlation between LMER and the percentage of people who take public transit, walk, or bike. Education is also strongly correlated with LMER. We also observed that many economic indicators (e.g., employment rate, per capita income, median property value) are also correlated with LMER. Finally, there is a high live music event rate when there is a high proportion of late teens and individuals in their twenties. We did not find a significant correlation between LMER and our race diversity index. This is not to say that no relationship exists, but rather our simplistic analysis did not reveal a statistically significant correlation.

5.1 Limitations

As mentioned in Section 3.2, the music events dataset was not collected for this research, but rather for our Localify.org [10] music events recommendation application. As a result, the scraping was limited in the number of data sources (Facebook & BandsInTown), collected in an ad-hoc manner (snowball sampling), only covers one year of data (2019), and only looks at one country (United States). It is probable that many active artists, venues, and events were not found using our music event data collection process.

To increase our coverage and add redundancy, we have since added additional scrapers (e.g., SongKick, Google, Eventbrite) but the music event data we have scraped in 2020 and 2021 is problematic since such a high percentage of scheduled music events were canceled due to COVID-19. However, even with a large number of scrapers, our approach necessarily ignores music events that do not have a digital footprint. This includes many underground (private house parties, DIY shows), music in religious spaces (e.g., churches), and impromptu performances (e.g., busking). Our future work will be to explore how our approach to scraping music event information might be incomplete and/or biased by taking a detailed census of music events in individual cities using more principled ethnographic techniques (e.g., observation, interviews, historical records).

As described in Section 3, the 28 socioeconomic indicators for each city were collected using three different web sources, rather than one unified source. A more systematic approach is to use one unified source for our data collection, such as ESRI datasets [11] . For certain indicators addressed in Section 2 and Table 1, such as mental/physical health, cultural heritage, and local government regulations on music, we could not find any available quantitative data sources to measure them.

5.2 Future Work

Both popular culture and academic research tend to focus on "music havens" like Nashville, TN and Seattle, WA. These are cities that are known to have a great local music scene and they reap economic, social, and cultural rewards because of it. We, by contrast, are especially interested in identifying cities with underdeveloped music scenes. We plan to study these "music deserts"' and explore how various strategies could be used to help them strengthen their local music scenes. For example, Terrill et al. [11] outlines a number of potential strategies which include developing music-friendly government policies, creating music-focused offices and advisory boards, investing in audience development, and creating music tourism plans. We argue that cities with low local music event rates (LMER) may be good initial candidates for future research involving the study of music deserts.

6. REPRODUCIBILITY

To make our research both fully reproducible and transparent, our full LocalifyMusicEvents-USA-2019 dataset and the associated data processing code (in the form of Jupyter Notebooks) can be found at `https://github.com/JimiLab/LocalifyMusicEventData`.

7. ACKNOWLEDGEMENTS

Doug Turnbull, Tim Clerico, John Hunter, and Emmett Barry all contributed to the Localify.org music event scraper code. This research was supported by NSF grant IIS-1901330/1901168 and NEH grant HAA-280975-21. Finally, we would like to thank the anonymous ISMIR reviewers for their highly constructive feedback.

ABSTRACT

Recent work in music structure analysis has shown the potential of deep features to highlight the underlying structure of music audio signals. Despite promising results achieved by such representations, dealing with the inherent hierarchical aspect of music structure remains a challenging problem. Because different levels of segmentation can be considered as equally valid, specifically designed representations should be optimized to improve hierarchical structure analysis. In this work, unsupervised learning of such representations using a contrastive approach operating at different time-scales is explored. The proposed system is evaluated on flat and multi-level music segmentation. By leveraging both time and the hierarchical organization of music structure, we show that the obtained deep embeddings can encode meaningful patterns and improve segmentation at various levels of granularity.

1. INTRODUCTION

Common approaches for music structure analysis can usually be broken down into two main steps: segmentation and structural grouping [1]. The segmentation task aims at determining the boundary locations between consecutive musical sections while the grouping step consists in assigning labels to each of the retrieved segments based on certain musical similarities. Traditional algorithms for structural segmentation use different hand-crafted features [2] and their combinations to detect abrupt changes of particular musical characteristics or repetitions of certain patterns throughout the song. However, recent progress in deep learning has given rise to new systems automatically producing more robust representations which manage to combine several acoustic characteristics to enhance the recognition of musical sections [3–5]. While these representations have consistently improved downstream segmentation methods, their performance is mostly evaluated on *flat* structural annotations and metrics. However, musical structure naturally exhibits a hierarchical organization where a variety of cues can trigger boundaries between segments of different length [6], depending on the time scale at which they are observed [1]. At the lowest temporal level, short segments might only last a few measures. Coarser annotation levels are generally composed of longer segments, grouping various shorter fragments into larger musically meaningful units (ex: chorus, verse ...). This nested organization of musical events at different levels holds crucial information about music structure [7]. While the original task of music structure analysis is commonly performed at a pre-defined level of granularity (i.e. *flat* segmentation), the problem of *hierarchical* structural analysis consists in predicting a set of segmentation candidates called hierarchy, ordered by their amount of detail (from the coarsest to the most refined level). Recent efforts have been made to compile datasets with multi-level structural annotations [2, 8], which greatly facilitates the study of musical structure in a hierarchical manner. Although a few methods have been proposed for such task, the role of hierarchy in music structure has never been explicitly considered while building better-suited representations of audio music signals prior to segmentation.

1.1 Our contributions

In this work, we propose a deep unsupervised hierarchical metric learning approach for music structure analysis. We show that leveraging both time information and the hierarchical structure of music can help building efficient representations for music segmentation at different levels without requiring any supervision from structural annotations. We demonstrate the effectiveness of these representations for both flat and multi-level segmentation and show that they can accommodate structural annotations of varying styles and levels.

1.2 Related work

The method proposed here builds upon recent work in music structure analysis devoted to finding efficient representations using deep learning methods to improve already existing downstream algorithms. The work by McCallum [3]

Crayencour, "Learning Multi-Level Representations for Hierarchical Music Structure Analysis", in *Proc. of the 23rd Int. Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

proposes an unsupervised method to learn deep features using a triplet-based approach. It relies on the assumption that frames temporally close to each other are more likely to belong to the same musical section than those separated by a certain amount of time. Therefore, triplets are sampled in such a way that the temporal distance between the anchor point and the positive example is smaller than the distance separating the anchor from the negative example. Wang et al. [4] adopt a similar approach by using structural annotations in a supervised fashion to mine informative sets of frames.

One of the main challenges in estimating the structure of a musical piece is to account for the different temporal levels at which it can be decomposed. Up to now, only a few approaches have been proposed for the task of multi-level segmentation. McFee and Ellis [9] use spectral clustering to decompose an enhanced self-similarity matrix and produce segmentations at different temporal levels. This approach is later improved by Tralie and McFee [10] where the input self-similarity matrix is obtained by combining different features using Similarity Network Fusion. Salamon et al. [5] further extend this method by employing two types of deep embeddings along with CQT features. They capture local timbral patterns with few shot-learning and long-term similarities with disentangled deep metric learning [11]. While these works demonstrate the advantage of combining multiple representations of a same signal to extract meaningful structural patterns, our approach shows instead that these can be directly encoded into the representations using time proximity and the hierarchy of music structure.

2. HIERARCHICAL REPRESENTATIONS

The method introduced here constructs deep representations which allow for structural segmentations at various time-scales. To facilitate the decomposition of a song at different levels, these representations should provide strong discriminative capabilities for time frames belonging to different musical sections and separated by a large amount of time. Conversely, they should be more homogeneous for frames belonging to the same section and happening within a short time interval. As section lengths might vary from one annotator to another due to the ambiguity of the task [1], the aforementioned constraint is imposed at different temporal scales. Additionally, most datasets for music structure analysis come with only one level of annotations, which motivates us to learn such representations in an unsupervised fashion, taking advantage of large quantities of unlabelled data. A base convolutional neural network is used to output embeddings which are divided into multiple sub-regions. Each of them is optimized independently using specific triplets of frames efficiently sampled to encode the temporal structure of the song at different levels. We show that each level of the final representations can model frames proximity with its own amount of granularity.

2.1 Sampling

The objective of the sampling method introduced by McCallum [3] is to build triplets of frames where the anchor and the positive example belong to the same musical section, while the anchor and the negative example are labelled differently. The method proposed here can be viewed as its multi-level extension. A hierarchy is defined as a set of L levels of structural segmentations ordered from the coarsest to the most refined. For each level $\ell \in \{0; \dots; L-1\}$ in the hierarchy, triplets of beat indices are sampled using a specific set of parameters $\delta = \{\delta^\ell_{p,min}, \delta^\ell_{p,max}, \delta^\ell_{n,min}, \delta^\ell_{n,max}\}$. Intuitively, they rule how "close" or "far away" from the anchor the positive and negative examples will be sampled throughout the song. More specifically, for a given anchor beat index i_a, positive and negative examples respectively located at beat indices i_p and i_n are uniformly sampled from the interval I^ℓ_p defined by $\delta^\ell_{p,min}$ and $\delta^\ell_{p,max}$ and I^ℓ_n specified by $\delta^\ell_{n,min}$ and $\delta^\ell_{n,max}$. An example for an arbitrary level ℓ is shown in Figure 1. The δ parameters actually define a notion of temporal distance d_ℓ between frames at a given level of the hierarchy (analogous to a notion of dissimilarity). Therefore, the set of triplets T_ℓ at level ℓ can be expressed as:

$$T_\ell = \{(i_a, i_p, i_n; l) \mid d_\ell(x_a, x_p) < d_\ell(x_a, x_n)\} \quad (1)$$

where x_k is the input feature patch observed at beat index i_k, $i^\ell_p \sim \mathcal{U}(I^\ell_p)$ and $i^\ell_n \sim \mathcal{U}(I^\ell_n)$.

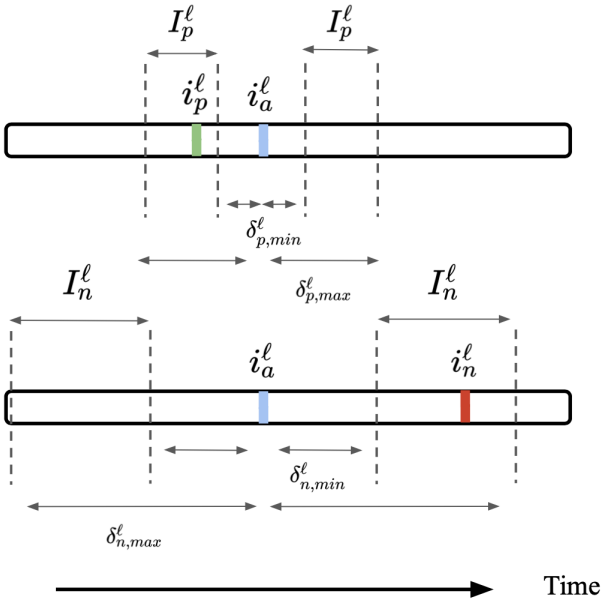

Figure 1. Initial triplet sampling method at level ℓ.

In order for the learned hierarchy levels to remain consistent with one another, monotonicity is encouraged by modifying the initial triplet mining technique. In addition to the time constraint imposed on triplets of the same level, their probability of being sampled is restricted from one level in the hierarchy to the next. For a randomly sampled anchor index at level $\ell = 0$, a complete triplet (i^a_0, i^p_0, i^n_0) is built only using time proximity (*i.e.* δ parameters). Then

for each level $\ell \in \{1; \ldots; L-1\}$, the positive example is sampled closer and closer to the same anchor (*i.e.* $\delta^{\ell}_{p,min}$ and $\delta^{\ell}_{p,max}$ decrease), whereas the negative is obtained by selecting the positive example from level $\ell - 1$. This way, going deeper into the hierarchy means that the representations get more refined to detect short-term musical patterns. The modified sampling method is summarized in Figure 2. The process is then repeated by starting over from level 0, going down the hierarchy with the same anchor index, transferring the negative example from the current to the next level, and uniformly sampling the positive ones using the right δ parameters. At the end, the whole training set for all levels of the hierarchy is given by combining every set of triplets T_ℓ level-wise: $T = \{T_\ell\}_{\ell=0}^{L-1}$.

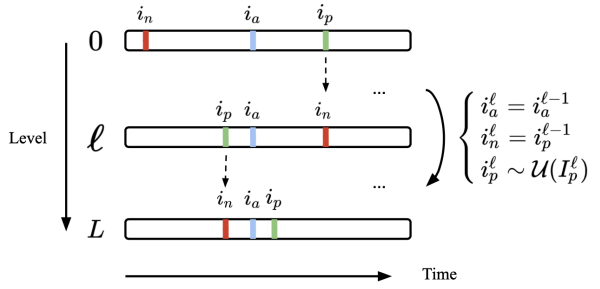

Figure 2. Modified triplet sampling, moving downwards in the hierarchy.

2.2 Disentangled hierarchy levels

During training, the model is shown triplets sampled at different hierarchy levels and should optimize the corresponding sub-regions of the output embeddings. We adapt the method introduced by Veit et al. [12], called Conditional Similarity Networks. This method has already proven to be efficient in the context of multi-dimensional music similarity learning [11], where a joint model learns compact representations of music audio signals complying with different similarity criteria, namely genre, mood, instrumentation and tempo. We propose to extend it to the hierarchical case: to model the different temporal distances d_ℓ, a set of L masking functions $m_\ell \in \{0,1\}^n$ that are applied to the embedding space of size n is defined. Each mask can be interpreted as an element-wise gating function selecting the relevant dimensions of the embedding corresponding to a particular level of the hierarchy. For a given triplet (x_a, x_p, x_n) at level ℓ, the training objective becomes:

$$\mathcal{L}(x_a, x_p, x_n) = [D_\ell(x_a, x_p) - D_\ell(x_a, x_n) + \alpha]_+, \quad (2)$$

$$D_\ell(x_i, x_j) = \| \, m_\ell \circ [f(x_i) - f(x_j)] \, \|_2^2 \quad (3)$$

where $\circ$ is the Hadamard product, $[.]_+$ denotes the Hinge loss, α the margin parameter and $f(x)$ is the projection of x into the embedding space by the convolutional neural network. An example is illustrated in Figure 3, where $L = 3$ and $\ell = 1$. Since going deeper into the hierarchy results in triplets of frames getting temporally closer to each other, it is unnecessary for the model to separate samples by the same distance margin at all levels. Therefore, margin values were evenly distributed within the range $[0.05, 0.1]$ so that for each level $\ell \in \{0; \ldots; L-2\}$, we have $\alpha_\ell > \alpha_{\ell+1}$.

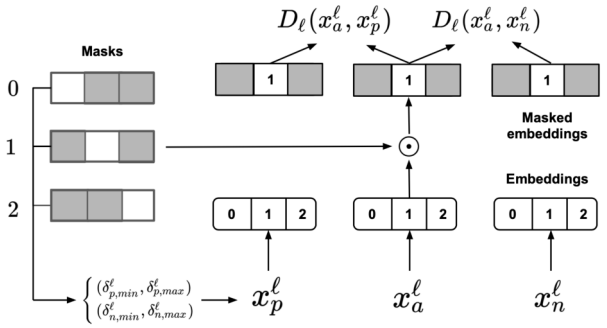

Figure 3. Training pipeline for $\ell = 1$ and $L = 3$. At each iteration, the current hierarchy level defines the set of δ parameters to sample the positive example. The mask here conserves the sub-region corresponding to level $\ell = 1$.

3. EXPERIMENTS

The evaluation of our method is divided into three distinct parts. First, we consider the problem of boundary detection on flat annotations using the SALAMI dataset. Second, we verify if the learned hierarchical representations improve multi-level segmentation predictions on that same dataset using the two-level structural annotations available. We finally demonstrate the flexibility of our approach and provide additional results on other commonly used datasets for music structure analysis where their original flat annotations have been automatically expanded beforehand [13].

3.1 Datasets

We use five different datasets in our evaluation:

SALAMI: the Structural Annotations for Large Amounts of Music Information (SALAMI) [8] is the most substantial dataset for music structure analysis. It contains $1,359$ tracks ranging from classical, jazz, popular to world and live music. Each track is provided with two levels of structural annotations. We use a subset of 884 songs labelled by two different annotators. Therefore, for each track contained in this subset, we end up with a total of 4 segmentation ground-truths (2 annotators $\times$ 2 levels of granularity). In the rest of this work, this subset is referred as SALAMI.

BeatlesTUT: a revised version of 174 annotated Beatles songs, originally released in the Isophonics dataset [14] and corrected by researchers from Tampere University of Technology.

RWC-Pop: the Popular subset of the RWC dataset [15] contains 100 songs with section annotations. Note that two versions of these annotations are available online; here the ones originally provided by the authors (AIST) are used.

RWC-Jazz: the Jazz subset of the RWC dataset [15] is composed of 50 songs from various Jazz sub-genres such as Vocal, Big Band, Modal, Funky, Free or Fusion Jazz.

JAAH: the Audio-aligned jazz harmony dataset (JAAH) [16] is composed of 113 tracks selected from "The Smithsonian Collection of Classic Jazz" and "Jazz: The Smithsonian Anthology", covering various performers, sub-genres and historical periods.

3.1.1 Obtaining multi-level annotations:

For all datasets but SALAMI, we apply automatic hierarchy expansion [13] before evaluating multi-level segmentation. As can be seen in the descriptive statistics from Table 1, both the distributions of section labels and segment durations vary from one dataset to another. This difference can either be explained by the style of annotations (*i.e.* label taxonomy, desired level of detail...) or the music genre. As a consequence, the average number of levels obtained after automatic hierarchy expansion is dependent on the repetition of section labels and their semantic structure, which varies with the annotation process as well.

Dataset	N	Uni	Seg	Dur	Levels
SALAMI^0 (upper)	884	5.3	10.9	63.5	2.0
SALAMI^0 (lower)	884	10.0	33.1	18.4	2.0
SALAMI^1 (upper)	884	5.0	11.2	61.1	2.0
SALAMI^1 (lower)	884	9.2	34.1	18.0	2.0
BeatlesTUT	174	5.6	10.1	36.1	2.5
RWC-Pop	100	8.9	16.4	28.5	2.9
RWC-Jazz	50	14.2	19.9	32.1	2.8
JAAH	113	6.2	8.0	63.1	2.0

Table 1. Datasets descriptive statistics. N: number of annotated songs. Uni: average number of unique section labels per song. Seg: average number of segments per song. Dur: average duration of each section per song (in beats). Levels: average number of annotation levels per song after automatic hierarchy expansion. SALAMI^i: ith annotator.

3.1.2 Training data:

Since this work falls under the scope of unsupervised learning, a non annotated external audio collection is used for training. It is composed of $23,725$ tracks, spanning various musical genres such as rock, popular, rap, jazz, electronic or classical. These were retrieved from publicly available playlists and the audio obtained from Youtube. Care has been taken to discard any track from this external collection also present in one of the testing datasets.

3.2 Evaluation metrics

3.2.1 Flat segmentation:

For boundary detection, we report the F-measure [1] of the trimmed boundary detection hit-rate with a 3-second tolerance window (F_3) on the original annotations. We also report the F-measure of frame pairwise clustering [18] (F_{pairwise}), which gives another view on flat segmentation performance in terms of frame-wise section assignment.

[1] All evaluations are done using the mir_eval package [17].

3.2.2 Multi-level segmentation:

The second part of the evaluation on multi-level segmentation is carried out using the L-measure [7]. This metric allows for comparing hierarchies of segmentations operating at different scales. First, the reference hierarchy H^R is decomposed into a finite number of time instants (*i.e.* frames). Then, the set $A(H^R)$ of all triplets of frames (i, j, k) such that i and j receive the same label deeper in the hierarchy than i and k is retrieved. The same process is repeated with the same set of time instants for the estimated hierarchy H^E to obtain $A(H^E)$. Finally, the L-precision, L-recall and L-measure are derived by comparing $A(H^R)$ against $A(H^E)$. As noted in previous work [5, 10], hierarchies estimated with greater depth than reference annotations can make the L-precision metric unreliable. Therefore, our evaluation focuses on the L-recall, indicating how much of the reference hierarchy is retrieved in the estimated one. For this part of the evaluation, the expanded version of each dataset is used except for SALAMI, where for comparison purposes, the reference hierarchy only comprises both of the original annotation levels provided by each annotator (*upper* and *lower*).

3.3 Input features

All tracks are resampled at 22.05 kHz. Previous work has demonstrated that homogeneous regions and sharp changes of timbral content can be a good indicator of section transitions [19]. Therefore, we use log-scaled mel-spectrograms, with a window and hop size of 2048 and 256 respectively. We compute 60 mel-bands per frame. Beats are estimated for all tracks using the Librosa [20] implementation of the beat tracking algorithm from Ellis [21]. For both feature types, patches of 512 frames ($\simeq 5.94$s) are observed, centered at each detected beat location.

3.4 Implementation details

3.4.1 Network architecture:

We use a basic convolutional neural network architecture composed of 3 convolutional blocks, each comprising a convolutional and a max-pooling layer and Relu activation, followed by two fully-connected layers with Relu activations and a third fully-connected layer with linear activation. All convolutional layers use a kernel size of $(6, 4)$. A common practice in contrastive learning is to constrain the learned representations to lie within the unit hypersphere [22]. Therefore, the output embeddings are L2-normalized prior to distance calculations. The models were implemented with Pytorch 1.7.1 [23]. The RMSProp optimizer with default parameters is used. All models are trained on the non-annotated external audio collection described in Section 3.1 for a maximum of 200 epochs. The learning rate is set to 10^{-4} and dropout [24] is applied with probability 0.1 after each convolutional block and 0.2 after each fully-connected layer. All models [2] return embeddings of dimension $n = 128$.

[2] Code: `github.com/morgan76/HE`

3.4.2 Masks design:

In previous work, it was found beneficial to learn the masks during training to promote information sharing across similarity dimensions [12]. As in the method proposed by Lee et al. [11], we found that this did not bring any major improvement. Since information is already shared implicitly among the different hierarchy levels by the sampling strategy detailed in Section 2.1, the masks are kept disjoint from one another with equal length. After some preliminary experiments, the number of hierarchy levels $L = 4$ has been found as a good compromise between the diversity of triplets at each level and the temporal scale between the top and bottom ones.

3.4.3 Batch sampling scheme:

During training, mini-batches of size 120 are composed of 10 anchor points uniformly sampled from one song, and from which 12 triplets are derived (3 for each level). To choose good sampling parameters, we used both annotation levels of the held-out subset of SALAMI and measured the amount of true positive and true negative examples while varying $\delta_{p,min}$ and $\delta_{p,max}$ of level $\ell = 0$. It was found that setting $\delta_{p,min} = 32$ and $\delta_{p,max} = 64$ provided a good balance between the true positives rate at level $\ell = 0$ and the true negatives rate at level $\ell = 1$. For the case where $L = 4$, the rest of the parameters were set such that each level spans the same duration in beats (i.e. 16 beats) under the maximum value of 64 beats. All sampling parameters δ used for each level are summarized in Table 2.

L	ℓ	$\delta_{p,min}$	$\delta_{p,max}$	$\delta_{n,min}$	$\delta_{n,max}$
1	0	1	16	1	128
4	0	48	64	64	128
	1	32	48	48	64
	2	16	32	32	48
	3	1	16	16	32

Table 2. Sampling parameters (in beats) used in our experiments for $L = 1$ and $L = 4$ hierarchy levels.

3.5 Downstream algorithms and baselines

A common way of evaluating deep representations for music structure analysis is to measure the improvement made when combined with downstream segmentation methods. While there exists a variety music segmentation algorithms in the literature [1, 2], the one employed in these experiments was chosen to facilitate comparison against previous work. Boundary detection and section grouping on flat annotations as well as multi-level segmentation are performed with spectral clustering [9], as it remains the only unsupervised method that can output multiple levels of segmentation while being competitive. Additionally, it appears as a well-suited downstream method for hierarchical features since it operates on a graph decomposition of the audio signal. The proposed triplet sampling method forces the learned features to discriminate frames temporally close to one another at different levels in the hierarchy. Consequently, each sub-region in the embeddings learns one possible decomposition of the song. Applied on each of these sub-regions, spectral clustering can take advantage of the graph sub-structures proper to each level in order to efficiently retrieve the overall structure of the song. The original algorithm [9] takes two distinct audio features as input (MFCC and CQT), here, both features are replaced by the representations proposed in this work. Results obtained with the whole embedding matrices are denoted by HE (Hierarchical Embeddings). As an upper-bound of the proposed system, section grouping and multi-level segmentation are also performed using each individual sub-region of the embeddings (*i.e.* hierarchy levels), and the best results obtained across levels (denoted by HE_{best}) are reported. In a use case scenario, this can be seen as selecting the most adapted level of representation for each track in the testing set given a desired amount of granularity. For SALAMI, boundary detection is performed per annotator. For each, the scores obtained on both annotation levels (*upper* and *lower*) are computed both separately and combined together (best score between both levels per annotator is kept, noted *combined*). As an example, "$\text{HE}_{0,\text{best}}$" corresponds to the score obtained for the first annotator, selecting for each track the embedding level which maximizes the metric considered. In addition to results from previous work [5,9], those obtained here are compared against the method proposed by McCallum [3] (which comes down to setting $L = 1$ as described in Table 2), it is denoted as FE (Flat Embeddings).

4. RESULTS

4.1 Flat segmentation

Flat segmentation results on SALAMI are given in Table 3. The representations proposed in this work yield competitive results against the reported baselines on all the metrics considered. This trend is accentuated when the best embedding sub-region is selected. For *lower* annotations, the learned representations improve over traditional features. However, they do not perform better than those from McCallum [3], since this method uses sampling parameters that are more adapted to this level of annotation. The best-level scenario shows that the smallest temporal scales used during training (levels $\ell = 2, 3$) allow for the detection of very small regions of homogeneous timbral content, which helps detecting section changes at this level of annotation. The higher pairwise clustering scores indicate that these small detected regions are homogeneous enough to be identically labelled with spectral clustering (k-means step).

For the *upper* annotations, the results for boundary detection and pairwise clustering constantly improve over the reported baselines, indicating that for higher levels in the hierarchy, the proposed representations improve homogeneity inside annotated sections. Long-term similarities are implicitly captured by the highest embedding levels ($\ell = 0, 1$), yielding discriminative features able to separate consecutive musical sections at that level.

Finally, for both annotation levels combined, all models

perform better than when considering each level independently. The fact that difficult examples at the *lower* level are better managed at the *upper* one and vice-versa indicates that the representations learned are not specific to any particular annotation level. The very small performance gap across annotators also shows that these same representations capture relevant structure characteristics that are shared between them.

Level	Method	F_3	$F_{pairwise}$
lower	LSD [9]	0.525 ± 0.19	0.561 ± 0.16
	FE_0 [3]	0.624 ± 0.14	0.561 ± 0.14
	HE_0	0.611 ± 0.16	0.580 ± 0.15
	$HE_{0,best}$	0.643 ± 0.15	0.580 ± 0.15
	FE_1 [3]	0.611 ± 0.14	0.563 ± 0.14
	HE_1	0.600 ± 0.15	0.581 ± 0.14
	$HE_{1,best}$	0.635 ± 0.15	0.580 ± 0.14
upper	SNF [10]	0.456	0.567
	DEF [5]	0.564	0.600
	LSD [9]	0.579 ± 0.15	0.652 ± 0.13
	FE_0 [3]	0.568 ± 0.17	0.694 ± 0.14
	HE_0	0.597 ± 0.18	0.714 ± 0.14
	$HE_{0,best}$	0.627 ± 0.16	0.719 ± 0.14
	FE_1 [3]	0.559 ± 0.17	0.697 ± 0.14
	HE_1	0.595 ± 0.18	0.718 ± 0.14
	$HE_{1,best}$	0.625 ± 0.16	0.720 ± 0.14
combined	HE_0	0.665 ± 0.13	0.730 ± 0.14
	$HE_{0,best}$	0.711 ± 0.12	0.733 ± 0.14
	HE_1	0.662 ± 0.13	0.731 ± 0.14
	$HE_{1,best}$	0.707 ± 0.12	0.731 ± 0.14

Table 3. Boundary detection and section grouping results on SALAMI.

4.2 Multi-level segmentation

The results obtained for multi-level segmentation are reported in Table 4. When employing the full embedding representation, the performance on multi-level segmentation is competitive in terms of L-recall with previous work. As well as for boundary detection, selecting the best embedding sub-region leads to even further improvement. The importance of keeping inter-annotator agreement as a reference for comparison in multi-level segmentation has previously been argued [10]. It is found that the proposed representations result in multi-level segmentations that adapt to both annotators, within the range of the inter-annotator agreement reported by Tralie and McFee [10].

Method	L-precision	L-recall	L-measure
Inter-annot	0.664	0.664	0.654
LSD [7]	0.419	0.636	0.498
SNF [10]	0.431	0.668	0.517
DEF [5]	0.435	0.673	0.520
FE_0 [3]	0.412 ± 0.10	0.677 ± 0.13	0.505 ± 0.11
HE_0	0.413 ± 0.11	0.680 ± 0.13	0.507 ± 0.11
$HE_{0,best}$	0.432 ± 0.11	0.694 ± 0.13	0.527 ± 0.11
FE_1 [3]	0.413 ± 0.10	0.663 ± 0.12	0.503 ± 0.10
HE_1	0.418 ± 0.11	0.671 ± 0.13	0.509 ± 0.11
$HE_{1,best}$	0.423 ± 0.11	0.686 ± 0.13	0.517 ± 0.11

Table 4. Multi-level segmentation results on SALAMI. Inter-annot denotes the inter-annotator agreement.

4.3 Additional evaluation

In Table 5, the results obtained for boundary detection, section grouping and multi-level segmentation on additional datasets using the whole embedding matrices are summarized. The boundary detection scores obtained for BeatlesTUT and RWC-Pop fall within the same range, where more specifically, the score on RWC-Pop is higher than the one obtained by Wang et al. [4] with representations learned via supervised contrastive learning. However, a significant drop is observed for the two remaining datasets: RWC-Jazz and JAAH. If the music genre might play a role in this performance gap, it is also worth considering some statistics of these datasets summarized in Table 1. For RWC-Jazz, the high number of unique section labels compared to the total number of segments might cause some errors during the section grouping step done at the frame level with k-means (last step of the spectral clustering method). Regarding the JAAH dataset, given the low average number of segments per track, the segmentation method returns more boundaries than those originally annotated, therefore reducing the hit-rate precision and F-measure. For all metrics considered, other experiments have shown that hierarchical representations also performed better than their flat counterparts [3], of which due to space constraints, the results are not reported here.

Dataset	F_3	$F_{pairwise}$	L-P	L-R	L-M
BeatlesTUT	71.77	72.25	49.32	75.25	59.37
RWC-Pop	68.07	65.35	47.02	77.06	58.30
RWC-Jazz	55.05	58.51	32.89	81.80	45.76
JAAH	55.57	76.72	46.49	81.18	58.55

Table 5. Boundary detection, section grouping and multi-level segmentation results on additional datasets (in percentage) with the whole embedding matrix. L-P: L-precision, L-R: L-recall, L-M: L-measure.

The L-recall values obtained across datasets remain within the same range, regardless of the performance achieved on flat segmentation or section grouping. The temporal notion induced during sampling helps adapting to different musical genres or annotation sources. Even though the learned representations may not always fit with one specific level in the annotations, most of the reference structure hierarchies are captured and more refined levels of segmentation are discovered.

5. CONCLUSION

In this work, unsupervised contrastive learning of deep representations for music structure analysis at different time-scales has been explored. By leveraging time information and the hierarchical aspect of music structure, the resulting representations facilitate single and multi-level segmentation while being robust against different types of annotations. Future work includes searching for better-suited architectures to detect musical patterns at different time scales and automatically combine them to accommodate specific annotation styles or levels.

ABSTRACT

An ideal music synthesizer should be both interactive and expressive, generating high-fidelity audio in realtime for arbitrary combinations of instruments and notes. Recent neural synthesizers have exhibited a tradeoff between domain-specific models that offer detailed control of only specific instruments, or raw waveform models that can train on any music but with minimal control and slow generation. In this work, we focus on a middle ground of neural synthesizers that can generate audio from MIDI sequences with arbitrary combinations of instruments in realtime. This enables training on a wide range of transcription datasets with a single model, which in turn offers note-level control of composition and instrumentation across a wide range of instruments. We use a simple two-stage process: MIDI to spectrograms with an encoder-decoder Transformer, then spectrograms to audio with a generative adversarial network (GAN) spectrogram inverter. We compare training the decoder as an autoregressive model and as a Denoising Diffusion Probabilistic Model (DDPM) and find that the DDPM approach is superior both qualitatively and as measured by audio reconstruction and Fréchet distance metrics. Given the interactivity and generality of this approach, we find this to be a promising first step towards interactive and expressive neural synthesis for arbitrary combinations of instruments and notes.

1. INTRODUCTION

Neural audio synthesis of music is a uniquely difficult problem due to the wide variety of instruments, playing styles, and acoustic environments. Among current approaches, there is often a trade-off between interactivity and generality. Interactive models, such as DDSP [3,4], offer realtime synthesis and fine-grained control, but only for specific types of instruments with domain-specific training information. On the other hand, models like Jukebox [5] are much more general and allow for training on any type of music, but are several orders of magnitude slower than realtime and offer more limited and global control, such as lyrics and global style (though with some early MIDI conditioning experiments).

Natural language generation and computer vision have seen dramatic recent progress through scaling generic encoder-decoder Transformer architectures [6, 7]. MT3 [8, 9] demonstrated that such an approach can be adapted to Automatic Music Transcription, transforming spectrograms to variable-length sequences of notes from arbitrary combinations of instruments. This generic approach enables training a single model on a wide variety of datasets: anything with paired audio and MIDI examples.

In this paper, we explore the inverse problem: finding a simple and general method to transform variable-length sequences of notes from arbitrary combinations of instruments into spectrograms. By pairing this model with a spectrogram inverter, we find that we are able to train on a wide variety of datasets and synthesize audio with note-level control over both composition and instrumentation.

To summarize, our contributions include:

- Demonstrating that the generic encoder-decoder Transformer approach used for multi-instrument transcription can likewise be adapted for multi-instrument audio synthesis.
- Realtime synthesis enabling interactive note-level control over both composition and instrumentation, by pairing a MIDI-to-spectrogram Transformer model with a GAN spectrogram inverter, and training on a wide range of paired audio/MIDI datasets (synthetic and real) with diverse instruments.
- Adapting DDPM decoding for arbitrary length synthesis without edge artifacts, through additional autoregressive conditioning on segments ($\sim$5 seconds) of previously generated audio.
- Quantitative metrics and qualitative examples demonstrating the advantages of segment-wise diffusion decoders over frame-wise autoregressive decoders for continuous spectrograms.

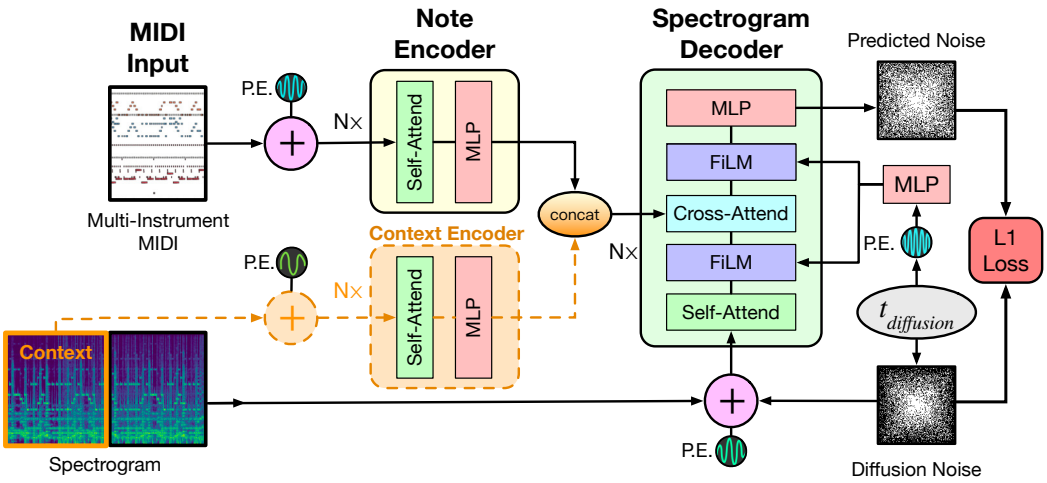

Figure 1. Training configuration for our spectrogram diffusion model. The architecture is an encoder-decoder Transformer that takes a sequence of note events as input and outputs a spectrogram. We train the decoder stack as a Denoising Diffusion Probabilistic Model (DDPM) [1], where the model learns to iteratively refine Gaussian noise into a target spectrogram (Figure 2). We generate ∼5 second spectrogram segments, and to ensure a smooth transition between these segments we (optionally) encode the previously generated segment in a second encoder stack. At inference time, a generated spectrogram is inverted to a waveform using a model similar to MelGAN [2]. "P.E." means Positional Encoding.

2. RELATED WORK

Neural audio synthesis first proved feasible with autoregressive models of raw waveforms such as WaveNet and SampleRNN [10, 11]. These models were adapted to handle conditioning from latent variables [12, 13] or MIDI notes [14–17], but suffer from slow generation due to needing to run a forward pass for every sample of the waveform. Real-time synthesis often requires the use of specialized CPU and GPU kernels [18, 19]. These models also have limited temporal context due to the high sample rate of audio (e.g., 16kHz or 48kHz), where even the largest receptive fields (thousands of timesteps) can equate to less than a second of audio.

Approaches to overcome these speed limitations of waveform autoregression have focused on generating audio directly with a single forward pass. Architectures commonly either use GANs [20–23], controllable differentiable DSP elements such as oscillators and filters [3,4,24–27], or both [28, 29]. These models often focus on limited domains such as generating a single instrument/note/voice at a time [4, 15, 16, 30]. Here, we focus our search on architectures capable of both realtime synthesis, note-level control, and synthesizing mixtures of multiple polyphonic instruments at once.

Researchers have also overcome temporal context limitations of waveform autoregression by adopting a multi-stage approach, first creating coarser audio representations at a lower sample rate, and then modeling those representations with a predictive model before decoding back into audio. For example, Jukebox and Soundstream [5,31,32] use a Transformer to autoregresively model the discrete vector-quantized codes [33] of a base waveform autoencoder.

Tacotron architectures [34–36] have demonstrated that straightforward spectrograms can be an effective audio representation for multi-stage generation, first autoregressively generating continuous-valued spectrograms, and then synthesizing waveforms with a neural vocoder. The success of this approach led to a flurry of research into spectrogram inversion models, including streamlined waveform autoregression, GANs, normalizing flows, and Denoising Diffusion Probabilistic Models (DDPMs) [1, 2, 18, 37–39]. Our approach here is inspired by Tacotron. We use an autoregressive spectrogram generator paired with a GAN spectrogram inverter as a baseline, and further improve upon it with a DDPM spectrogram generator.

DDPMs and Score-based Generative Models (SGMs) have proven well-suited to generating audio representations and raw waveforms. Speech researchers have demonstrated high-fidelity spectrogram inversion [38, 39], text-to-speech [40, 41], upsampling [42], and voice conversion [43, 44]. Musical applications include singing synthesis of individual voices [45, 46], drums synthesis [47], improving the quality of music recordings [48], symbolic note generation [49], and unconditional piano generation [50]. Similar to singing synthesis, here we investigate DDPMs for spectrogram synthesis, but focusing on arbitrary numbers and combinations of instruments.

3. ARCHITECTURE

We approach the problem of audio synthesis using a two-stage system. The first stage consists of a model that produces a spectrogram given a sequence of MIDI-like note events representing any number of instruments. We then use a separate model to invert those spectrograms to au-

[1] https://github.com/magenta/music-spectrogram-diffusion

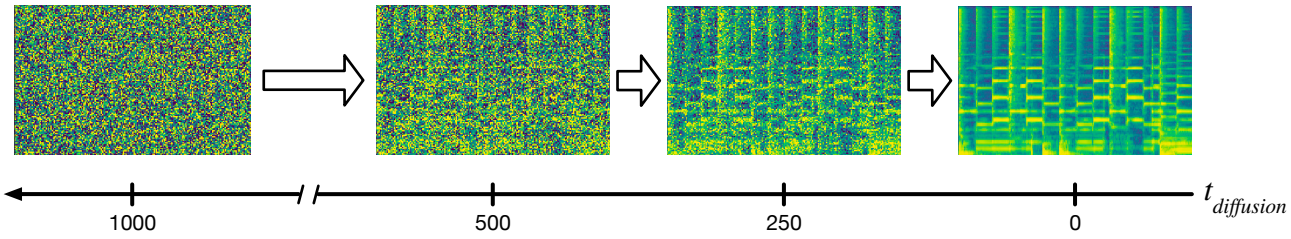

Figure 2. Our decoder stack is trained as a Denoising Diffusion Probabilistic Model (DDPM) [1]. The model starts with Gaussian noise as input and is trained to iteratively refine that noise toward a target, conditioned on a sequence of note events and the spectrogram of the previously rendered segment. This figure illustrates the diffusion process for one example segment.

dio samples. Our model for the first stage is an encoder-decoder Transformer architecture, shown in Figure 1. The encoder takes in a sequence of note events and, optionally, a second encoder uses an earlier part of the spectrogram as context. These embeddings are passed to a decoder, which generates a spectrogram corresponding to the input note sequence. Here, we explore training the decoder autoregressively (Section 3.1) or as a Denoising Diffusion Probabilistic Model (DDPM) [1] (Section 3.2).

Our architecture uses the encoder-decoder Transformer from T5 [51] with T5.1.1 [2] improvements and hyperparameters. We use the same note event vocabulary and note sequence encoding procedure as MT3 [8]. We find that training on a full song is prohibitive in terms of memory and compute due to the quadratic scaling of self-attention with sequence length, so we split note sequences into segments. Specifically, we train models with 2048 input positions for note events and 256 output positions for spectrogram frames. Each spectrogram frame represents 20 ms of audio, so each segment is 5.12 seconds.

Rendering audio segments independently introduces the problem of how to ensure smooth transitions between the segments once they are eventually concatenated together to form a full musical piece. We address this problem by providing the model with the spectrogram from the previously rendered segment, meaning that this model is autoregressive at the segment level. This context segment has its own encoder stack with 256 input positions. As seen in Figure 1, the outputs of both encoder stacks are concatenated together as input for cross-attention in the decoder layers.

We use sinusoidal position encodings, as in the original Transformer paper [52]. However, we found better performance if we decorrelated the position encodings of each network, as they have different meanings. We decorrelate the encodings by applying a unique random channel permutation and phase offset for the sinusoids used in each of the encoder and decoder stacks.

3.1 Autoregressive Decoder

As an initial approach, we took inspiration from Tacotron [34, 35], and trained the decoder as an autoregressive model on the continuous spectrograms. In this setting, standard causal masking was applied throughout the self-attention layers. The inputs and outputs are continuous spectrogram frames, and the model was trained with a mean-squared error (MSE) loss on those frames. Mathematically, this is equivalent to training a continuous autoregressive model with a Gaussian output distribution with isotropic and fixed variance. We also tried training models using mixtures of several Gaussians, but they tended to be unstable during sampling.

For sampling we use a fixed variance (0.2 in units of log magnitude) that is added to the outputs of every inference step. In practice, this "dithering" reduced strong audio artifacts due to overly smooth outputs.

Despite this, these baseline models still produce spectrogram outputs that tend to be blurry and contain jarring artifacts in some frames. We hypothesized an approach enabling incremental, bidirectional refinement, and model dependencies between frequency bins, could help resolve these issues.

3.2 Diffusion Decoder

Taking inspiration from recent successes in image generation such as DALL-E 2 and Imagen [53, 54], we investigated training the decoder as a Denoising Diffusion Probabilistic Model (DDPM) [1].

DDPMs are models that generate data from noise by reversing a Gaussian diffusion process that turns an input signal $\mathbf{x}$ into noise $\epsilon \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$. This *forward* process occurs over diffusion timesteps $t \in [0, 1]$ (not to be confused with time for the audio) resulting in noisy data $\mathbf{x_t} = \alpha_t \mathbf{x} + \sigma_t \epsilon$, where $\alpha_t \in [0, 1]$ and $\sigma_t \in [0, 1]$ are noise schedules that blend between the original signal and the noise over the diffusion time. In this work, the decoder, ϵ_θ with parameters θ, is trained to predict the added noise given the noisy data by minimizing an L1 objective,

$$\mathop{\mathbb{E}}_{\mathbf{x},\mathbf{c},\epsilon,t} w_t ||\epsilon_\theta(\mathbf{x_t}, \mathbf{c}, t) - \epsilon||_1^1 \quad (1)$$

where w_t is a loss weighting for different diffusion timesteps and $\mathbf{c}$ is additional conditioning information for the decoder. Schedules for w_t, α_t and ϵ_t are hyperparameters chosen to selectively emphasize certain steps in the reverse diffusion process.

[2] https://github.com/google-research/text-to-text-transfer-transformer/blob/main/released_checkpoints.md#t511

During sampling, we follow the *reverse* diffusion process by starting from pure independent Gaussian noise for each frame and frequency bin and iteratively use noise estimates to generate new spectrograms with gradually decreasing noise content. Full details of this process can be found in Ho et al. [1] and source code is provided for clarity [3]. A visualization of the forward and reverse diffusion process can be seen in Figure 2.

Because the diffusion process expects inputs to be in the range $[-1, 1]$, we scale spectrograms used for training targets and audio context to that range before using them. During inference, we scale model outputs back to the expected spectrogram range before converting them to audio.

During training, we used a uniformly-sampled noise time step in $[0, 1]$ for each training example and run the diffusion process forward to that step with randomly sampled Gaussian noise. The noisy example is then used for input, and the model is trained to predict the Gaussian noise component with Equation (1). During inference, we run the diffusion process in reverse using 1000 linearly spaced steps in $[0, 1]$.

Based on the implementation of Imagen [54], we also incorporated several recent DDPM improvements, including using logSNR [55, 56], a cosine noise schedule [57] of $\cos(t * \pi/2)^2$, and Classifier-Free Guidance [58] during sampling. In particular, we found that using Classifier-Free Guidance during sampling led to samples that were less noisy and more crisp sounding. After a coarse sweep of values, we train with a conditioning dropout probability of 0.1 and sample with a conditioned sample weight of 2.0.

Many diffusion models use a UNet [59] architecture, but in order to stay close to the architecture used in MT3, we used a standard Transformer decoder with no causal masking. We incorporate the noise time information by first converting the continuous time value to a sinusoid embedding using the same method as the position encodings in the original Transformer paper [52] followed by an MLP block. That embedding is then incorporated at each decoder layer using a FiLM [60] layer before the self-attention block and after the cross-attention block. The outputs of note events and spectrogram context encoder stacks are concatenated together and incorporated using a standard encoder-decoder cross-attend layer.

3.3 Spectrograms to Audio

To translate the model's magnitude spectrogram output to audio, we use a convolutional spectrogram inversion network as proposed in MelGAN [2]. In particular, we base our implementation on the more recent SEANet [61] and SoundStream [31]. This model first applies a 1D-convolution with kernel size 3 and stride 1. It then cascades four blocks of layers. Each block is composed of a transposed convolution followed by three residual units, applying a dilated convolution with kernel size 3 and dilation rate 1, 3, and 9 respectively. ELUs [62] are used after each convolution. As in [31], the model is trained with a mix of three loss functions. The first is a multi-scale spectral reconstruction loss, inspired by [63]. The second and third losses are an adversarial loss and a feature matching loss, computed with two discriminators, one STFT-based and one waveform-based. We train this spectrogram inverter on an internal dataset of 16k hours of uncurated music with Adam [64] for 1M steps with a batch size of 128.

The spectrograms used for training both the spectrogram inverter and the synthesis models used audio with a sample rate of 16 KHz, an STFT hop size of 320 samples (20 ms), a frame size of 640, and 128 log magnitude mel bins ranging in frequency from 0 to 8 KHz.

4. DATASETS

Our architecture is flexible enough to train on any dataset containing paired audio and MIDI examples, even when multiple instruments are mixed together in the same track (e.g., individual instrument stems are unavailable). Thus, we are able to use all the same datasets used to train the MT3 transcription model: MAESTROv3 [14] (piano), Slakh2100 [65] (synthetic multi-instrument), Cerberus4 [66] (synthetic multi-instrument), Guitarset [67] (guitar), MusicNet [68] (orchestral multi-instrument), and URMP [69] (orchestral multi-instrument).

We use the same preprocessing of these datasets as MT3, including the data augmentation strategy used for Slakh2100 where 10 random subsets of instruments from each track were selected to increase the number of tracks. We also use the same train/validation/test splits. Our coarse hyperparameter sweeps (e.g., for selecting Classifier-Free Guidance weighting) were done using only validation sets. Results are reported on the test splits, except for Guitarset and URMP which do not have a test split, and so the validation split was used for final results.

The datasets used in these models contain a wide variety of instruments, both synthetic and real. In order to simplify training, we map all MIDI instruments to the 34 Slakh2100 classes plus drums. These mappings cover all General MIDI classes other than "Synth Effects", "Other", "Percussive", and "Sound Effects". As a result, the trained model is capable of synthesizing arbitrary MIDI files while retaining clear instrument identity.

We use the same note event vocabulary as MT3, which is similar to MIDI events. Specifically, there are events for Instrument (128 values), Note (128 values), On/Off (2 values), Time (512 values), Drum (128 values), End Tie Section (1 value), and EOS (1 value). A full description of these events can be found in Section 3.2 of the MT3 paper [8]. Because not all datasets include velocity information, we do not currently include velocity events (as in MT3) and rely on the model's decoder to produce natural sounding velocities given the music context.

Training on such a diverse set of examples gives the model flexibility during synthesis. For example, we can synthesize a track with realistic piano sounds learned from MAESTRO, orchestral instruments from URMP, and synthesizers and drum beats from Slakh.

[3] https://github.com/magenta/music-spectrogram-diffusion

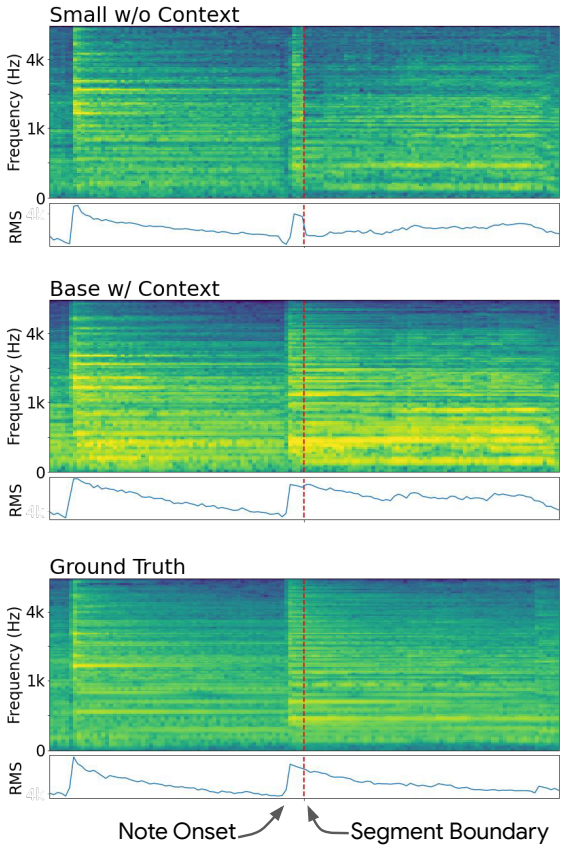

Figure 3. The "Small w/o Context" model (top) does not receive the previously rendered segment as conditioning input and exhibits clear artifacts at segment boundaries (note the dip in RMS after the segment boundary). The "Base w/ Context" model (middle) has access to the previous segment as conditioning information and achieves smooth transition between segments. By repeating the process of rendering a segment and then feeding that segment in as context for the next segment, this model is capable of rendering arbitrary length pieces.

5. EXPERIMENTS

We used the MT3 codebase as a starting point [72], and experiments were implemented using `t5x` for model training and `seqio` for data processing and evaluation [6].

We used the T5.1.1 "small" or "base" Transformer hyperparameters. For "small", there are 8 layers on the encoder and decoder stacks, 6 attention heads with 64 dimensions each, 1024 MLP dimensions, and 512 embedding dimensions. For "base", there are 12 layers on the encoder and decoder stacks, 12 attention heads with 64 dimensions each, 2048 MLP dimensions, and 758 embedding dimensions. We used float32 activations for all models.

Using the datasets described above, we trained four versions of the synthesis model: an 85M parameter "small" autoregressive model with no spectrogram context, an 85M parameter "small" diffusion model with no context, a 104M parameter "small" diffusion model with context, and a 412M parameter "base" diffusion model with context. Training used a batch size of 1024 on 64 TPUv4s with a constant learning rate of $1e^{-3}$ for 500k steps with the Adafactor [73] optimizer. Depending on model size and hardware availability, training took 44–134 hours.

5.1 Metrics

We evaluate model performance on the following metrics:

Reconstruction Embedding Distance For this metric, we pass an individual audio clip and a synthesis model's reconstruction of that audio into a classification network and calculate the distance in the classification network's embedding between the two signals. Here, we report numbers from both VGGish [70] and TRILL [71]. To compute the distance we use the Frobenius norm of the network's embedding layer, averaged over time frames. VGGish outputs 1 embedding per input audio second, and we use the model's output layer as the embedding layer. TRILL outputs $\sim$5.9 embeddings per input audio second, and we use the network's dedicated "embedding" layer.

Fréchet Audio Distance (FAD) FAD measures the perceptual similarity of the distribution of all of the model's output over the entire evaluation set of note events to the distribution of all of the ground truth audio [74].

MT3 Transcription This metric measures how well the synthesis model is reproducing the notes and instruments specified in the input data. We pass the synthesis model output through a pretrained MT3 transcription model and compute an F1 score using the "Full" metric from the MT3 paper as calculated by `mir_eval` [75]. A note is considered correct if has a matching note onset within ± 50 ms, an offset within $0.2 \cdot$ reference_duration or 50 ms (whichever is greater), and has the exact instrument program number as the input data.

Realtime (RT) Factor This measures how fast synthesis is compared to the duration of the audio being synthesized. For example, an RT Factor of 2 means that 2 seconds of audio can be created with 1 second of wall time compute. Inference is performed on a single TPUv4 with a batch size of 1. Here, we include both spectrogram inference and spectrogram-to-audio inversion.

The reconstruction and FAD metrics require embedding both model output and ground truth audio using a model sensitive to perceptual differences. Following the original FAD formulation, we use the VGGish model [70]. To avoid any biases from that particular model, we also compute embeddings using the TRILL model [71]. Pretrained models for computing these embeddings were obtained from the VGGish [4] and TRILL [5] pages on TensorFlow Hub. Due to the large size of the datasets and the high compute and memory requirements for these metrics, we limit metrics calculation to the first 10 minutes of audio for each example.

Model	VGGish [70]		TRILL [71]		Transcription F1 ↑	RT Factor ↑
	Recon. ↓	FAD ↓	Recon. ↓	FAD ↓		
Small Autoregressive	3.70	1.03	7.27	0.39	0.31	**10.55**
Small w/o Context	3.49	1.07	6.16	0.46	0.31	2.82
Small w/ Context	3.56	1.10	6.40	0.53	0.25	3.07
Base w/ Context	**3.13**	**1.00**	**2.74**	**0.27**	**0.36**	1.05
Ground Truth Encoded	2.14	0.51	1.54	0.05	0.36	12.25
Ground Truth Raw	0.00	0.00	0.00	0.00	0.63	–

Table 1. Synthesis model experiment results. Metrics are the mean across all evaluation datasets. "Small" and "Base" refer to model capacity (Section 5). "Ground Truth Encoded" refers to the ground truth audio encoded by the spectrogram inverter (Section 3.3) and represents an upper limit on synthesis model performance. "Ground Truth Raw" refers to the unprocessed ground truth audio and represents an upper limit on transcription model performance. Metrics are fully described in Section 5.1 and results are discussed in Section 5.2.

5.2 Results

We first evaluated a "small" autoregressive model (Section 3.1). Initial results were promising, but quantitative and qualitative evaluation of results made it clear that this approach would not be sufficient.

We then investigated using a diffusion approach (Section 3.2). Results from a "small" model were impressive (nearly maxing out the Transcription metric), but we noticed abrupt timbre shifts and audible artifacts at segment boundaries, as illustrated in Figure 3. This makes sense because the synthesis problem from raw MIDI is underspecified: input to the model specifies notes and instruments, but the model has been trained on a wide variety of sources, and the audio corresponding to a given note and instrument combination could just as likely be synthetic or real, played in a dry or reverberant room, played with or without vibrato, etc.; the model has to sample from this large space of possibilities independently for each segment.

To address this issue, we added a context spectrogram input encoder to encourage the model to be consistent over time. We first experimented with adding this context input to a "small" model, but got poor results, possibly due to insufficient decoder capacity for incorporating the additional encoder output. We then tried scaling up to a "base" model that included context. The additional model capacity resulted in generally higher audio quality and also did not have segment boundary problems. This is reflected in the metrics, where this model achieves the best scores by far. Also, even with the larger model size, the synthesis process is still slightly faster than realtime.

Qualitatively, we find that the model does an especially impressive job rendering instruments where the training data came from real audio recordings as opposed to synthetic instruments. For example, when given a note event sequence from the Guitarset validation split, the model not only accurately reproduces the notes but also adds fret and picking noises. Sequences rendered for orchestral instruments such as the ones found in URMP add breath noise and vibrato. The model also does a remarkably good job of rendering natural-sounding note velocities, even though no velocity information is present in our note vocabulary.

Results for these experiments are presented in Table 1. Additional results, including audio examples demonstrating the ability to render out-of-domain MIDI files and modify their instrumentation, are in our online supplement [6] . Results on a per-dataset basis are in Appendix A.

These results are encouraging, but there is still plenty of room for improvement. Particularly, the synthesized audio has occasional issues with inconsistent loudness and audio artifacts, and its overall fidelity does not match the training data. However, in all our experiments, we observed no overfitting on the validation sets, so we suspect that even larger models could be trained for higher fidelity audio.

Another limiting factor of our approach is the spectrogram inversion process, which represents an upper bound on audio quality. This is apparent in the Transcription F1 score, where our models have already achieved the maximum score possible, even though that score is only a little over half of what is achievable with raw audio.

6. CONCLUSION

This work represents a step toward interactive, expressive, and high fidelity neural audio synthesis for multiple instruments. Our flexible architecture allows incorporating any training data with paired audio and MIDI examples. Improved automatic music transcription systems such as MT3 [8] point toward being able to generate high quality MIDI annotations for arbitrary audio, which would greatly expand the available training data and range of instruments and acoustic settings. Using generic Transformer encoder stacks also presents the possibility of utilizing conditioning information beyond note events and spectrogram context. For example, we could add finer grained conditioning such as control over note timbre, or more global controls such as free text descriptions. This model is already slightly faster than realtime, but ongoing research into diffusion models shows promising directions for speeding up inference [56], giving plenty of room for larger and more complicated models to remain interactive. This may be especially important as we explore options for higher quality audio output than our current spectrogram inversion process enables.

ABSTRACT

FM Synthesis is a well-known algorithm used to generate complex timbre from a compact set of design primitives. Typically featuring a MIDI interface, it is usually impractical to control it from an audio source. On the other hand, Differentiable Digital Signal Processing (DDSP) has enabled nuanced audio rendering by Deep Neural Networks (DNNs) that learn to control differentiable synthesis layers from arbitrary sound inputs. The training process involves a corpus of audio for supervision, and spectral reconstruction loss functions. Such functions, while being great to match spectral amplitudes, present a lack of pitch direction which can hinder the joint optimization of the parameters of FM synthesizers. In this paper, we take steps towards enabling continuous control of a well-established FM synthesis architecture from an audio input. Firstly, we discuss a set of design constraints that ease spectral optimization of a differentiable FM synthesizer via a standard reconstruction loss. Next, we present Differentiable DX7 (DDX7), a lightweight architecture for neural FM resynthesis of musical instrument sounds in terms of a compact set of parameters. We train the model on instrument samples extracted from the URMP dataset, and quantitatively demonstrate its comparable audio quality against selected benchmarks.

1. INTRODUCTION

Sound generation and transformation tools are ubiquitous in music composition and production. The electronic synthesizer has enabled musicians to access forms of timbre beyond the capabilities of acoustic or amplified instruments. Chowning's FM Synthesis [1] is a widely used technique that is flexible to create complex, harmonic and inharmonic spectra from a reduced set of controls. Its long-standing presence in the audio industry has shaped traditional and contemporary sound design techniques [2–4] across musicians and producers, with a wide number of current commercial synthesizer keyboards, modules and software plugins featuring it.

Sandler, "DDX7: Differentiable FM Synthesis of Musical Instrument Sounds", in *Proc. of the 23rd Int. Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

For most of its history, the digital synthesizer has been inextricably associated with the MIDI keyboard. Several historical technical and social factors contributed to making the keyboard the de-facto control interface for the synthesizer [5]. The legacy of this association continues to steer synth design, favouring triggers and envelope generators over continuous control strategies.

Developing alternative interfaces for controlling digital synthesis remains an active area of research [6]. Many such digital musical instruments (DMIs) are based on mappings between sensor data and synthesis parameters [7, 8]. An alternative approach uses features extracted from the audio signal of an acoustic instrument to control a digital synthesis process. In that context, previous works employed audio signals from musical instrument as oscillators [9], in a configuration that can be seen as a special application of Adaptive Digital Audio Effects [10, 11].

More recently, Neural Audio Synthesis (NAS) algorithms have employed Deep Neural Networks (DNNs) to map audio features to synthesizer parameters, in tasks such as realistic audio synthesis from a compact set of control signals [12–14], timbre transfer from one instrument to another [15, 16] and enhancement of symbolic musical expression [17]. While the results are impressive, we observe that the employed synthesis architectures are overly complex, featuring dozens of time-evolving parameters that hinder intervention, with users defaulting to indirect methods to intervene with the synthesis process, such as network bending [18].

We are interested in an audio-based, continuous control technique for a well-established synthesis architecture, that can potentially offer musicians similar sound design primitives and outcomes available to keyboard players. Furthermore, we want the model to be compatible with live use, therefore it should be able to work in real-time.

In this work, we take steps towards enabling interpretable sound design controls for NAS algorithms, and present Differentiable DX7 (DDX7), a causal and lightweight DNN architecture that maps continuous audio features to the synthesis parameters of a well-known FM synthesizer. We train DDX7 in single instrument datasets and evaluate its resynthesis performance against selected benchmarks. We provide full source code, and an online supplement [1] with audio examples and a preliminary analysis of the model's real-time execution capabilities.

2. BACKGROUND

2.1 Linear FM Synthesis

Linear FM modulation for audio signals, originally described by Chowning [1] in the early 1970s, is a well-known sound design technique that powered the first massively available and commercially successful digital synthesizer, the Yamaha DX7, defining an era in music production [2]. Since then, it that has retained a fair amount of attention by the research community [19], being present in a variety of topics from timbre semantic analysis [13], to empirical [4] and computer assisted sound design [20], and adaptive effects [11]. Commercially, manufacturers continue to release as of today a sizable number of new instruments based on this technology [21, 22].

Linear FM synthesis is actually a phase modulation technique aimed at generating different timbres with few parameters and low computational resources. Expressed in term of sine waves, the instantaneous FM modulated signal can be written as shown in Equation 1, where f_c is the carrier frequency, f_m is the modulator frequency and I is the modulation index. In this work, we denote this particular linear phase modulation technique simply as FM Synthesis.

$$y(t) = sin(2\pi f_c t + Isin(2\pi f_m t)) \quad (1)$$

The side-bands of an FM signal are equally spaced around the carrier frequency, and their separation determined by f_m, while the number of harmonics depends on the modulation index and follows a Bessel function of the first order (Equation 2).

$$y(t) = \sum_{n=-\infty}^{n=+\infty} J_n(I) sin(2\pi(f_c + nf_m) \cdot t) \quad (2)$$

By controlling the modulation indexes and ratios, users can generate rich and complex timbre with a small set of oscillators modulated in frequency. For instance, the simple modulator-carrier setup can be extended with a new carrier that is modulated by the output of the previous pair. This *stacked* arrangement spreads the bands of the initial modulator-carrier pair across another carrier, adding a new layer of complexity to the timbre. Furthermore, outputs from many stacks can be mixed in an *additive* approach. Next, by setting the frequency ratio r in such a way that $f_c = r \cdot f_m$, with $r \in \mathbb{Q}$, FM generates harmonic spectra.

2.2 The DX7 Synthesizer

The Yamaha DX7 synthesizer is probably the best-known FM synthesizer, and it features a linear FM synthesis architecture that has been previously used by other synth models as well, making it an excellent candidate for integration to a continuous control strategy.

The sound of the DX7 is generated by six frequency-modulated sinusoidal oscillators, and it is programmed by means of setting up a *patch*. For each oscillator, a patch describes their routing (i.e. how the oscillators are interconnected in a stacked or additive fashion), the Attack-Decay-Sustain-Release (ADSR) envelope generator parameters and the frequency ratios with respect to the note that is being played. Fixed frequencies can also be assigned to the oscillators. The ADSR parameters control the *output levels* of each oscillator; affecting their output volume or modulation index depending on their interconnection. Finally, in the DX7, the oscillators' frequency ratios and routing remain *fixed* during audio rendering. Sound dynamics are generated mainly by the ADSR envelopes controlling the volume or modulation index of the carriers and modulators respectively.

2.3 Sound Matching

Sound matching is the process of estimating a set of synthesis parameters that approximate a given audio signal as best as possible. The task of matching an audio input to synthesizer controls is not new especially for FM, where evolutionary methods have been used to optimize a patch for a particular given sound [20, 23].

More recently, DNNs have been studied for supervised sound matching from an annotated dataset of patches and synthesized audio excerpts. The approaches include classification [24], where the network predicts a patch based on an input spectrogram, variational inference [25], with the DNN learns an invertible mapping between a dataset of audio and patches, and multi-modal analysis [26] that employs multiple aggregated audio features for prediction.

While these methods are effective, they usually process long audio windows on the order of seconds, required to estimate the values of the ADSR envelope generator. Furthermore they can only estimate parameters from audio excerpts at specific pitch values. These approaches are not suitable for continuous control of a synthesizer from an audio signal.

2.4 Neural Audio Synthesis

DNNs can capture complex relations from a dataset. This can be exploited in a generative approach to produce realistic sounding audio. Neural Audio Synthesis (NAS) algorithms employ DNNs as powerful synthesizers that can capture structure and nuances from a corpus of music and produce new audio with similar characteristics during inference. Furthermore, these algorithms can be conditioned at train or inference time, modifying the output on-the-fly.

Since the introduction of the seminal autoregressive architectures Wavenet [27] and SampleRNN [28], the NAS field has included generation approaches such as Generative Adversarial Neural Networks (GANs) [29–31], probabilistic models [32, 33] and style transfer methods [15, 34]. Furthermore, a branch of the field has focused on controllable music generation, in an effort to bring interaction possibilities to users, with NAS algorithms supporting control inputs such as MIDI [17], timbre descriptors [29] and pitch and loudness signals [12–14].

2.5 Differential Digital Signal Processing

Differential Digital Signal Processing (DDSP) [12] is one approach for efficient, high quality audio rendering from

a compact set of input controls. It biases a DNN towards generating and processing audio by the insertion of signal processing elements, such as oscillators and filters, in the network structure. These are implemented using differentiable operators from a neural network training framework and therefore can back-propagate gradients during training.

DDSP methods have been successfully employed in resynthesis and tone transfer [16] tasks, where they are conditioned on a set of time-evolving inputs, including the fundamental frequency of the target signal, and generate audio on a frame-by-frame basis. Some approaches such as the Neural Source Filter (NSF) [14, 35] or the Neural Waveshaper [13] learn to control a non-linear filter that shapes a harmonic source towards a particular target sound. Other DDSP architectures [12, 17] directly drive a Harmonic plus Noise (HpN) synthesizer [36], effectively learning a mapping between the input controls and the synthesizer parameters that generate the output.

While the previous resynthesis architectures can generate realistic tone transfer, there is little users can do to manipulate the resulting audio other than controlling the pitch and loudness inputs. The DNN controls spectral modelling algorithms, which do not have musically meaningful parameters. In this work, we present a differentiable FM synthesizer module that features a compact set of well-known sound design controls driven by a DNN, enabling a potential user intervention into the synthesis process.

While the idea of differentiable FM is not new, we have not been able to find published literature with details and evaluations of systems employing it. We highlight two web repositories, one involving a 2-oscillator FM optimization strategy of audio excerpts [37] and another presenting an extension of the original DDSP project with a Differentiable FM synthesizer [38], where the experiments fail to reproduce musical instrument sounds. Our approach imposes a set of constraints on the FM synth that allows a DNN to generate instrument sounds.

2.6 Training objective for DDSP resynthesis

The training process for the DDSP algorithms usually involves a multi-scale spectral (MSS) loss function that includes the L_1 distance of the amplitude spectrograms of a synthesized and a target audio excerpt, in linear and logarithmic form [12]. This function is used as a reconstruction loss, with the DDSP model aiming to replicate the target spectra during training.

Despite its widespread use, the MSS loss and more generally, spectral-based distance metrics present pitch-based failure modes that can conspire against the generalization capabilities of NAS algorithms when trained with gradient descent, as demonstrated by Turian et. al. [39]. The authors show how such functions fail to propagate informative gradients for fine-tuning oscillator frequencies towards a frequency target due to fine grained ripple on the loss surface. Furthermore, they indicate that for the MSS distance, jointly optimizing amplitude and frequency generates misleading gradients for both tasks; this loss function can match spectral amplitudes only when the harmonics of target and prediction are aligned in frequency.

We argue that the MSS loss works well for DDSP because of two main reasons: Firstly, these models drive highly parameterized spectral modelling synthesizers with fine control on the output, either in the form of filter-distortion DNNs [14, 35], multiple parallel waveshapers [13], or the HpN synthesizer [12]. Secondly, and most importantly, all DDSP resynthesis architectures require as conditioning the fundamental frequency from the target signal, extracted with an estimator [40]. This ensures a harmonic alignment between the target and the prediction, and effectively avoids the problem of having to optimize pitch using gradient descent and the MSS loss during training.

A loss function that cannot propagate informative gradients cannot be employed to train a DNN. This is particularly disadvantageous for the case of FM generation, where the synthesis parameters include the modulation index I and the frequency ratios r that determine distance between the side-bands and the carrier. A small mismatch on ratio estimation can generate an unwanted vibrato-like effect, due to small frequency differences between oscillators. A big mismatch can hinder the joint optimization of the harmonics' positions and amplitudes. A DNN that does not learn how to precisely control the ratios could very easily incur either of those problems.

3. METHOD

In this section, we propose a set of constraints that ease training of a DNN with a differentiable FM synthesizer. Next, we present DDX7, a NAS architecture for FM synthesis controlled by a Temporal Convolutional Network (TCN) [41]. We train the DDX7 model for FM resynthesis of musical instrument sounds. This effectively results in a DX7 patch that is playable by an arbitrary audio input. A diagram of the architecture is shown in Figure 1.

3.1 Differentiable DX7

Our aim is to provide continuous control possibilities for a well-known FM synthesizer. We choose the Yamaha DX7 for its lasting influence on musical practice.

Considering the DX7 patch design, we observe that when fixing the frequency ratios and the routing of the oscillators, all the harmonics and overtones that can be generated take a fixed position in the spectrum. This *patch constraint* can allow the synthesis model to propagate informative gradients from the MSS reconstruction loss, provided the FM partials are pre-aligned with the ones of the target audio by means of pitch conditioning, as in the case of DDSP resynthesis.

We propose a control scheme for an FM synthesizer where a DNN controls the modulation indices and volume of the oscillators. The oscillator routing and frequency ratios remain fixed. One problem may arise when considering the maximum values that the modulation index I can take. For different ranges of I, the Bessel functions can create local minima during spectral optimization due to

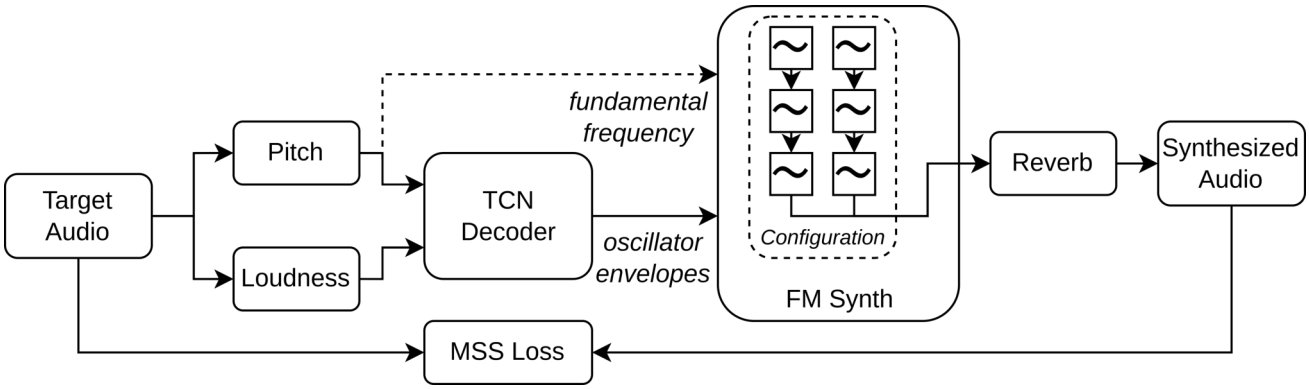

Figure 1. The DDX7 architecture employs a TCN decoder conditioned on a sequence of pitch and loudness frames to drive the envelopes of a few-oscillator differentiable FM synthesizer that features a fixed FM configuration with fixed frequency ratios, effectively mapping continuous controls of pitched musical instruments to a well-known synthesis architecture.

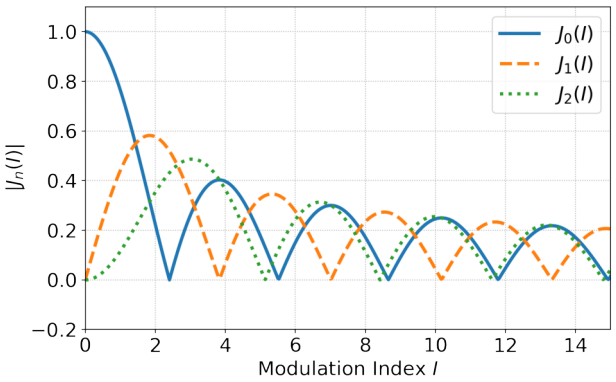

Figure 2. Absolute amplitudes of the first three harmonics generated by FM in function of I.

their oscillatory nature. In the DX7, the modulation index envelopes can take values of as much as 4π [42], but only for $I < 1.83$, are the Bessel functions strictly monotonic, with the carrier just exchanging energy with the sidebands, as shown in Figure 2. We analyze the effect of the maximum ranges through experiments in Section 5.

We implement the FM modulation algorithm in Pytorch, and adapt it manually for the different *FM configurations* that are tried in this work. Each configuration defines a fixed oscillator routing and a set of frequency ratios.

3.2 TCN Decoder

TCNs have been successfully employed a number of sequential modelling tasks, including for audio processing and generation [14, 27, 43]. These are fully-convolutional networks that employ 1-dimensional convolutions and exponentially growing dilations to efficiently model long sequences within their receptive field [41]. We choose TCNs for our DDX7 implementation for their fast training capabilities and good sequential modelling performance.

In our FM resynthesis problem, we aim to map a set of synchronous input sequences of pitch $f_{01}, ..., f_{0T} \in \mathbb{R}$ and loudness $ld_1, ..., ld_T \in \mathbb{R}$ to the controls of our constrained synthesizer, i.e. the output levels $ol_1, ..., ol_T \in \mathbb{R}^6$ of the six oscillators. We define the parameterized mapping function f_θ as shown in Equation 3, where the conditioning sequence $c_1, ..., c_T \in \mathbb{R}^2$ is obtained by concatenating along a new dimension both pitch and loudness sequences, $\sigma(.)$ is the sigmoid activation function and A_{max} is the maximum output level value that the envelopes can take for that oscillator, as shown in Equation 4, where I_{max} is a hyperparameter describing the maximum modulation index range that the system can realize.

$$\hat{ol}_1, ...\hat{ol}_T = A_{max} \cdot \sigma(f_\theta(c_1, ...c_T)) \tag{3}$$

$$A_{max} = \begin{cases} 1 & \text{if carrier} \\ I_{max} & \text{otherwise} \end{cases} \tag{4}$$

We implement our mapping function f_θ with a simple, causal TCN architecture following [41], with 2 input and 6 output channels, processed by 5 TCN residual blocks with skip connections and 128 hidden channels each. Each residual block features two convolutional layers of kernel size 3, and the dilation increases by a factor of 2 in each block. Weight normalization, dropout with probability of 0.5 and ReLU activation functions are used throughout the network, with the exception of the output layer that features a sigmoid layer. This yields a relatively lightweight decoder, with about 400k parameters, and a receptive field T of 125 pitch and loudness frames.

3.3 Learnable Reverb

We employ a differentiable reverb module, similar to the one employed for the DDSP decoder [12], featuring learnable mix and decay parameters, and a trainable impulse response of 1 second length. This is used to estimate the room response of the dataset recordings, decoupling it from the FM sound generation block. It is applied directly to the FM synthesizer output and it is jointly optimized with the DNN during training.

4. TRAINING

4.1 Loss function

The DDX7 architecture can be trained with a corpus of audio from a musical instrument as supervision, employing stochastic gradient descent on minibatches with a spectral reconstruction objective. We employ the MSS reconstruction loss shown in Equation 5, where S_i and $\hat{S}_i$ are the magnitude spectrograms of the target and synthesized audio respectively, $||.||_1$ denotes the L_1 norm, and i is a particular Fourier transform analysis window on which the spectrogram is computed. We use $i \in \{64, 128, 256, 512, 1024, 2048\}$ with an overlap of 75% between windows.

$$L = \sum_i (||S_i - \hat{S}_i||_1 + ||logS_i - log\hat{S}_i||_1) \quad (5)$$

4.2 Dataset

We train our DDX7 models on audio samples of instruments extracted from the University of Rochester Music Performance (URMP) dataset [44], an audio-visual dataset that contains classical pieces. We select the separated audio stems for violin, flute and trumpet as our training data, down-sample them to 16 kHz, remove silences and crop the audio files to instances of 4 seconds. We extract the A-weighted loudness [45] and fundamental frequency employing the CREPE [40] pitch estimator. We discard all instances that yield a mean pitch confidence smaller than 0.85, with the exception of the flute corpus, for which we relax the requirement down to 0.80 due to its short length. We further normalize pitch and loudness values within a range between 0 and 1.

We process each annotation with a hop size of 64 samples, yielding pitch and loudness sequences of 1000 frames for each 4-second instance. The selection of hop size and sample rate results in our TCN model featuring a receptive field of 0.5 s, and dictates the frame rate at which it drives the oscillators, 250 Hz. We linearly interpolate the envelope frames before feeding them into the oscillators. Finally, we separate the dataset into train, validation and test sets with 0.75 / 0.125 / 0.125 splits respectively.

4.3 FM configurations

For each target instrument, we select a different FM configuration extracted from the original patch set of the Yamaha DX7, which we retrieve from the web. [2] Then, we load the patches in Dexed [46], a DX7 emulator, and audit them searching for most similar to the target instruments. We select "STRINGS 1" for violin, "FLUTE 1" for flute and "BRASS 3" for the trumpet. We deploy the oscillator routing with the frequency ratios rounded up to one decimal point (to avoid vibrato-like effects) as differentiable FM modules, as shown in Figure 3. We do not deploy the oscillator feedback feature of the DX7 in our implementation, as it cannot be computed in parallel and we find it is very slow to render using a standard for loop in Python.

[2] http://bobbyblues.recup.ch/yamaha_dx7/

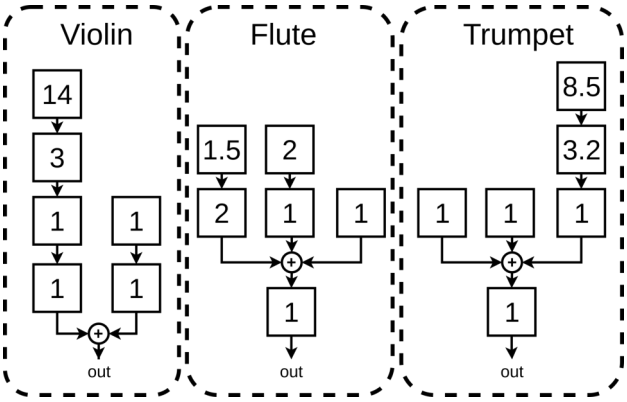

Figure 3. FM configurations used for training. Squares indicate sinusoidal oscillators and their frequency ratios.

4.4 Training process

Our models are trained for 120k steps, with the Adam optimizer, set with an initial learning rate of 3e-4, decreasing with a factor of 0.98 each 10k steps. We clip gradients to a maximum norm of 2, and employ a batch size of 16.

5. EVALUATION

We evaluate the performance of DDX7 on the resynthesis task, training the model on the flute, trumpet and violin corpus, and evaluate its performance on selected benchmarks with the Fréchet Audio Distance (FAD).

5.1 Fréchet audio distance

The Fréchet Audio Distance (FAD) presented by Kilgour et. al. [47] serves as a quality metric for audio enhancement, that correlates better with human listeners than SDR (signal-to-distortion ratio) or spectral differences such as the MSS loss. This is in line with other deep neural features used in Computer Vision that are found to outperform heuristic metrics by great margins [48]. It has been used to assess synthesis quality in previous works [13, 29, 31]. The FAD computes the Fréchet distance between multivariate Gaussian distributions inferred from the embeddings of a pre-trained VGGish model [49]. The compared distributions are generated from the embeddings of a corpus of audio for evaluation and a "background" corpus of high quality audio as reference.

5.2 Benchmarks

5.2.1 Maximum modulation index

We are interested into knowing which are the best modulation index limits for which our model can successfully render the instrument audio. Taking into account that optimizing for a particular spectra may be difficult for the original maximum modulation index range of the DX7 of 4π, we train our model for each instrument with three different maximum modulation index ranges for the oscillators: $I_{max} = \{4\pi, 2\pi, 2\}$, including the original DX7 range, a halved one and one limited at two, which includes the

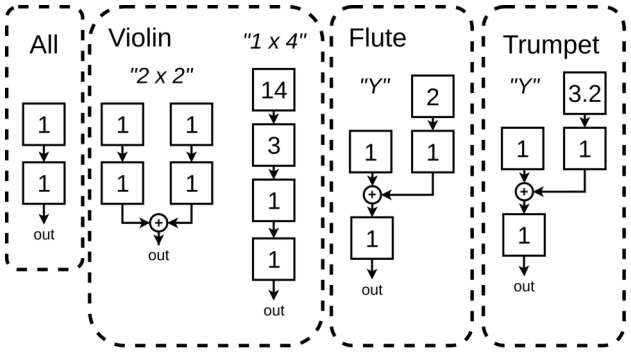

Figure 4. Ablated FM configurations.

global maximum of the first harmonic $J_1(I)$, but limits the other Bessel functions to a space where they are strictly monotonic. Finally, we load the corresponding configuration for each instrument selected, and we train three versions of DDX7, to account for each of the values of I_{max}.

Our FM model learns to control the envelopes of 6 oscillators frame-wise. As a baseline, we assess the performance of the common Harmonic plus Noise spectral modelling synthesizer employed for resynthesis tasks. We train a baseline pitch and loudness decoder that controls 121 frame-wise parameters of an HpN synthesizer, similar to the original solo instrument DDSP Decoder [12], but implemented in the same training framework as DDX7, to ensure that we use exactly the same dataset, preprocessing and frame rate. The model is roughly 11 times bigger than DDX7, with about 4.5 M parameters. We train it for 120k steps for parity with our model, with a batch size of 16, and an initial learning rate of 1e-4, decreasing to a factor of 0.98 for each 10k steps.

For evaluation with FAD, we generate background embedding distributions of the complete audio corpus of each instrument. Next, we generate embeddings distributions from the resynthesized excerpts of the test set for each model and instrument. We compute the FAD of these and the original test set against their corresponding background distribution. Results are shown in Table 1. We observe that the HpN baseline outperforms our model in violin and trumpet, but controlling 121 parameters instead of 6, and at a higher computational cost. Surprisingly, DDX7 outperforms the baseline on flute, suggesting that our *patch constraint* approach can bias a DNN towards a usable FM timbral space. We observe the best DDX7 performance is obtained with $I_{max} = 2$ for flute and violin and $I_{max} = 2\pi$ for trumpet. This may be correlated with the different spectra of the instruments, suggesting that the trumpet may require a bigger I_{max} for an improved reconstruction. Finally, for some configurations of I_{max} the models sound unnatural and fail at the estimation of the room response. We leave further analysis of this issue for future work.

5.2.2 Oscillator ablation test

We want to assess if our model is effectively optimized to leverage all of the modulators for the reconstruction task. We propose ablated versions of the previous patches with two and four oscillators, as shown in Figure 4. We train the DDX7 models on the ablated patches using the optimal I_{max} found with the previous benchmark and compare their resynthesis quality with the FAD following the same previous procedure. The results shown in Table 2 suggest that the violin and flute model benefit from the extra degrees of freedom present with more oscillators. On the other hand, the trumpet model works best with the smallest configuration, possibly due to an incorrect patch selection that hindered the optimization process. Finally, the 2-oscillator trumpet model outperforms the HpN baseline, suggesting that good results can be achieved with a small number of frequency-modulated oscillators.

	Fréchet Audio Distance

6. CONCLUSION

We presented DDX7, an approach for FM resynthesis of musical instrument sounds that yields good reconstructions controlling few parameters, with relatively smaller models. We have shown that FM with a *patch constraint* can perform comparably well to a more complex baseline with just 6, and even less oscillators; we hope this motivates further research along this line, including for instance sound matching techniques to find suitable configurations.

Current resynthesis architectures feature synthesizers that are difficult to intervene in a musically meaningful way. In contrast, DDX7 learns to control an FM synthesizer that is common in the sound design practice. It replaces the ADSR generator of the original DX7 with a TCN that infers the envelopes from continuous control inputs. At runtime, it is possible to manipulate the timbre on-the-fly, either by re-shaping the spectrum with the ratios, altering dynamics on the envelopes, or by re-routing the oscillators. Finally, the small model size and causal temporal dependency make DDX7 an interesting candidate for real-time implementation. We leave an exploration of these affordances and possibilities for future work.

7. ACKNOWLEDGEMENTS

We would like to thank the ISMIR reviewers for their valuable feedback. Also, we would like to thank our colleagues Ben Hayes and Rodrigo Diaz for their advice and many compelling discussions about audio rendering and DNN optimization. This work was supported by UK Research and Innovation [grant number EP/S022694/1]. ABSTRACT

Tracking beats of singing voices without the presence of musical accompaniment can find many applications in music production, automatic song arrangement, and social media interaction. Its main challenge is the lack of strong rhythmic and harmonic patterns that are important for music rhythmic analysis in general. Even for human listeners, this can be a challenging task. As a result, existing music beat tracking systems fail to deliver satisfactory performance on singing voices. In this paper, we propose singing beat tracking as a novel task, and propose the first approach to solving this task. Our approach leverages semantic information of singing voices by employing pre-trained self-supervised WavLM and DistilHuBERT speech representations as the front-end and uses a self-attention encoder layer to predict beats. To train and test the system, we obtain separated singing voices and their beat annotations using source separation and beat tracking on complete songs, followed by manual corrections. Experiments on the 741 separated vocal tracks of the GTZAN dataset show that the proposed system outperforms several state-of-the-art music beat tracking methods by a large margin in terms of beat tracking accuracy. Ablation studies also confirm the advantages of pre-trained self-supervised speech representations over generic spectral features.

1. INTRODUCTION

Music tempo and beat detection are two of the core and well-defined MIR topics, and scholars have proposed many approaches to addressing different aspects of them for various music genres. For instance, some works such as [1–4] proposed some unsupervised approaches to detect music beat and tempo by using some low-level features like onset strengths. More recently, several more recent approaches employ neural networks to address the mentioned tasks [5–8]. Extracting singing rhythmic parameters makes it possible to address several MIR problems such as automatic instrumental and singing tracks alignment, automatic music mix, and remix, interactive content creation on social media platforms, etc.

Many of the proposed music rhythmic analysis approaches [1, 5, 7] perform in an offline fashion while others [6, 9, 10] are capable of extracting music rhythmic features causally and even in real-time.

In contrast to all of the mentioned models, beat and tempo detection for singing voice is an untapped MIR task. There are significant inherent differences between the natures of complete music and singing voices. One of those differences is that complete music pieces usually contain rich percussive and harmonic profiles while singing tracks usually lack such beneficial parameters making their rhythmic analysis more demanding compared to the former group. Their other important difference is that music beat tracking models usually only use acoustical clues such as magnitude spectrogram as input features while singing tracks are more similar to speech signals where the models may require to deal with para-linguistics, semantic, and phonemic level inputs in addition to acoustical features.

Our contributions in this paper are as follows:

1- We introduce singing beat tracking as a novel MIR task. We propose two strategies to tackle the lack of annotated data for this task by leveraging pre-existing datasets and beat tracking and source separation techniques. We also propose a new evaluation scheme that can account for phase ambiguities of beat annotation for vocal music.

2- We propose two neural models for the singing beat tracking task. These models leverage pre-trained speech self-supervised models to extract feature embeddings, which are then fed into a linear transformer network to output beat predictions.

3- We evaluate the proposed models on hundreds of vocal tracks with diverse genres. Experiments show that the proposed models outperform three representative baselines designed or trained for general music beat tracking by a large margin. An ablation study is also performed to investigate the effect of speech self-supervised models over commonly used generic spectral features, and results again show an outperformance by a large margin.

The remainder of the paper is organized as follows: In Section 2, we describe the proposed vocal beat tracking task with dataset curation and a new evaluation scheme. In Section 3, we describe our proposed models with details. In Section 4, we present experimental comparisons with baselines and an ablation study on the feature extraction

front end. Finally, Section 5 concludes the paper.

2. THE PROPOSED TASK

We propose singing beat tracking as a new MIR task, which aims to design algorithms that can track beats of singing voices in online or offline fashion. In this section, we describe the two cornerstones for this task: datasets and evaluation metrics.

2.1 Singing Data and Label Generation

Data for training and evaluating singing beat tracking algorithms require both singing voice recordings and their beat annotations. As there is no existing datasets that meet this requirement, we need to design a mechanism to collect such data. Instead of recording singing voices and annotating their beats manually, we propose to leverage existing MIR datasets and techniques to collect data for singing beat tracking, as illustrated in Figure 1.

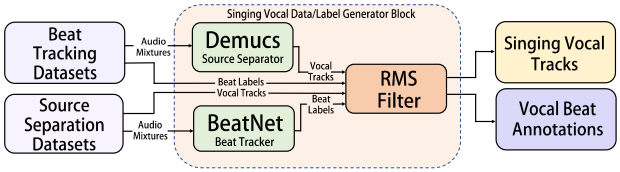

Figure 1. Singing data and label generation pipeline.

The first strategy we propose is to use pre-existing music beat tracking datasets in which the beat annotations are available. The idea is to obtain their singing tracks through music source separation. State-of-the-art (SOTA) singing voice separation methods have been shown to achieve outstanding results on popular genres of music, and the separated singing voice contains little interference from the background music. For this task, we employ Demucs Hybrid [11], one of the superior music source separation models. It uses a waveform-to-waveform convolutional autoencoder with a U-Net structure and bidirectional LSTM layers, and is designed to separate the music mixture into four sources including bass, drums, vocals, and others. We use the pre-trained model [1] which was trained on all 150 songs of MusDB [12] dataset. It is noted that source separation is used in some related works e.g. [13–15] to improve music beat tracking while in this work, we utilize it as one of the suggested systematic ways to generate singing vocal beat tracking datasets.

The second strategy we propose leverages pre-existing music source separation datasets, in which the isolated vocal tracks are available as a part of those datasets. To obtain beat annotations, we apply BeatNet [6] offline version on the complete songs (i.e., music mixtures). BeatNet is a SOTA online beat tracking method that uses a convolutional recurrent neural network (CRNN) and a hidden Markov model (HMM) decoder to extract music beats and downbeats. We modify the HMM decoder from particle filtering inference to Viterbi algorithm to improve its performance in the offline scenario. The reason that we run BeatNet on music mixtures instead of the separated vocal tracks is because it, the same as all other beat tracking methods, is trained on complete music pieces. While BeatNet has been shown to be fairly accurate on many songs with different genres, there are still annotation errors. To fix them, we also perform a manual revision by listening to the separated vocal track together with synthesized beeping sounds of the beat annotations and correcting errors.

While the beat annotations are obtained for the entire song, the ground-truth or separated vocal tracks show long chunks of silence due to the inactivity of singing. These long silent chunks are not useful and even are distracting for singing rhythmic analysis. Therefore, we normalize the energy of each vocal track using the root-mean-square (RMS), calculate a frame-wise RMS, and set a threshold to detect long silent chunks and split the vocal track into vocal segments. The RMS threshold is set to 0.01, and silent chunks shorter than 8 seconds are kept.

We apply these two strategies to a total of 8 existing beat tracking and music source separation datasets to obtain a total of 2248 vocal excerpts with beat annotations. The entire length of the vocal segments is 34h 35m. The datasets are summarized in Table 1.

2.2 Evaluation Metrics

For evaluation metrics, we adopt the commonly used F-measure in beat tracking. A beat is considered correctly detected if it is matched with a ground-truth beat with a time deviation smaller than 70 ms. In addition, we employ three additional metrics including P-score, Cemgil and Goto to provide a more detailed evaluation. Details about these three metrics can be found in [3].

For many music pieces, vocal tracks can align with the offbeat position (i.e., middle point between two adjacent ground-truth beats) rather that the beats. In fact, it also can be quite natural for humans to clap on the 180-degree phase shifted positions While this inherent ambiguity also exists in some instrumental music, it is much more common for singing voices. Apparently, the off-beat predictions would

Dataset	*# Number of vocal excerpts*	*Total Length*
Ballroom [16, 17] *	452	2 h 38 m
GTZAN [18, 19] *	741	5 h 44 m
Hainsworth [20]*	154	1 h 47 m
MUSDB18 [12]†	263	6 h 21 m
Rock Corpus [21]*	315	9 h 23 m
RWC pop [22, 23]*	188	5 h 06 m
RWC Royalty free [22,23]*	29	19 m
URSing [24]†	106	3 h 17 m

Table 1. Datasets collected and adapted for singing beat tracking. $*$ denotes beat tracking datasets and † denotes music separation datasets.

[1] https://github.com/facebookresearch/demucs

be evaluated poorly against the ground-truth beat annotations for all of the abovementioned metrics.

To address this problem, we propose an additional Phase Inclusive (PI) evaluation scheme with existing metrics. In this scheme, a metric is computed twice, one comparing the predicted beat positions with the ground-truth beat annotations and the other comparing with the 180-degree shifted ground-truth. The maximum is reported as the final metric under the PI evaluation scheme.

3. THE PROPOSED METHOD

To address the singing beat tracking task, we propose two models that take advantage of pre-trained WavLM and DistilHuBERT SSL representations respectively to extract the input features. Then we build the same linear multi-head self-attention network on top of them to fine-tune the models for our task. Finally, a hidden Markov model decoder is used to infer the singing beat positions using the activations provided by the respective neural networks. The source code and system demos are available [2] .Figure 2 demonstrates the overall structure of all proposed models and Figure 3 demonstrates the neural network structures of all proposed models.

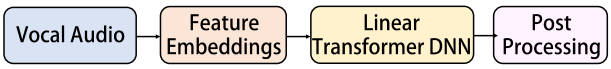

Figure 2. General pipeline of the proposed method.

3.1 Feature Embedding

Neural networks benefit from large quantities of labeled training data. However, in many cases including that of our task, labeled data is much harder to obtain than unlabeled data. Self-supervised learning has emerged as a paradigm to learn general data representations from unlabeled examples and fine-tuning the model on labeled data [25]. On the other hand, as demonstrated in [6], selecting appropriate input features plays an important role in music rhythmic analysis tasks. Due to acoustic and linguistic similarities between singing voices and speech, our main assumption is that self-supervised speech representations are helpful as feature embeddings in singing rhythmic analysis.

SSL achieves great success in speech-related tasks such as Automatic Speech Recognition, Phoneme Recognition and Emotion Recognition. Each task can be addressed by fine-tuning a universal pre-trained self-supervised model or training a neural network on top of the contextualized self-supervised representation of the input. In recent years, several pre-trained self-supervised models (e.g. [25–30]) attempt to provide such universal speech representations. The most successful models such as [25, 26] usually encode speech audio through a multi-layer convolutional neural network and then mask some chunks of the resulting latent speech representations. Then, a contrastive learning step is performed by feeding the latent representations to a transformer network to distinguish true latents [25].

WavLM: WavLm [26] is one of the recent universal self-supervised pre-trained models on 94k hours of data to solve full-stack downstream speech tasks. It jointly predicts masked speech and performs denoising in the pre-training stage. The denoising module helps to enhance the potential for non-ASR tasks. Moreover, it uses gated relative position bias in its transformer structure to improve capturing sequence ordering of input speech. WavLM has three different versions, Base, Base+, and Large. WavLM Base and WavLM Base+ include 12 encoder layers, 768-dimensional hidden states, and 8 attention heads. The WavLM Large contains 24 encoder layers, 1024-dimensional hidden states, and 12 attention heads. According to the SUPERB [31], which is an evaluation benchmark designed to provide a standard and comprehensive testbed for pre-trained models on several speech tasks, WavLM outperforms the other counterparts for several speech downstream tasks.

Since WavLM model has demonstrated promising results for several downstream speech tasks, we employ it as the front-end model for our first proposed approach to prepare contextualized input embeddings. Among three pre-trained options, we chose the Base+ model, becasue of its better performance than the Base model and similar performance with the Large model on many downstream tasks.

According to some works on the layer-wise analysis of self-supervised models (e.g. [32, 33]), using their last layer's output is not necessarily the best option to leverage the SSL model's maximum capability. This is because the desired feature aspects of the input signal are distributed differently through internal encoder layers. For example, [33] demonstrated that in Wav2Vec2 self-supervised model, for some properties like word meaning, intermediate layers play a much more important role than the output layer, while for acoustical features, early layers carry the most important information. Therefore, in order to capture different aspects of the input signal, we use a weighted sum of all encoder layers of WavLM in which each weight is a learnable parameter during the training phase.

DistilHuBERT: Although WavLM demonstrated the most successful results for several downstream tasks, it is a large model which requires large memory and high pre-training and inference costs imposing a speed bottleneck for the system. DistilHuBERT [29], is a novel multi-task learning framework to distill hidden representations from a HuBERT [27] model directly. It is initialized with the HuBERT's parameters. Then, its prediction heads learn to generate the teacher's hidden representations by minimizing the loss function. DistilHuBERT reduces the model size by 75% and increases the inference speed by 73% from HuBERT while retaining most performance in ten different speech tasks. Moreover, it requires little training time and data, opening the possibilities of pre-training personal and on-device SSL models for speech.

Therefore, we propose a second model that switches the heavy WavLM front-end model with DistilHuBERT,

[2] https://github.com/mjhydri/singing-vocal-beat-tracking

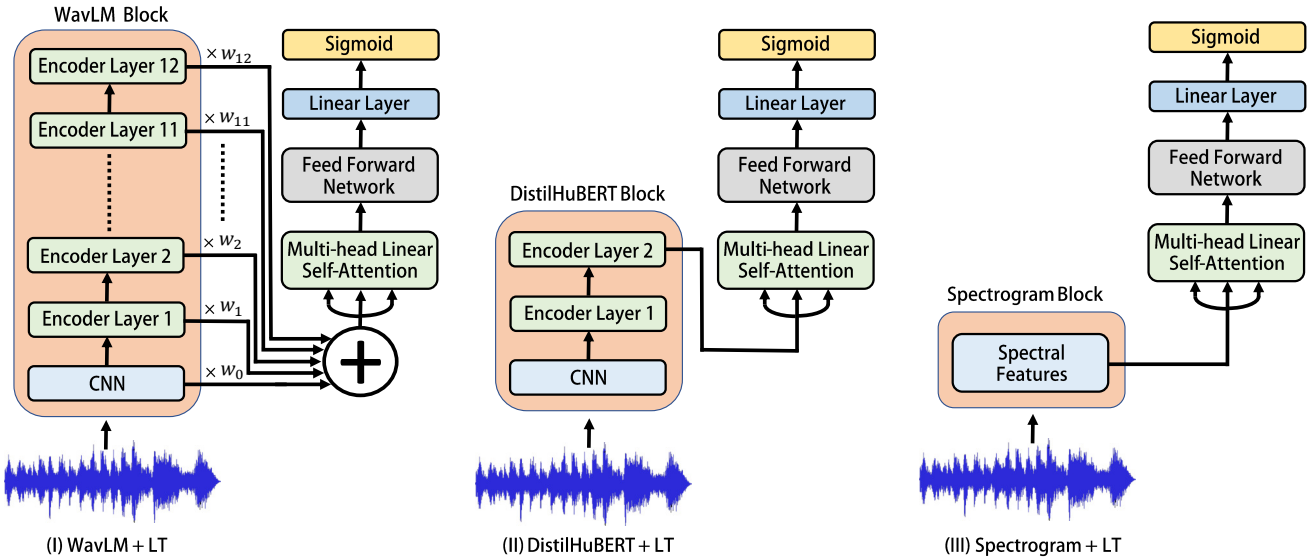

Figure 3. Neural network structures of the proposed models. (I), (II) and (III) use WavLM, DistilHuBERT and Spectrogram front-ends blocks, respectively, followed by the same linear transformer network.

a much lighter model, leading to a much faster inference process. DistilHuBERT includes a CNN network and two self-attention layers. According to its evaluation results [29], DistilHuBERT delivers comparable performance to the teacher HuBERT model with much less computational cost. It is noted that as the training objective of the DistilHuBERT student model is to learn directly from several internal encoder layers of the teacher model, the weighted sum strategy is not needed for this model and its last layer's output is used as the feature embeddings.

Spectrogram: We also perform an ablation study to evaluate the effect of using self-supervised models on the system performance by replacing the self-supervised pre-trained feature embeddings with spectral features that are commonly used in SOTA music beat tracking methods [6, 7]. These spectral features include log-magnitude mel-frequency spectrogram with three window sizes of 1024, 2048, and 4096 samples and their first-order time differences.

3.2 Linear Transformer Network

Transformers achieve remarkable performance in many tasks, but due to their quadratic complexity with respect to the input length, they are prohibitively slow for long sequences [34]. To address this limitation and to improve transformers' computational cost, several approaches are proposed. For instance, Linformer [35] is a model that reduces the transformer complexity in both time and space from $O(N^2)$ to $O(N)$ by approximating the self-attention mechanism by a low-rank matrix. It is noted that N is the sequence length. Another model [34]reduces the complexity to linear by expressing the self-attention as a linear dot-product of kernel feature maps and making use of the associativity property of matrix products. It achieves similar performance to vanilla transformers and they are up to 4000x faster on auto-regressive prediction of very long sequences. Another recent model [36] removes the softmax in self-attention by using the Gaussian kernel function to replace the dot-product similarity without further normalization. It enables a full self-attention matrix to be approximated via low-rank matrix decomposition.

In our proposed method, we build a linear multi-head self-attention layer using [34] on top of the feature embedding blocks for all three proposed models.

Our encoder comprises a self-attention layer with four attention heads with query and value dimensions of 192 and a feed-forward network with the size of 1024. The encoder network is followed by a linear layer and a sigmoid layer. The final output can be viewed as the beat salience for the input audio frame.

To train the proposed models, we use binary cross-entropy with logits between model output and the ground-truth beat annotations as the loss function. Only the linear transformer and its following layers are trained, while the self-supervised front ends are pre-trained and fixed.

4. POST-PROCESSING

In order to decode the beat positions, we employed a DBN approximated using HMM from Madmom library [37] with the default parameters. It is noted that the mentioned inference block is shared between all reported models in the evaluation table except BeatRoot [2].

5. EXPERIMENTS

5.1 Experimental Setup

We use all of the datasets collected in Section 2 except GTZAN for training the models with 80% of the songs randomly allocated for training and 20% for validation. Following several previous music beat tracking works, we keep the entire GTZAN dataset as the test set. It contains

1000 music excerpts covering 10 different music genres, out of which 741 of them contain vocal tracks. It ensures genre diversity in the test set and such a training/test dataset partition reduces the possibility of overfitting as well.Moreover, it is unseen in the training blocks of all compared methods. However, one drawback of it is that GTZAN's vocal tracks are separated from the whole songs. Hence, they may contain some information leakage from other musical instruments, which may boost the system performance compared to testing on isolated vocal tracks. To address this issue, we took the following steps. First, We used one of the best-performing supervised source separation models [11] and listened through the separated vocal tracks to ensure that they do not contain obvious music signal leakage. Second, when tuning the RMS filter, we discarded some sparse, abrupt and short signal segments that are more likely to be percussive sounds instead of vocal signals. Third, we compared with several high performing music beat tracking methods in the evaluation section; The leakage of musical signals into the separated tracks, if any, would improve the performance of these comparison models as well.

For the mentioned reason and given that singing beat tracking is a novel MIR task with no specifically design existing models, in this paper, we compare our proposed models against general music beat tracking models including two supervised models, BeatNet [6] and Böck [7] and an unsupervised signal-processing model, BeatRoot [2]. BeatNet is the SOTA online joint beat, downbeat, and meter tracking model that uses convolutional recurrent neural networks and particle filtering. It can also operate in an offline fashion by switching its particle filtering inference block with an offline hidden Markov model decoder. Böck uses a recurrent neural network to predict beat and downbeat saliences of each audio frame, and uses a Dynamic Bayesian Network (DBN) to infer beat and downbeat positions from the salience function. In our implementation, we use the same HMM decoder as that in BeatNet to replace the DBN. BeatRoot is a unsupervised method with a multiple agent architecture that simultaneously considers several different hypotheses of beat positions and tempi.

5.2 Training Details

To train the proposed models, we freeze the self-supervised front-end blocks and train the rest of the model including the multi-head self-attention layer and its following feed-forward and linear layers. For the WavLM+LT model, in addition to the abovementioned items, the 12 weights to combine different encoder layer's output are also trained.

The mentioned weights are initialized as ones and the rest of the weights and biases are initialized randomly. We use the Adam optimizer with a learning rate of 5×10^{-5} and a batch size of 10. The batches comprise 15-second long excerpts randomly sampled from all audio files in the training set. As the audio files have different length, to ensure a fair distribution, we sample with a probability that is proportional to the length of the files.

5.3 Results and Discussions

To assess the computational cost of the models, we report the inference speed for all of them. The reported numbers are the average computational time for all 741 excerpts with the average duration of 28 seconds each. Note that we measure the speed of all methods using CPU processing on the same Windows machine with an AMD Ryzen 9 3900X CPU and 3.80 GHz clock. Table 2 demonstrates the evaluation results.

Table 2 shows the evaluation results of the baselines and the proposed models using the four metrics presented in Section 2.2. It also includes the Phase Inclusive (PI) evaluation scheme for the proposed models. Several interesting observations can be made. First, all of the three proposed models outperform the three baselines by a large margin. This difference is especially pronounced for more strict metrics such as Goto [3]. This confirms our hypothesis that vocal tracks show very different patterns from complete songs, and the baseline models that are trained on complete songs do not perform as well as the proposed models that are trained on the vocal tracks. This hypothesis is further validated by the fact that BeatRoot outperforms BeatNet and Böck, while the latter two models are shown to outperform BeatRoot in previous studies on complete songs [6, 7]. It is noted that BeatNet and Böck are data-driven approaches and are trained on complete songs, while BeatRoot is a signal processing model without training. The mismatch between complete songs and vocal tracks does impose a strong negative bias to the data-driven baselines.

Second, the two proposed models that leverage speech SSL feature embeddings (i.e., WavLM+LT and DistilHuBERT+LT) improves over Spectrogram+LT by a large margin, and this improvement is even bigger than that from the best baseline to Spectrogram+LT. This shows the significant advantage of using feature embeddings learned on speech data and suggests that this advantage is even more significant than training on the vocal tracks. As the spectrogram features used in Spectrogram+LT are the same as those in BeatNet and Böck and transformers have been shown to outperform RNNs in various tasks, it is reasonable to believe that even if BeatNet and Böck are trained on the vocal tracks, their performance would be only comparable to that of Spectrogram+LT.

Third, WavLM+LT delivers the best scores for all of the evaluation metrics except the computation time, showing that stronger feature embeddings lead to better vocal beat tracking accuracy. However, the attention layers' complexity in WavLM is quadratic to the length of input; while the average computational time (4.09 seconds) is acceptable for vocal segments (28 s long on average) in this experiments, as the length increases, the computational time will soon become prohibitive. Figure 4 shows the learned weights of different encoder layers of the WavLM SSL model. It can be seen that earlier layers generally contribute more to forming the feature embeddings compared to latter layers. Layers 3, 2 and 1 contribute the most. Note that Layer 0 represents the CNN network output.

	Method	F-Measure	P-Score	Cemgil	Goto	Comp. Time
Baseline	BeatNet	0.243	0.327	0.173	0.003	0.13 (s)
	BeatRoot	0.301	0.394	0.22	0.066	**0.03 (s)**
	Böck	0.171	0.195	0.122	0.009	1.56 (s)
Proposed	WavLM + LT	**0.733**	**0.704**	**0.618**	**0.560**	4.09 (s)
	DistilHuBERT + LT	0.703	0.668	0.593	0.516	1.83 (s)
	Spectrogram + LT	0.454	0.438	0.367	0.223	0.32 (s)
Proposed (PI Results)	WavLM + LT	0.745	0.715	0.627	0.574	4.09 (s)
	DistilHuBERT + LT	0.721	0.684	0.608	0.537	1.83 (s)
	Spectrogram + LT	0.489	0.477	0.391	0.265	0.32 (s)

Table 2. Average performance and speed across segments of several methods on the GTZAN separated vocal tracks.

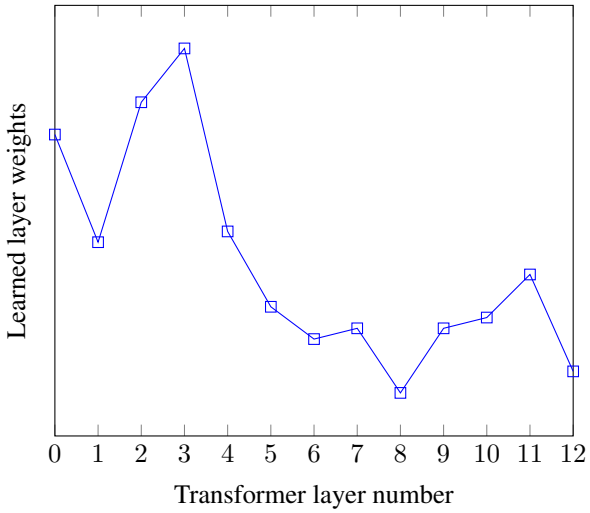

Figure 4. Illustration of the learned weights for different encoder layers of WavLM in the WavLM+LT model.

Fourth, with slight performance drop, the second proposed model which employs LT and DistilHubert delivers the next best performance among all models. DistilHubert uses a much lighter structure with fewer parameters than WavLM, making it ideal for time-sensitive inferences.

Finally, the PI evaluation scheme shows a slight improvement of all of the proposed models on all accuracy metrics. In particular, the improvement of Spectrogram+LT is greater than that of the other models. This suggests that the SSL pretrained speech embedding features are helpful to reduce the phase shift ambiguity.

Figure 5 shows the performance of our proposed WavLM + LT model for different music genres. According to the table, the best and worst performances belong to *disco* and *blues* respectively. One reason for that may be the stronger and punchier stresses in *disco* vocal tracks comparing to that of *blues* tracks. Another important reason may be the different syncopation ratio among vocal track of different music genres. Syncopation is a musical term that defines the placement of rhythmic stresses or accents where they would not normally occur, making part or all of a tune or piece of music off-beat [38]. Therefore, a higher syncopation ratio leads to a more difficult beat tracking process. Nate that in Figure 5 we only report the evaluation results of the genres that contain at least 80 separate singing tracks. It leaves out the *classical* and *jazz* genres which have only two and zero separated tracks.

6. CONCLUSION

In this paper we introduced singing beat tracking as a novel MIR task. We proposed two approaches to obtain labeled data for the mentioned task and introduced two methods to accomplish the mentioned task using pre-trained speech self-supervised models and multi-head linear self-attention networks. We also conducted an ablation study to investigate the effect of speech self-supervised models on the system performance. Experiments on a collection of vocal tracks with diverse genres show that the proposed models that combine self-supervised models and transformers outperform three representative baselines designed or trained for beat tracking for general music. The ablation study also shows that the self-supervised speech embeddings outperform generic spectral features that are commonly used in music beat tracking. In the future we will extend this research to cover real-time applications and more challenging singing tracks such as human humming and operas.

ABSTRACT

Music source separation research has made great advances in recent years, especially towards the problem of separating vocals, drums, and bass stems from mastered songs. The advances in this field can be directly attributed to the availability of large-scale multitrack research datasets for these mentioned stems. Tasks such as separating similar-sounding sources from an ensemble recording have seen limited research due to the lack of sizeable, bleed-free multitrack datasets. In this paper, we introduce a novel multitrack dataset called EnsembleSet generated using the Spitfire BBC Symphony Orchestra library using ensemble scores from RWC Classical Music Database and Mutopia. Our data generation method introduces automated articulation mapping for different playing styles based on the input MIDI/MusicXML data. The sample library also enables us to render the dataset with 20 different mix/microphone configurations allowing us to study various recording scenarios for each performance. The dataset presents 80 tracks (6+ hours) with a range of string, wind, and brass instruments arranged as chamber ensembles. We also present our benchmark on our synthesised dataset using a permutation-invariant time-domain separation model for chamber ensembles which produces generalisable results when tested on real recordings from existing datasets.

1. INTRODUCTION

Audio source separation aims to extract individual sound sources from a digital audio mixture. Based on the constituents of the input mixture and the target output, the problem definition can be further refined to specific audio separation tasks like speech separation, speech enhancement, and music source separation [1]. While specific subtasks in the speech-domain like speech denoising, multi-speaker separation and dereverberation have been thoroughly explored, music separation research has largely been focused on the demixing challenge [2] aided by the popular MUSDB dataset [3]. The demixing challenge is targeted at solving the problem of separation of vocals, bass and drums from mixed and mastered pop songs. This has greatly benefited the field by demonstrating that source separation is indeed possible at a commercial scale with state-of-the-art deep learning based architectures. Unfortunately, this also has resulted in the research towards this specific task to dwarf other problems that would also fall under the umbrella of music source separation, to the extent that music source separation has become synonymous with the task of separating vocal, drums and bass stems from mastered songs.

In this paper, we explore a different area in music source separation with a focus on separation of chamber ensembles, where the target sources are harmonised and have very high spectral overlap. The music demixing challenge has shown successful separation of instruments with distinct spectro-temporal cues like vocals, drums and bass. Separating monotimbral ensembles is an inherently challenging task as they combine challenging aspects of both speech and music separation. In chamber ensembles we find the sources to occupy similar frequency ranges, may have label ambiguity [4, 5] due to multiple sources belonging to the same instrument family meanwhile being temporally and harmonically correlated, due to their musical structure which further increases their spectral overlap.

To address this challenge, we present a novel chamber ensemble dataset titled EnsembleSet [6]. EnsembleSet was synthesised using a realistic sample library Spitfire BBC Symphony Orchestra (BBCSO) [7] utilising the MIDI transcriptions from the RWC Classical Music Database [8] and lilypond scores from Mutopia [9] (refer to Section 3.4 for details). In Section 4 we utilise EnsembleSet to train a source separation model based on the Dual-path Transformer architecture (DPTNet) [10, 11] for separating mixtures of chamber ensembles. We achieve very good and generalisable separation performance which we exhibit through cross-dataset performance evaluation in Section 5. Other applications of EnsembleSet may include topics such as multi-instrument transcription [12], instrument recognition [13], score-informed source separation [14], microphone translation [15], automatic mixing [16] and other tasks that may benefit from score-aligned multitrack multi-instrument data.

2. BACKGROUND

Although the term "Music Source Separation" sounds like an umbrella-term for all applications of source separation

© S. Sarkar, E. Benetos, and M. Sandler. Licensed under a Creative Commons Attribution 4.0 International License (CC BY 4.0).
Attribution: S. Sarkar, E. Benetos, and M. Sandler, "EnsembleSet: a new high quality synthesised dataset for chamber ensemble separation", in *Proc. of the 23rd Int. Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

in music, in research the use of this term is largely used to describe the specific task of vocals/drums/bass instrument stem separation from mastered tracks [2, 17]. A music source separation task which is relatively unexplored is the challenge of separating similar sounding instruments from a mixture. This problem has two significant differences from the aforementioned task. Firstly, if the sources in the mixtures are similar sounding (e.g., mixture of a strings section), it results in high spectral energy overlap. This is further compounded by the fact that such sources often play in a very synchronised fashion while harmonising each other. Secondly, often in such mixtures we may have multiple sources of the same type present, which makes it an unsuitable problem to be solved using *class-based* separation methods [4]. We define the task of separating such mixtures with constituent sources suffering from label ambiguity and high timbral similarity as *monotimbral ensemble separation*.

2.1 Datasets

Training supervised source separation models typically requires datasets which provide the clean target sources as a reference for the deep learning models to learn from. While the majority of popular music can be recorded in separate takes for different performers, with a reference metronome or a backing track, ensembles are usually recorded together in the same take. This is due to the fact that ensemble performers rely on being able to hear each other during performance to be able to synchronise perfectly. This raises the problem that the majority of stems available from recording projects of monotimbral ensembles contain bleed [1] from non-target sources [18, 19]. This becomes problematic for training models for source separation as we do not have the clean ground truth as a target result for the model. This lack of clean and sizeable datasets for ensembles has affected the amount of research seen in this domain.

The URMP dataset [20] addresses this problem by making the performers record isolated takes and then subsequently re-align, dereverberate and downmix them to be present in a physical space. Another work [21] presented a dataset recorded by minimising the amount of bleed using soundproofing across booths while recording multiple performers in the same take. Bach10 [22] also presents multitrack recordings of chamber ensembles where each song consists of four parts (Soprano, Alto, Tenor and Bass) which were performed by violin, clarinet, saxophone and bassoon, respectively. The TRIOS dataset [23] consists of 5 bleed-free multitracks and synchronised MIDI files of 4 classical music pieces and 1 jazz piece.

2.2 Prior work

There are some tasks which fit our definition of monotimbral separation that have been explored recently. One is vocal harmony separation [11,24–26]. While the label ambiguity problem does exist for this task, some approaches have circumvented it by looking at the problem in a class-based separation fashion by categorising the constituent sources based on their registers i.e. alto, soprano, bass and tenor. One method of solving the label ambiguity problem is to tackle this problem in a score-conditioned fashion as in [25]. Another method of tackling this problem is called permutation invariant training (PIT) [27] which has been the preferred solution to tackle the label ambiguity problem for speech separation research [10, 28, 29]. PIT has been utilised for choral separation in [11]. Another approach has been to use multi-task learning by utilising score-information to simultaneously separate and transcribe mixtures of 2-source chamber ensembles which has shown some success for scenarios with small datasets [30].

3. DATASET

To overcome the challenge of bleed-free real recorded datasets for ensembles, we introduce a novel dataset “EnsembleSet", which utilises a highly realistic orchestral sample library by Spitfire Audio called "BBC Symphony Orchestra" (BBCSO) [7]. We use this sample library to render digital chamber ensemble scores from MIDI and MusicXML format to 18 unique multi-mic recordings and 2 professional mixes. For this work, we utilised the RWC Classical Music Database [8] and Mutopia [9] to source our chamber ensemble MIDI and MusicXML (converted from lilypond) scores. It must be noted that MIDI data are not ideal to capture string, wind and brass instrument scores as they do not encapsulate articulation information. On the other hand lilypond scores contain minimal dynamics (velocity) information, which is essential for realistic rendering using virtual instruments. In order to address these challenges, we utilise expression maps provided by Dorico [31], a scorewriter software which allows us to determine the articulation mode for each note in the piece.

3.1 Collecting Digital Music Scores

3.1.1 RWC Classical Music Database

The RWC Classical Music Database [8] consists of 50 public-domain classical pieces performed by musicians and then manually transcribed to MIDI with high-quality tempo and velocity mapping. Since the database only provides the final mix of these performances, its applications are limited especially in the context of source separation. We choose a subset of these pieces which contain chamber ensembles which can be rendered using our method. Our 9 selected pieces (1h 3m 34s) [2] consist of 4 string quartets, 2 clarinet quintets, 2 piano trios and 1 piano quintet. It must be noted that for the piano trios and quintet, we only render the string instrument parts. Because MIDI files lack articulation information, we modify the MIDI files using Dorico to automatically add it using keyswitches, which are then subsequently rendered as multitracks on Reaper [32].

[1] Sound picked up by a microphone from a source other than that which is intended.

[2] Rendered duration in dataset.

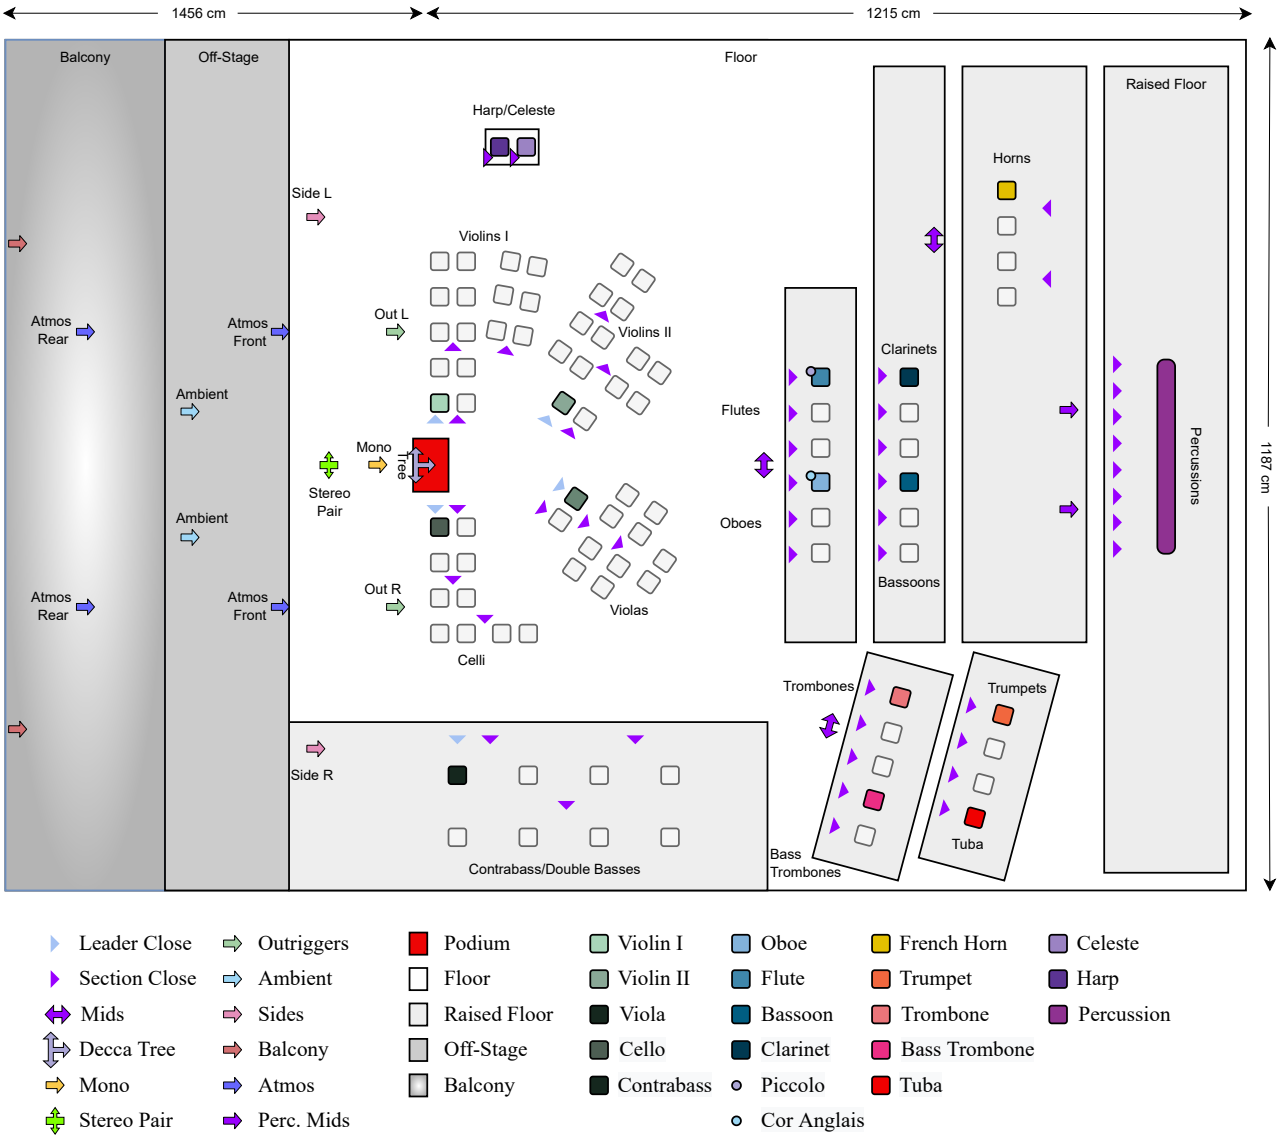

Figure 1. Recording configuration for the Spitfire Audio BBC Symphony Orchestra sample library depicting the placement of individual microphones, performers. The scale of the image is not uniform as the off-stage elements are placed further than they appear.

3.1.2 Mutopia

The Mutopia project [9] is a publicly sourced and manually verified free content sheet music library. The sheet music scores are manually annotated from old scores that are now public domain, and digitally archived using the lilypond format which can be converted to MusicXML and MIDI. This library has a large collection of string ensembles, of which we utilise 71 pieces (5h 5m 35s)[2] comprising a variety of chamber ensembles primarily composed of string quartets but also including other instruments such as Trumpet, Horn, Oboe, Clarinet, Flute and Bassoon. Although all the lilypond files come with their standard MIDI conversions, we utilise the lilypond to MusicXML conversion python library [33], to preserve the articulation information present in the lilypond files. For the files which we are able to convert to MusicXML, we import them to Dorico, where these articulations are translated to keyswitches (described in Table 2) and rendered to MIDI format which can then be utilised by the BBCSO plugin when rendered on Reaper [32].

3.1.3 Data Cleaning

Many of the scores used to render our dataset contain instruments that are absent (e.g., piano, vocals) in our sample library. Since the intent of EnsembleSet is to generate realistic renders of instruments performing and being recorded in the same physical space, we chose to remove the incompatible instruments as rendering them using other plugins will not be consistent. While converting Mutopia based files using the lilypond to MusicXML conversion tool, many files resulted in erroneous MusicXML files. For the corrupted conversions, we used the MIDI files directly from the database and were unable to preserve articulation for those pieces. For these pieces we use the same

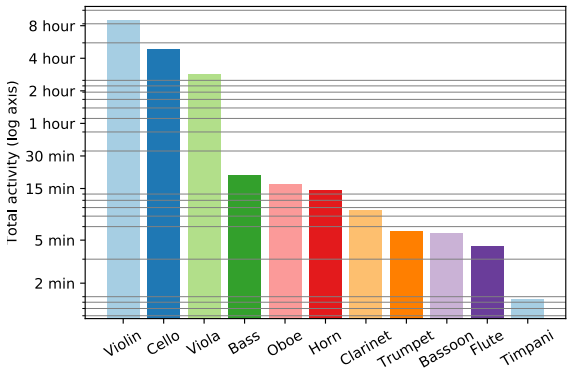

Figure 2. Instrument wise activity duration in EnsembleSet

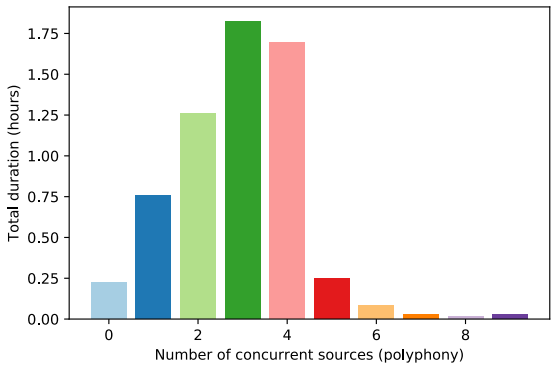

Figure 3. Polyphony distribution across EnsembleSet

articulation generation pipeline as the RWC sourced files. For some other files where the errors were minor (incorrect timing and track assignments), we used their corresponding MIDI files from the library to manually inspect and correct these MusicXML files.

3.2 BBC Symphony Orchestra Sample Library

This library was developed in partnership between BBC Studios and Spitfire Audio, by capturing a full orchestra as sections as well as individual section leaders. Each instrument was recorded for each note in a variety of articulation modes using multiple microphones placed at different positions in the room. For shorter notes, multiple iterations were recorded which are rendered in a round-robin fashion to simulate microtiming variations of real performers. The sample library was recorded in the same fashion as a film score would be recorded in a studio with a multi-microphone setup that enables the capture of each performer from different perspectives in the room. This is what allows us to simulate high quality recordings of chamber ensemble pieces from digital music scores, rendered using individual section leaders.

No.	Render Name	Type	# Mics	Pan
1	Mono	Bidirectional	1	Mono
2	Leader	Unidirectional	1	Stage Pan

19	Mix 1	Mix	12	Stage Pan
20	Mix 2	Mix + FX	12	Stage Pan

Table 1. List of available renders in EnsembleSet. It must be noted that the Leader microphone is only available for string instruments.

3.2.1 Microphone Renders

The BBCSO sample library provides an entire portfolio of recording stems/microphones that a mix engineer would rely on while producing orchestral scores including traditional mixing setups like decca tree, outriggers, ambient microphones, far balcony mics, side mics and more modern setups including Atmos front and back mics placed at a height in the room. The placement of the individual microphones and each performer is shown in Figure 1. These recorded samples not only preserve the timbral changes that occur for a source recorded at various positions based on their distance, microphone type and directionality, but also preserves the phase shifts that occur across these different microphones placed at different distances w.r.t. the sources. The recorded samples are rendered without any time-correction, which implies that different mic renders would have different time delays and phase shifts based on the distance between the source and the mic. The renders also realistically reflect the timing adjustments performers for different sections make based on their instruments dynamics and position on stage.

It must be noted that in EnsembleSet, the positions for the close microphones are unique for each instrument, but the remaining room microphones are common across all instruments. Thus to simulate a realistic microphone bleed scenario, one can simply render each source at any given room microphone and downmix the resulting instrument stems. On the other hand, downmixing the close microphones would simulate the more typical scenario of music separation from a mixed song. Further details about individual microphone/mix setups can be found in Table 1.

3.2.2 Mixes

Apart from the individual microphone stems, the plugin also provides two professionally mixed stems. Mix 1 is a

Switch	Strings	Horn & Trumpet	Flute & Clarinet	Oboe & Bassoon
C-1	Legato	Legato	Legato	Legato
C#-1	Long	Long	Long	Long
D-1	Long Con Sordino	Staccatissimo	Trill Major 2nd	Trill Major 2nd
D#-1	Long Flautando	Marcato	Trill Minor 2nd	Trill Minor 2nd
E-1	Spiccato	Long Cuivre	Staccatissimo	Staccatissimo
F-1	Staccato	Long Sforzando	Tenuto	Tenuto
F#-1	Pizzicato	Long Flutter	Marcato	Marcato
G-1	Col Legno	Multi-tongue	Long Flutter	Multi-tongue
G#-1	Tremolo	Trill Major 2nd	Multi-tongue	-
A-1	Trill Major 2nd	Trill Minor 2nd	-	-
A#-1	Trill Minor 2nd	Long (muted)	-	-
B-1	Long Sul Tasto	Staccatissimo (muted)	-	-
C0	Long Harmonics	Marcato (muted)	-	-
C#0	Short Harmonics	-	-	-
D0	Bartok Pizzicato	-	-	-
D#0	Marcato	-	-	-

Table 2. List of keyswitch-articulation mappings for different instruments.

general starting point for a mix engineer with a good balance of the commonly used microphones like Decca Tree, Outriggers, Ambient, Balcony, Mids and Close mics. Mix 2 provides a more intense sound with some added compression, EQ and reverb. These stems are ideal to simulate the typical music separation scenario as the mixes provided present a good simulation of an unmastered and a mastered mix for an orchestral ensemble.

3.3 Articulation Automation

The BBCSO plugin allows rendering each note in a variety of articulations that are particular to each instrument. We use Dorico which in case of importing scores as MusicXML files, is capable of mapping articulations from MusicXML to keyswitches in the -1 octave in MIDI. Alternatively if articulations are unavailable, as is the case for importing scores as MIDI files, Dorico automatically selects either staccato or long articulation based on individual note lengths with a crossover at 187.5ms (16th note at 80bpm). The list of keyswitches and articulation mappings for each of the instruments available in EnsembleSet is shown in Table 2.

3.4 Dataset Contents

EnsembleSet contains a total of 6 hours and 9 minutes of multi-instrument, multi-mic data and is available on Zenodo [3] . The resulting total active duration of each instrument in EnsembleSet can be seen in Figure 2. The dataset presented is focused around string ensembles, and each of the 80 tracks presented in the dataset contains at least one string instrument, while the majority of pieces comprise string quartets. EnsembleSet also contains other woodwind and brass instruments, although their distribution is rather sparse. The overall polyphony distribution across the dataset is shown in Figure 3. Each song is also paired with its accompanying MIDI file which was used to generate the renders, and also contains the articulation information. Our implemented data preprocessing (described in section 4.2), data augmentation pipeline and other metadata related to the tracks such as song title, author, instrumentation and audio examples are available online [4] .

3.5 Limitations

While we have tried our best to make the synthesised recordings sound as realistic as possible, the achieved quality was still limited by the amount of information available in the source MIDI/lilypond files. All of the 9 tracks sourced from the RWC database have very good dynamics and realistic tempo variations in the renders, but since the source data was MIDI, the articulations are limited to long, staccato and pizzicato. For the 71 songs sourced from Mutopia, we were able to render from MusicXML for 30 of them, thus these are the only songs that are able to map to all possible articulations present in the source sheet music. For the remaining 41 tracks which were rendered from MIDI, the articulations are similarly limited to long, staccato and pizzicato. For all the songs sourced from Mutopia, the dynamics mapping available was limited due to limitations of the source lilypond format, thus resulting in each note having only one of 3 levels of velocity. While the instrument names in the renders have been standardised across the dataset, the accompanying MIDI files provided with each of the renders do not have standardised track names as they were preserved from the original track names from the source MIDI/Lilypond files.

4. EXPERIMENTS

To exhibit the value of our synthesised dataset, we use EnsembleSet to train a source separation model that is able to separate any chamber ensemble duet as explored in [30]. While we are training our model exclusively on our generated data, we evaluate on real-world data from the URMP dataset [20]. We make use of the multi-mic renders that are available in EnsembleSet as a form of data augmentation by randomising the mix/mic(s) presented to the

Model	Train	Eval	SDR	SI-SDR
MSI [30]	URMP	URMP	+6.33 dB	-
DPTNet	URMP	ES	+6.29 dB	+4.37 dB
DPTNet	ES	URMP	+11.37 dB	+9.06 dB
DPTNet	ES	ES	+14.17 dB	+12.87 dB

Table 3. 2-source Chamber Ensemble Separation results.

model at each epoch. In addition, we use other augmentations including pitch shift and gain modulation to help the model generalise better to unseen source/microphone configurations. We utilise the same architecture as presented in [11] which is based on [10], modified to accommodate for 44.1kHz sample rate audio.

4.1 Model

We utilise the Dual-path Transformer (DPTNet) [10] based architecture using PIT [27] and modify the filterbank, scheduler and other network parameters to accommodate input segments at a sampling rate of 44.1kHz. Our model takes 2.97 second input frames (131072 samples) with 8 repeating separator units. We define the 1-D encoder filterbank to have a filter length of 32 samples with a hop size of 4 samples which resulted in best results in our experiments. Utilising a PIT loss for monotimbral ensembles is particularly well suited, as this enables our model to be able to separate any two monotimbral instruments regardless of their class.

4.2 Data

We train the model using all possible combinations of chamber ensemble duets playing simultaneously from EnsembleSet (ES) amounting to about 53 hours of data. To achieve this we implemented a novel dataloader that measures instrument activity confidence for each instrument track and identifies pairs of instrument segments where both the sources have some overlapping activity in all possible combinations (for eg: a string quartet piece for 2 source separation can be used as 6 different pairs of string duets). We used the URMP dataset (URMP) [20] to generate real examples for cross-validation and testing in a similar fashion resulting in 4.5 hours of 2 source mixtures. We utilise torch-audiomentations [34,35] for data augmentation such as gain modulation, channel swap and pitch-shifting by up to +/- 2 semitones. We also use the multi-mic renders of each instrument track as data augmentation by randomly choosing one of the 20 renders for each instrument for each iteration. It must also be noted that we maintain temporal and harmonic integrity of the mixtures through all the data augmentations. This is unlike the typical music separation data augmentation pipeline where the constituent parts of the mixtures are randomised across different songs at every epoch during training [36].

4.3 Training

We train the models for 100 epochs with early stopping patience of 10 epochs. We start with a learning rate of $5 \times e^{-3}$ with a scheduler that halves the learning rate if the validation loss does not improve for 3 epochs. We train the models on 4 x NVIDIA A100 GPUs using a distributed data parallel back-end. Each epoch in our experiments took 40 minutes with a batch size of 1 per GPU.

5. RESULTS

We present our baseline results based on the experiments described above and compare it to previous experiments conducted for a similar task as described in [30]. The results from [30] are based on a zero-shot learning + multi-task source informed (MSI) separation model designed to tackle the limitation of a very small training dataset. We compare our model's cross-dataset evaluation performance between the URMP Dataset [20] and EnsembleSet (ES) with the experiments from [30] as shown in Table 4.1. We find that our model trained on URMP and tested on ES reports similar separation quality as the MSI experiments from [30], although the test sets were not identical. The same model trained on ES and tested on URMP reports an improvement of 5dB in separation quality.

6. CONCLUSION

In this paper we introduced a new dataset constructed using digitised chamber ensemble scores and a professional orchestral sample library to address the lack of multitrack chamber ensemble datasets. We described our data generation process and data augmentation methods to enable generalisable deep learning solutions using the same. We provided a baseline for the task of separating 2 monotimbral instruments playing simultaneously and are able to show that models trained exclusively on our synthesised dataset are able to generalise to real world data for the same task. This outcome emphasises the strong dependence of the performance of deep learning on training regimes, in particular the quality of the training dataset.

The presented dataset not only contains high quality multi-microphone renders of various instruments, but is also accompanied by the MIDI files that were utilised for generating this dataset. This paired data can be utilised for various tasks including multi-instrument transcription [12], instrument recognition [13], score-informed source separation [13], microphone simulation [15], and automatic mixing [16].

While PIT is well suited for monotimbral ensemble separation as it can separate any 2 sources regardless of their instrument class, it is limited by polyphony where a model only works for mixtures with a fixed number of sources. In the future we intend to explore source conditioned separation models which would enable separating any particular source from a mixture. Although the efficacy of such solutions in the case of mixtures with multiple instances of same instruments has to be tested. In our current work we perform the separation on single channel audio, but we would like to extend our model to be capable of handling multi-channel audio input and utilise spatial information implicitly during separation.

ABSTRACT

This paper presents an automatic lyrics transcription (ALT) method for music recordings that leverages the framewise semitone-level sung pitches estimated in a multi-task learning framework. Compared to automatic speech recognition (ASR), ALT is challenging due to the insufficiency of training data and the variation and contamination of acoustic features caused by singing expressions and accompaniment sounds. The domain adaptation approach has thus recently been taken for updating an ASR model pre-trained from sufficient speech data. In the naive application of the end-to-end approach to ALT, the internal audio-to-lyrics alignment often fails due to the time-stretching nature of singing features. To stabilize the alignment, we make use of the semi-synchronous relationships between notes and characters. Specifically, a convolutional recurrent neural network (CRNN) is used for estimating the semitone-level pitches with note onset times while eliminating the intra- and inter-note pitch variations. This estimate helps an end-to-end ALT model based on connectionist temporal classification (CTC) learn correct audio-to-character alignment and mapping, where the ALT model is trained jointly with the pitch and onset estimation model. The experimental results show the usefulness of the pitch and onset information in ALT.

1. INTRODUCTION

Automatic lyrics transcription (ALT) refers to a task that aims to estimate the sung texts from music recordings, typically under the presence of accompaniment sounds. Since music composition and sharing have become very popular among non-professional people (e.g., YouTube), the number of non-annotated music data without lyrics transcriptions has been increasing rapidly. ALT has thus gained a lot of attention from the music information retrieval (MIR) community because of its usefulness in karaoke subtitle generation and text-based indexing.

Considering the similarity between ALT and automatic speech recognition (ASR), most studies on ALT have attempted to use ASR techniques, with some modifications if necessary. The hybrid approach based on a hidden Markov model (HMM) enhanced by a deep neural network (DNN), for example, has been used, where only the acoustic model was optimized for ALT [1]. Another way of ALT is to take the end-to-end approach that directly learns a sequence-to-sequence (audio-to-text) mapping. While the connectionist temporal classification (CTC) [2] and/or the attention mechanism [3] have widely been used for ASR [4, 5], the CTC has mainly been used for ALT [6, 7], in conjunction with the attention mechanism [8]. One reason is that the CTC considers only the monotonic audio-to-text alignment, which is relatively easier to infer from a limited amount of training data.

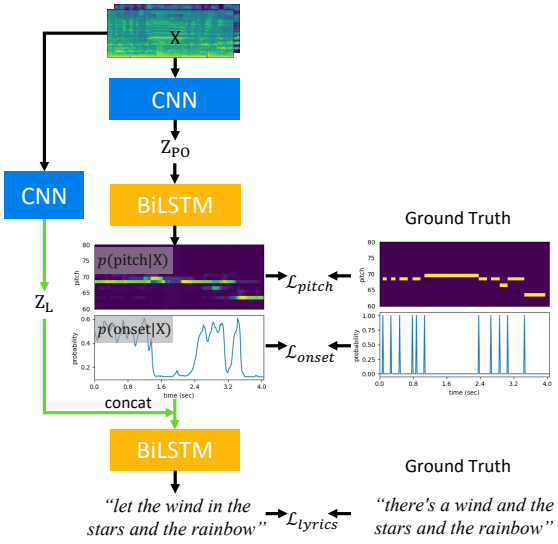

Figure 1. The proposed lyrics transcription method that estimates the pitches and onsets of singing voice and then uses them for character-level lyrics transcription.

The audio-to-text alignment plays a key role in end-to-end ALT and still remains a challenging problem. Firstly, the acoustic characteristics of singing voice vary over time in various ways according to the underlying sung notes and singing expressions. While the phones of speech tend to have particular durations and pitches specific to the speaker, those of singing voice may have time-stretched durations and semi-stepwisely time-varying pitches determined by the singer and the score. Secondly, the acoustic features of singing voice are contaminated by accompaniment sounds

Yoshii, "End-to-End Lyrics Transcription Informed by Pitch and Onset Estimation", in *Proc. of the 23rd Int. Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

or distorted by singing voice separation. It is, however, difficult to collect as training data a sufficient amount of music recordings with aligned lyrics annotations that cover a wide variety of recording conditions and singing styles.

To solve these problems, we make effective use of the framewise pitches and onset times of sung notes as acoustic features exclusive for ALT. In musical scores, lyrics are typically described synchronously with notes, i.e., words or characters tend to coincide with notes. This implies that the note onset information can be used for guiding an end-to-end ALT model to efficiently find the correct audio-to-lyrics alignment from a limited amount of training data. Multi-conditional training with the note pitch information is also expected to make the ALT model robust against the pitch variations.

In this paper, we propose an ALT method based on a cascading multi-task architecture that estimates the pitches and onset times of sung notes and then transcribes the lyrics at the character level in a pitch- and onset-conditioned manner (Fig. 1). More specifically, a convolutional recurrent neural network (CRNN) is used for jointly estimating the semitone-level pitches and onset times while eliminating the intra- and inter-note pitch variations (e.g., vibrato and glissando). Informed by this estimation, another CRNN is then used with CTC for learning audio-to-character alignment and mapping. These two CRNNs are trained jointly with backpropagation such that the sum of the pitch, onset, lyrics estimation losses is minimized. To mitigate the data insufficiency problem, we also use a domain adaptation method that fine-tunes a baseline ASR model pre-trained from huge speech data.

The main contribution of this paper lies in the first attempt for joint lyrics and pitch transcription towards comprehensive singing voice analysis. We experimentally show that the score information exclusive to music can be used effectively for finding audio-to-text alignment in end-to-end ALT with insufficient training data.

2. RELATED WORK

This section reviews related work on automatic lyrics transcription (ALT) and singing voice transcription (SVT).

2.1 Automatic Lyrics Transcription

ALT for music recordings under the presence of accompaniment sounds is still a difficult task due to the contamination of acoustic features [6–8]. A standard way of mitigating the adverse effect of accompaniment sounds is to take the two-step approach that performs singing voice separation [9] and lyrics transcription in this order. Although the remarkable improvement has been made in terms of the pure signal processing performance typically measured by the signal-to-distortion ratio (SDR) [10], the separated singing voice, however, is hard to transcribe, *i.e.*, the word error rate (WER) might be low, because an ALT model trained with clean isolated singing voice would suffer from the distortion of acoustic features and the mismatch between the training and test conditions. Although even ALT for clean singing voice [1] has much room for performance improvement due to the considerable variation of acoustic features caused by singing expressions, working directly on music recordings without singing voice separation could achieve better performance of ALT [7].

Inspired by the great success of the end-to-end approach to ASR, several attempts have been made for directly learning the mapping between non-aligned input and output sequences (audio and lyrics) of different lengths [6–8]. At the heart of the end-to-end learning is the audio-to-lyrics alignment based on the connectionist temporal classification (CTC) [2] and/or the attention mechanism [3]. The CTC-based approach estimates the posterior probabilities of labels (*e.g.*, words and characters) at the frame level and aims to maximize the total score obtained by efficiently accumulating the posterior probabilities of all possible *monotonic* alignment paths between the estimated and ground-truth label sequences. The attention-based approach is more powerful in that it can consider non-monotonic alignment and is thus useful for a wider variety of tasks (*e.g.*, machine translation). In general, however, the latter needs a larger amount of training data for finding the correct alignment and is thus hard to apply solely to ALT.

Some studies on audio-to-lyrics alignment have reported the effectiveness of using pitch information [11, 12]. Considering the semi-synchronous relationships between notes and characters, joint estimation of the pitches, onset times, and lyrics of singing voice would help an end-to-end model find the correct audio-to-lyrics alignment.

2.2 Singing Voice Transcription

The ultimate goal of SVT, a special case of automatic music transcription (AMT), is to estimate a human-readable vocal score underlying a given music recording. Towards this goal, a lot of efforts have been made for estimating the continuous fundamental frequencies (F0s) or discrete semitone-level pitches of singing voice at the frame or note level [13,14]. In particular, frame-level F0 estimation (*a.k.a.* melody extraction) has conventionally been considered as a subtask of SVT and intensively studied thanks to the great advance of supervised deep learning [15, 16]. There is, however, a big gap between melody extraction and genuine SVT because accurate scores are hard to obtain just by quantizing continuous F0 contours, typically at the tatum level, due to the large fluctuations and smooth transitions of F0s (*e.g.*, vibrato or glissando).

The latest study on SVT attempted to directly estimate a note sequence with discrete pitches and score positions [17]. This method is based on a hierarchical hidden semi-Markov model (HHSMM) that represents the generative process of observed singing spectra from a latent sequence of notes whose pitches and onset positions are assumed to follow a key-dependent Markov model and a metrical Markov model, respectively. The emission model was implemented with a CRNN that is pretrained to estimate the pitches of singing voice at the frame level from music spectra such that the intra- and inter-note F0 variations are eliminated. This technique forms the basis of the pitch and onset estimators used in our study.

3. PROPOSED METHOD

This section describes the proposed ALT method based on a cascading multi-task architecture.

3.1 Multi-task Learning Approach

Our method takes as input the mel-spectrogram of a music recording and that of the singing voice extracted from the recording with a DNN-based music separation method called Open-Unmix [18]. Since the singing voice separation is known to affect ALT, the original recording is thus used as well as the separated singing voice. Let $\mathbf{X} \in \mathbb{R}^{C \times F \times T}$ be the set of the input mel-spectrograms, where C is the number of channels ($C = 2$ in this paper), F is the number of frequency bins, and T is the number of frames.

We use as a basic building block a convolutional recurrent neural network (CRNN) consisting of a convolutional neural network (CNN) working as an encoder and a recurrent neural network (RNN) working as a decoder. The encoder extracts latent features from the input spectrograms and then the decoder estimates an output sequence while considering the sequential dependency of the latent features. The CRNN consists of residual CNN blocks with skip connections and RNN blocks (Fig. 2). Each CNN has a rectified linear unit (ReLU) and implemented with instance normalization. In contrast, each RNN block is a bidirectional LSTM (BiLSTM) [19] with layer normalization.

As shown in Fig. 1, our method uses two CRNNs. One CRNN is used for jointly estimating the posterior probabilities of the semitone-level pitches and those of the onset presence at the frame level. Given the estimated pitch and onset probabilities, the other CRNN is used for transcribing the lyrics from the spectrograms. Specifically, the estimated pitch and onset probabilities are fed together with the latent features extracted from the CNN into the RNN. Both CRNNs are trained jointly such the sum of the framewise pitch and onset estimation losses and the CTC-based lyrics transcription loss is minimized.

3.1.1 *Pitch and Onset Estimation*

The goal of pitch and onset estimation (supplementary task) is to estimate the framewise pitch and onset probabilities, denoted by $p(\text{pitch}|\mathbf{X}) \in \mathbb{R}^{K \times T}$ and $p(\text{onset}|\mathbf{X}) \in \mathbb{R}^{1 \times T}$, respectively, from the input data $\mathbf{X} \in \mathbb{R}^{C \times F \times T}$, where K is the number of the semitone-level pitches corresponding to MIDI note numbers plus no-pitch ($K = 128 + 1$).

Specifically, $\mathbf{X}$ is first fed to the series of multiple residual CNN blocks as follows:

$$\mathbf{Z}_{\text{PO}} = \text{CNN}(\mathbf{X}), \tag{1}$$

where $\mathbf{Z}_{\text{PO}} \in \mathbb{R}^{C' \times F \times T}$ is the output of the CNN and C' is the number of channels. Note that the zero padding is performed so that the output of each residual CNN block retains the shape of $\mathbf{X}$ except for the number of channels. Then $\mathbf{Z}_{\text{PO}}$ is reshaped into $\mathbf{Z}'_{\text{PO}} \in \mathbb{R}^{C'F \times T}$ and fed to the RNN as follows:

$$\mathbf{Y}_{\text{PO}} = \text{RNN}(\mathbf{Z}'_{\text{PO}}), \tag{2}$$

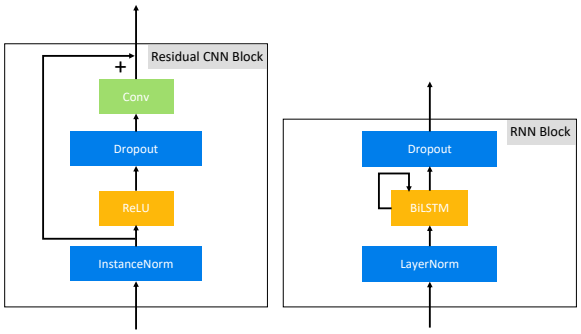

Figure 2. The residual CNN block and the RNN block.

where $\mathbf{Y}_{\text{PO}} \in \mathbb{R}^{C'' \times T}$ is the output of the RNN and C'' is the number of channels. Finally, $p(\text{pitch}|\mathbf{X})$ and $p(\text{onset}|\mathbf{X})$ are computed by feeding $\mathbf{Y}_{\text{PO}}$ to a fully-connected (FC) layer and the softmax and sigmoid functions, respectively, as follows:

$$[\mathbf{Y}_{\text{pitch}}, \mathbf{Y}_{\text{onset}}] = \text{FC}(\mathbf{Y}_{\text{PO}}), \tag{3}$$

$$p(\text{pitch}|\mathbf{X}) = \text{softmax}(\mathbf{Y}_{\text{pitch}}), \tag{4}$$

$$p(\text{onset}|\mathbf{X}) = \text{sigmoid}(\mathbf{Y}_{\text{onset}}), \tag{5}$$

where $\mathbf{Y}_{\text{pitch}} \in \mathbb{R}^{K \times T}$ and $\mathbf{Y}_{\text{onset}} \in \mathbb{R}^{1 \times T}$ are the intermediate outputs from the FC layer.

3.1.2 *Lyrics Transcription*

The goal of lyrics transcription is to estimate the framewise character probabilities, denoted by $p(\text{character}|\mathbf{X}) \in \mathbb{R}^{V \times L}$ from the input data $\mathbf{X} \in \mathbb{R}^{C \times F \times T}$, where V is the number of characters (dictionary size) including a special blank label used for CTC ($V = 33 + 1$ in this paper).

Specifically, in the same way as pitch and onset estimation, $\mathbf{X}$ is first fed to the series of multiple residual CNN blocks as follows:

$$\mathbf{Z}_{\text{L}} = \text{CNN}(\mathbf{X}), \tag{6}$$

where $\mathbf{Z}_{\text{L}} \in \mathbb{R}^{C' \times F \times T}$ is the output of the CNN. Then $\mathbf{Z}_{\text{L}}$ is reshaped into $\mathbf{Z}'_{\text{L}} \in \mathbb{R}^{C'F \times T}$, stacked with the estimated pitch probabilities $p(\text{pitch}|\mathbf{X}) \in \mathbb{R}^{K \times T}$ and onset probabilities $p(\text{onset}|\mathbf{X}) \in \mathbb{R}^{1 \times T}$, and fed to the RNN as follows:

$$\mathbf{Y}_{\text{L}} = \text{RNN}([\mathbf{Z}'_{\text{L}}, p(\text{pitch}|\mathbf{X}), p(\text{onset}|\mathbf{X})]), \tag{7}$$

where $\mathbf{Y}_{\text{L}} \in \mathbb{R}^{C'' \times L}$ is the output of the RNN and C'' is the number of channels. For computational simplicity, $\mathbf{Z}_{\text{L}}$ as well as $p(\text{pitch}|\mathbf{X})$ and $p(\text{onset}|\mathbf{X})$ are downsampled to $T/2$ frames with a 2-dimensional max-pooling layer. Finally, $p(\text{character}|\mathbf{X})$ is computed by feeding $\mathbf{Y}_{\text{L}}$ to a fully-connected (FC) layer and the softmax function as follows:

$$\mathbf{Y}_{\text{character}} = \text{FC}(\mathbf{Y}_{\text{L}}), \tag{8}$$

$$p(\text{character}|\mathbf{X}) = \text{softmax}(\mathbf{Y}_{\text{character}}), \tag{9}$$

where $\mathbf{Y}_{\text{character}} \in \mathbb{R}^{V \times T}$ is the intermediate output from the FC layer.

3.1.3 Joint Training with Domain Adaptation

The CRNN used for pitch and onset estimation and that for lyrics transcription are mutually dependent and thus trained jointly such that the sum of the framewise pitch and onset estimation losses (cross-entropies) and the lyrics transcription loss (CTC loss) is minimized. The CTC loss is computed from the framewise estimate $p(\text{character}|\mathbf{X})$ by efficiently accumulating the costs of all possible character sequences that can be reduced to the ground-truth character sequence by removing the blank labels. The pitch and onset probabilities $p(\text{pitch}|\mathbf{X})$ and $p(\text{onset}|\mathbf{X})$ and the underlying boundary information are considered to make $p(\text{character}|\mathbf{X})$ consistent with the ground-truth character sequence.

To mitigate the insufficiency of music data with lyrics annotations (DALI dataset [20]), we take the domain adaptation approach based on transfer learning [21]. Specifically, the CRNN used for lyrics transcription is trained using sufficient speech data (LibriSpeech corpus [22]) and then fine-tuned using both speech and music data.

3.2 Decoding

At run-time, we aim to estimate a series of note events with semitone-level pitches (MIDI note numbers) and onset times (frames) and transcribe the lyrics (Fig. 3). Specifically, the pitches with the maximum probabilities are taken from the estimated pitch probabilities $p(\text{pitch}|\mathbf{X})$. The onset times are determined with a peak picking strategy [23] with a window of 50 [ms] and a threshold of 0.4. A frame is counted as the onset time if the onset probability at this frame is maximal within 25 [ms] around this frame, where frames whose probabilities are less than 0.4 are excluded. The lyrics (best character sequence) are determined using a CTC decoder based on beam search [24] with a beam size of 25 frames and a 5-gram language model trained on the LibriSpeech corpus with a vocabulary of 200K words.

4. EVALUATION

This section reports a comparative experiment conducted for evaluating the effectiveness of the multi-task learning with pitch and onset estimation in ALT.

Details about data selection and training conditions can be found in the GitHub repository [1] of this paper.

4.1 Experimental Conditions

We explain the data used for evaluation, network configurations, compared methods, and evaluation measures.

4.1.1 Data

We used the DALI dataset [20] consisting of 5358 pieces of popular music in the English language along with fine-grained lyrics and pitch annotations. This dataset was made by collecting karaoke subtitle data and then searching for the corresponding audio data on the Internet, where an automatic alignment method was used for obtaining aligned

[1] https://github.com/TengyuDeng/lyrics-transcription-with-pitch-onset/

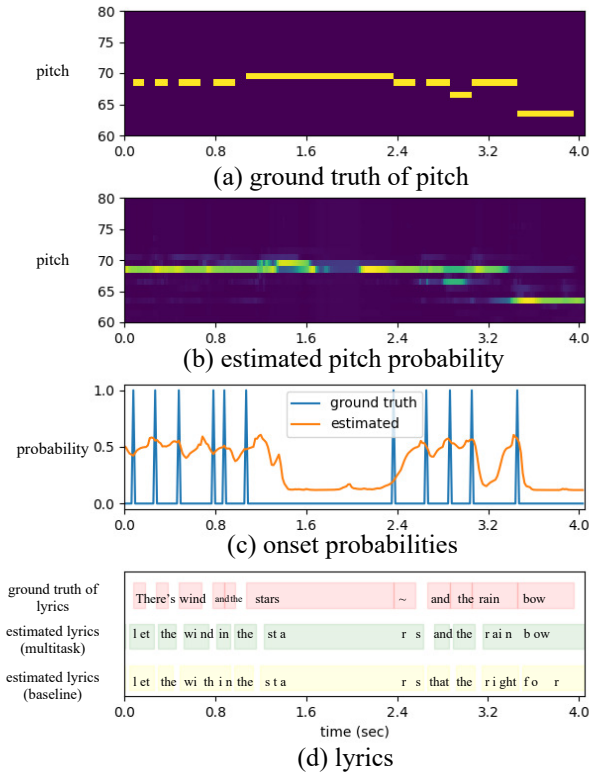

Figure 3. Example of estimations on a segment of a popular song from DALI. In (d), an estimated character is placed where the CTC decoder responds with the peak probability.

annotations. This dataset thus suffers from severe annotation errors [25]. First, the original karaoke data contained many problematic annotations such as global pitch shifts, wrong spellings, and onset time errors. Second, the automatic global alignment method often failed.

We thus filtered out music data with obviously wrong lyrics annotations and/or global pitch shift errors. The data selection procedure was based on the pitch estimation model and RWC Popular Music Database [26, 27]. This dataset contains 80 Japanese songs and 20 English songs, all of which are original popular songs and are provided with careful manual annotations. For simplicity, we used the framewise error rate given by

$$1 - \frac{\#\{\text{Frames Estimated Correctly}\}}{\#\{\text{Total Frames}\}}. \qquad (10)$$

We chose the 80 Japanese tracks of the RWC database and split them into a training set of 64 tracks and a test set of 16 tracks. The CRNN-based pitch estimation was trained on the training set, and attained 26.05% error rate on the test set, which was considered as a standard level.

The model trained on the training set from the RWC database was then exploited to test on the whole DALI dataset. The annotation of each song was shifted by -12, -11, ..., 0, ..., 11, and 12 semitones, and the predicted pitches of the pre-trained model were compared to all 25 pitch-shifted versions of annotations. The pitch shift value with the minimal framewise error rate was considered as the global pitch shift value of the annotation for a song, and

the minimal framewise error rate was recorded. Finally, the DALI dataset was filtered by the recorded framewise error rates. Specifically, songs with framewise error rates larger than a certain threshold were considered to be with problematic annotations.

Of all 5358 songs in the DALI dataset, 3272 songs could be accessed in our region and were in the English language. We selected 2515 songs with the data selection procedure, with a threshold of 50%. They were then split into a train set of 2263 songs, a validation set of 125 songs, and a test set of 126 songs. The total durations were 148.82 hours, 8.16 hours, and 8.47 hours, respectively.

For the transfer learning procedure, we used the LibriSpeech corpus [22] that contains 1000 hours of reading English speech sampled at 16 kHz. The CRNN described in Section 3.1.2 was trained on the train-clean-360 and train-other-500 sets of the LibriSpeech corpus, where all-zero matrices were used as $p(\text{pitch}|\mathbf{X})$ and $p(\text{onset}|\mathbf{X})$ in Eq. (7). This model was then fine-tuned with the training set of the DALI dataset.

4.1.2 Configurations

As described in Section 3.1, the audio signals, sampled at a rate of 48 kHz, were first separated into singing-voice-only signals with model umxhq from open-unmix [18]. Then for computational simplicity, the separated signals and the original mixed signals were resampled to 16 kHz, before they were converted to mel-spectrogram features, respectively. The audio signals were converted to mel-spectrogram with a window size of 32 ms and a hop length of 16 ms, and the resulted mel-spectrogram contained 80 mel-scaled features. We clipped the mel-spectrograms into pieces of 1000 frames, with a duration of about 16 s. Therefore, following the annotations in 3.1.1, we had $C = 2, F = 80, T = 1000$.

In the pitch and onset estimation network, 6 residual convolution blocks were stacked. The kernel sizes were (5,5), (5,5), (3,3), (3,3), (3,3), (1,1), and the numbers of output channels were 64, 32, 32, 32, 32, 1, respectively. After that, only 1 RNN block was applied to obtain the pitch and onsest estimation results. The dropout probability was set to 0 in each layer. In other words, we didn't adopt dropout in the pitch and onset estimation network.

In the lyrics transcription network, 6 residual convolution blocks were stacked. The kernel sizes were (5,5), (5,5), (3,3), (3,3), (3,3), (3,3), and the numbers of output channels were 64, 32, 32, 32, 32, 16, respectively. After that, 3 RNN blocks were stacked, and the number of hidden units in each LSTM was 512. The dropout probability was set to 0.2 in each layer.

When training the model, the Adam optimizer was used, and the parameters were $\beta_1 = 0.9, \beta_2 = 0.999$, and $\epsilon = 10^{-8}$. The model was trained with a learning rate of 5×10^{-4}, and a warming up strategy was used. The learning rate linearly increased from 0 to 5×10^{-4} for the first 100 batches. We used an early stop strategy to manage the learning process. As mentioned in Section 4.1.1, the dataset was split into a training, a validation, and a test set. After training for an epoch, the model was tested on the validation set, and the learning process was terminated when the test statistics for the validation set stopped improving for 10 epochs.

Method	DALI-test	Jamendo
Ours (baseline)	69.22	77.3
Ours (oracle)	**64.41**	/
Ours (multi-task)	68.29	**76.2**
[6]	/	77.8
[7]	/	87.9

Table 1. Comparison of WER (%) with different methods.

4.1.3 Compared Methods

In order to test the performance of our system, we compared a couple of different settings. We also compared the proposed system with previous related works.

For lyrics transcription, in addition to the multi-task architecture, we also trained a model using zero dummy pitch and onset probabilities as a baseline model. Besides, a model was also trained using the ground truth pitches and onset times as oracle information. In order to compare with related works, the multi-task architecture was also tested on the jamendo dataset [6], and the results were compared with the end-to-end models in [6] and [7].

For pitch and onset estimation, we trained the model in Section 3.1.1 without the lyrics transcription part as the baseline model, and the results were compared with that in the multi-task scenario. We also evaluated the test data on VOCANO [28], a note-level vocal melody estimation toolkit available in public.

4.1.4 Evaluation Measures

The lyrics transcription was evaluated using word error rate (WER). The pitch and onset estimation was evaluated using the method first proposed in [29]. We considered the Correct Onset (COn) and the Correct Onset, Pitch (COnP) measures.

4.2 Experimental Results

Before fine-tuning on lyrics data, the lyrics transcription model was trained on LibriSpeech ASR corpus. The model reached a WER of 6.56% on the test-clean dataset and 20.86% on the test-other dataset.

WERs on the DALI-test dataset and the jamendo dataset are shown in Table. 1. On the DALI-test dataset, where the ground truth of pitch and onset information was available, the model reached the best performance when provided with this ground truth information. This shows that correct pitch and onset information can guide the system to find the correct alignment, so that the performance can be increased. In the multi-task architecture, the lyrics transcription model was trained with joint pitch and onset estimation. Although not as good as the oracle-given situation, the performance still gained some improvement. On the jamendo dataset, our multi-task architecture achieved

	COn			COnP		
	precision (%)	recall (%)	F value (%)	precision (%)	recall (%)	F value (%)
Ours(baseline)	53.21	**30.99**	**38.77**	36.92	**21.49**	**26.90**
Ours(multi-task)	**59.84**	28.69	38.41	**40.49**	19.57	26.14
VOCANO [28]	18.78	20.45	19.07	7.46	7.71	7.40

Table 2. Comparison of pitch and onset estimation results.

a similar improvement compared with our baseline model and beat main previous end-to-end ALT systems.

Table. 2 shows the pitch and onset evaluation results. Compared to the baseline model, the pitch and onset estimation jointly trained with the lyrics transcription model remained the same performance. However, for both the COn and COnP statistics, the multi-task scenario had a higher precision but a lower recall value than the baseline model. This shows that being jointly trained with the lyrics transcription model, especially the onset estimation was guided to be in favor of more confident onset positions. This lead to higher precision and lower recall values. It is notable that our models, both the baseline and the multi-task scenario, also gained better results than the results obtained when the VOCANO system was applied to the same test dataset.

5. CONCLUSION

This paper has presented a neural ALT method based on a multi-task learning architecture that estimates the pitch and onset information jointly and then transcribes the lyrics at the character level in a pitch- and onset-conditioned manner. The experiment using the DALI dataset showed that joint pitch and onset estimation can improve the performance of lyrics transcription. Although no significant overall improvement was attained in pitch and onset estimation, higher precision but lower recall rates were observed in the multi-task learning scenario. Our future work includes more comprehensive evaluation by gathering reliable data with accurate aligned lyrics and pitch annotations and using a data augmentation technique.

ABSTRACT

As one of the most intuitive interfaces known to humans, natural language has the potential to mediate many tasks that involve human-computer interaction, especially in application-focused fields like Music Information Retrieval. In this work, we explore cross-modal learning in an attempt to bridge audio and language in the music domain. To this end, we propose MusCALL, a framework for Music Contrastive Audio-Language Learning. Our approach consists of a dual-encoder architecture that learns the alignment between pairs of music audio and descriptive sentences, producing multimodal embeddings that can be used for text-to-audio and audio-to-text retrieval out-of-the-box. Thanks to this property, MusCALL can be transferred to virtually any task that can be cast as text-based retrieval. Our experiments show that our method performs significantly better than the baselines at retrieving audio that matches a textual description and, conversely, text that matches an audio query. We also demonstrate that the multimodal alignment capability of our model can be successfully extended to the zero-shot transfer scenario for genre classification and auto-tagging on two public datasets.

1. INTRODUCTION

Developing effective methods for finding music is at the core of Music Information Retrieval (MIR). Over the years, many approaches have been proposed to browse, search and discover music through a variety of interfaces. Beyond simple search by metadata, existing music retrieval systems allow to express queries via lyrics [1,2], audio examples [3], videos [4] and humming [5], among others [6–8]. Although each of these query types has its merits, none of these systems supports another popular way of searching for music today: through free-form text. For example, we commonly look for songs by typing text into a search engine [9] or by asking online song naming communities to identify a piece of music we do not have bibliographic information about [10]. It becomes evident then that enabling MIR systems to interpret natural language queries can have far-reaching benefits. This idea is not entirely new to MIR, with prior work [11–13] suggesting similar research directions in the past. So far, however, multimodal systems that integrate natural language have not been widely adopted within the MIR community, possibly due to a lack of suitable datasets or to the practical limitations of NLP methods predating modern language models.

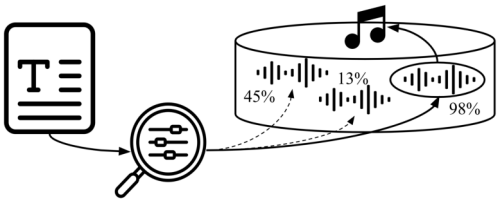

Figure 1: **Illustration of text-based music retrieval**, where audio items in a database are ranked according to their relevance to a free-form language query.

In light of recent breakthroughs in language modelling, we argue that audio-and-language learning has now the potential of closing the semantic gap in MIR [14], providing a bridge between computational representations of music signals and the high-level abstractions needed to use those representations in real-world scenarios. With this in mind, we propose MusCALL, a method for learning alignment between music-related audio and language data via multimodal contrastive learning. Our choice of a contrastive approach is inspired by the recent success of similar methods for joint visio-linguistic modelling (see Section 2.3). In designing MusCALL, we prioritise the ability to perform retrieval at scale and adopt a dual-encoder architecture, where modalities are processed independently. Compared to multimodal architectures with joint encoders and cross-modal attention mechanisms [15], this design allows to share embedding computations among pairs, resulting in a computationally more efficient model.

With this work, we aim to unify audio and language modelling, paving the way for MIR systems that can interpret language-based queries, as illustrated in Figure 1. Our primary contributions can be summarised as follows: (i) we explore multimodal contrastive learning in the context of music-related audio and language for the first time; (ii) we introduce a method for cross-modal retrieval of music, providing the first example of sentence-based music search; (iii) we perform an extensive set of experiments to systematically validate details of our approach and evaluate its performance on popular MIR tasks in a zero-shot setting. 2. RELATED WORK

2.1 Natural Language Processing in MIR

Prior works in the MIR literature have explored leveraging natural language in the music domain from different angles. Early efforts focused on text as a modality in isolation, adopting NLP techniques to construct knowledge bases from music-related text corpora [16], build semantic graphs for artist similarity from biographies [17], or perform genre classification based on album reviews [18]. Recent efforts, more closely related to the present work, have instead started favouring multimodal approaches. These have explored deep learning with multimodal input data, typically audio combined with text such as reviews or lyrics, for applications as varied as music classification and recommendation [19], mood detection [20], music emotion recognition [21] and music captioning [22–24].

2.2 Audio-Text Cross-modal Learning

Another related line of work is cross-modal learning that leverages audio and tags as text input. Works in this area have proposed contrastive learning-based approaches to enrich audio representations via cross-modal alignment, either for general-purpose audio classification [25, 26] or for music-focused tasks [27]. Differently from our work, these approaches require finetuning on the downstream tasks and none of them directly uses cross-modal representations. Others have explored pre-trained word embeddings in triplet networks to perform tag-based music retrieval via a multimodal embedding space [28, 29]. At a high level, these works share a similar approach to ours and all aim to learn multimodal audio representations by leveraging text. Unlike our work, however, none of them makes use of natural language, using tags as text input instead.

Finally, similarly to our work, [30] also addresses the problem of matching audio and long-form text for music retrieval, but offers a fundamentally different approach, which relies on bridging the audio and text modalities via a common emotion embedding space.

2.3 Learning from Language Supervision

In the previous sections, we have highlighted some research efforts towards bringing together audio and language, but, ultimately, multimodal learning still occupies a marginal role in MIR and has yet to fully enjoy the benefits of modern language models. In adjacent fields such as computer vision, jointly modelling vision and language has instead become a very active area of research, with several successful attempts at using multimodality to develop task-agnostic models that can easily adapt to novel tasks [31–34]. The key insight behind these models is that language captures many of the abstractions humans use to navigate the world and can therefore act as a rich supervisory signal for general-purpose learning, even in tasks that are not directly based on language [35]. Among these works, CLIP [33] is a particularly influential example, having demonstrated for the first time that supervision from natural language can induce highly generic visual representations at scale.

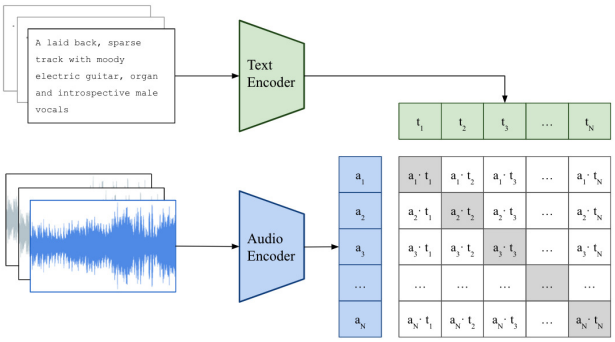

Figure 2: **Overview of MusCALL**. An audio encoder and a text encoder are trained via a contrastive loss to maximise the similarity between representations of N aligned (audio, text) pairs within a mini-batch. At test time, the similarity between embeddings in the learnt multimodal space is used to rank database items and perform cross-modal retrieval.

These breakthroughs suggest that natural language supervision has a large potential beyond the image domain. This has recently prompted the adoption of similar approaches in machine listening, where applications to both music [15] and non-music audio [36, 37] have started to emerge. A subset of works in this area have proposed to directly extend CLIP by incorporating audio as an additional modality [38–40]. Although similar in spirit to our work, these approaches exploit audio-visual correspondences in video, thus requiring large-scale visio-linguistic pre-training. Like these works, we also borrow from CLIP's contrastive dual-encoder approach, but we adapt this framework to the audio modality without any pre-training, while also addressing the specific set of challenges that arise from joint audio-linguistic modelling in the music domain.

3. MUSCALL

3.1 Multimodal Contrastive Learning (MCL)

Contrastive learning has emerged as a powerful paradigm in self-supervised representation learning for images [41] and audio [42–45]. At their core, all flavours of contrastive learning rely on constructing different views of the data and forcing representations of positive pairs of such views to have, on average, higher similarity than those of negative pairs. This encourages a model to learn representations that are *discriminative* with respect to changes to the content and *invariant* to nuisance transformations. In representation learning, this is a useful property, since it results in more robust and effective representations [46–48]. Most formulations of contrastive learning in unimodal scenarios use data augmentations to create multiple views of the inputs. When switching to the multimodal setting, however, different views naturally co-occur in the data, making this a natural testbed for contrastive learning [33, 49, 50].

3.2 Extending MCL to Music and Language

In this work, we explore multimodal contrastive learning (MCL) in the context of audio-linguistic data. More specifically, we consider pairs of music audio tracks and their

associated textual descriptions and aim to learn a model that is able to predict when items from a given pair match, i.e. when they are semantically aligned. An overview of our approach is shown in Figure 2. In practice, our goal is to learn two encoders, $f_a(\cdot)$ for the audio modality and $f_t(\cdot)$ for the text modality, such that for any given (audio, text) pair formed by the tuple (a_i, t_i), the resulting L2-normalised embeddings $\boldsymbol{z}_{a,i} = f_a(a_i)$ and $\boldsymbol{z}_{t,i} = f_t(t_i)$ lie closely in the joint embedding space, with respect to some distance metric, only if a_i and t_i represent similar content. Given our problem definition, we achieve this by optimising a type of N-pair contrastive loss, known as InfoNCE [51]. Based on this, our audio-to-text loss can be defined as follows:

$$\mathcal{L}_{a\to t} = -\frac{1}{N}\sum_{i}^{N}\log\frac{\exp\left(\boldsymbol{z}_{a,i}\cdot\boldsymbol{z}^{+}_{t,i}/\tau\right)}{\sum\limits_{\boldsymbol{z}\in\left\{\boldsymbol{z}^{+}_{t,i},\boldsymbol{z}^{-}_{t,i}\right\}}\exp\left(\boldsymbol{z}_{a,i}\cdot\boldsymbol{z}/\tau\right)}, \quad (1)$$

where N is the batch size, $\boldsymbol{z}^{+}_{t,i}$ and $\boldsymbol{z}^{-}_{t,i}$ are embeddings of positive and negative text samples for item a_i, and τ is a temperature parameter used to scale the similarity scores. By noting that $\mathcal{L}_{t\to a}$ can be defined symmetrically to Eq. (1), the total loss over all (audio, text) pairs in a mini-batch is simply obtained by summing the two losses together:

$$\mathcal{L}_{a\leftrightarrow t} = \mathcal{L}_{a\to t} + \mathcal{L}_{t\to a}. \quad (2)$$

Given a dataset of tuples $\mathcal{D} = \{(a_i, t_i)\}_{i=1:D}$, there are several plausible strategies for constructing positive and negative pairs. One such way, and arguably the most intuitive, is to follow the implicit alignment found in the data. In this case, for each sample i, the positive and negative sets within a mini-batch become: $\boldsymbol{z}^{+}_{x,i} = \{\boldsymbol{z}_{y,i}\}$ and $\boldsymbol{z}^{-}_{x,i} = \{z_{y,j} \mid \forall j \in \{1,\ldots,N\}, j \neq i\}$, where x and y denote the two different modalities. We refer to this sampling strategy as *instance discrimination* [52].

3.2.1 Content-Aware Loss Weighting

Constructing positive and negative samples by instance discrimination is a design choice that relies on two implicit assumptions: firstly, that all items in the dataset are correctly aligned, i.e. that each (audio, text) pair is formed by the most semantically close items amongst all possible pairings; secondly, that all non-aligned pairs represent sufficiently different content and are therefore equally valid as negatives. In a real-world dataset, this is unlikely to hold true in all cases. Intuitively, within a randomly sampled mini-batch, some tracks will share similarities with other tracks, and so will their respective captions.

The above observations suggest that a more informed sampling procedure or an alternative way to define our cross-modal loss may better suit the structural properties of our data. Due to its simplicity, we focus on the latter option and test this hypothesis by introducing some modifications to Eq. (1). By observing that similar captions are likely to correspond to similar audio, we can leverage this side information to estimate the *relevance* between non-paired (negative) items in a mini-batch. Since more relevant items should contribute more to the learning process, similarly to [53], we can introduce a relevance-based weight:

$$w_i = \exp\left(\frac{\frac{1}{N}\sum_{j}^{N}\mathrm{sim}(t_i, t_j)}{\kappa}\right), \quad (3)$$

where κ is a temperature hyperparameter and $\mathrm{sim}(t_i, t_j)$ a similarity score between text sample t_i and text sample t_j. We can then redefine our audio-to-text loss in Eq. (1) as follows:

$$\mathcal{L}^{*}_{a\to t} = -\frac{1}{N}\sum_{i}^{N} w_i \log\frac{\exp\left(\boldsymbol{z}_{a,i}\cdot\boldsymbol{z}^{+}_{t,i}/\tau\right)}{\sum\limits_{\boldsymbol{z}\in\left\{\boldsymbol{z}^{+}_{t,i},\boldsymbol{z}^{-}_{t,i}\right\}}\exp\left(\boldsymbol{z}_{a,i}\cdot\boldsymbol{z}/\tau\right)} \quad (4)$$

and obtain the total loss by summing this to its symmetrical counterpart $\mathcal{L}^{*}_{t\to a}$. We dub this procedure *content-aware loss weighting*, or *loss weighting* for short.

3.3 Combining MusCALL with Audio Self-Supervision

At its core, the design of our approach is centred around audio-text matching. However, we are also interested in learning representations that can be transferred to other tasks, especially in a zero-shot way. Prior work has demonstrated the benefit of using self-supervised learning (SSL) [54] to improve representation quality in a similar setting in the image domain [55]. We hypothesise that our model may also benefit from this and experiment with combining our multimodal contrastive objective with self-supervision on the audio modality. Similarly to the approach proposed in [55], we do this via multi-task learning, using an adaptation of SimCLR [48] to the audio modality as the self-supervised component. Two correlated views of the audio input are produced via a data augmentation pipeline and passed through a shared audio encoder. The SSL objective is then computed on the embeddings resulting from the two views and added to our cross-modal objective as follows:

$$\mathcal{L} = \lambda\mathcal{L}_{SSL} + (1-\lambda)\mathcal{L}_{a\leftrightarrow t}, \quad (5)$$

where $\mathcal{L}_{SSL}$ is the *NT-Xent* loss used in SimCLR [48] and $\lambda \in [0, 1]$ is a scalar weight.

We refer to the SSL-enhanced variant by $\text{MusCALL}_{\text{SSL}}$ to distinguish it from the base variant $\text{MusCALL}_{\text{BASE}}$.

3.4 Audio & Text Encoding

As our audio backbone, we choose ResNet-50 [57] operating on melspectrogram representations of the input and adopt the same architectural modifications introduced in CLIP [33]: 3 stem convolutions followed by average pooling instead of max pooling and anti-aliased blur pooling. We obtain fixed-length audio representations via an attention pooling mechanism: we append the average-pooled audio feature to the backbone output and compute multi-head self-attention, taking the output corresponding to the average-pooled feature as the global audio representation. Also analogously to CLIP, our text encoder is a Transformer [58, 59]. To avoid overfitting on our dataset, which is $\sim$ 2K times smaller than the dataset used to train CLIP,

Method	Text → Audio					Audio → Text				
	R@1	R@5	R@10	mAP10	MedR ↓	R@1	R@5	R@10	mAP10	MedR ↓
DCASE [56]	2.3	10.4	17.4	5.5	50	1.1	5.6	10.1	3.0	84
DCASE + CL	3.9	12.4	18.1	6.8	81.5	2.0	8.6	16.4	4.5	64
MusCALL (ours)	**25.9**	**51.9**	**63.3**	**36.0**	**5**	**25.8**	**53.0**	**63.0**	**35.9**	**5**

Table 1: **Cross-modal retrieval results**. MusCALL improves performance on all metrics by a large margin, compared to two variants of the baseline: one with the original triplet ranking loss (DCASE) and one with our loss (DCASE + CL).

we downsize the network and use 4 hidden layers, as we empirically find this to be the optimal depth (see Figure 3).

Two learned linear projections are applied to map the audio and text features produced by the audio and text backbones onto a 512-dimensional multimodal embedding space respectively. The resulting features are then L2-normalised before their dot product is calculated in the contrastive loss.

4. EXPERIMENTAL DESIGN

4.1 Dataset

We train and evaluate our model on a dataset of 250k (audio, text) pairs created from a production music library. This consists of full-length audio tracks, covering a broad range of genres, and a piece of text describing the overall musical content of each track, as shown in Table 3. For training, validation and testing, we use a random 80/10/10 split.

4.2 Implementation Details

For each audio track, we take a $20s$ random crop at training time, and the central $20s$ segment at testing time. Unless otherwise specified, we then apply a stochastic data augmentation pipeline, where each transformation is applied with an independent probability p. We adopt some of the same transformations, such as noise injection and pitch shift, as prior work on music audio representation learning [45, 60]. For each audio caption in the dataset, we take the text input in full and tokenise it following the same procedure as in CLIP, based on byte pair encoding [61] with a 49K token vocabulary and maximum sequence length of 77.

As an estimate for text-text similarity in the calculation of our loss scaling weight w_i in Eq. (4), we use the cosine distance between L2-normalised embeddings produced by a pre-trained Sentence-BERT [62]. We set the loss weighting temperature parameter κ to 0.005, following [53].

For the SimCLR module in $\text{MusCALL}_{\text{SSL}}$, following [45] we use a 256-dimensional non-linear projection layer and set the temperature parameter to 0.5. The loss scaling parameter λ in Eq. (5) is set to 0.3 as we find this to yield best results.

Together with the parameters for the audio and text encoders and multimodal projections, we also learn the temperature parameter τ in Eq. (1) to avoid tuning it as a hyperparameter. We train using the Adam optimizer, with weight decay 0.2, batch size of 256, initial learning rate of 5e-5, reduced throughout training following a cosine schedule. After training for a maximum of 150 epochs, we select the best model based on the R@10 score (see Section 5.1) computed on the validation set. To save GPU memory, we perform training with automatic mixed precision.

5. EXPERIMENTS & RESULTS

In this section we first describe our experimental setup and report our main results on cross-modal retrieval (Section 5.1), which constitute the focus of the paper. We then explore transferring our model to zero-shot music classification, highlighting key findings (Section 5.2).

5.1 Cross-Modal Retrieval

In cross-modal retrieval, given a query item of modality A, our goal is to identify the matching item of modality B. We can do this by casting the retrieval as a ranking problem: for a given query item of modality A, we rank all candidate items of modality B by the cosine similarity between the query embedding and each candidate embedding. The retrieval performance is then evaluated by computing the Recall at K (R@K) over the testing set as the percentage of correctly retrieved items within the top-K items for each query, with $\text{K} = \{1, 5, 10\}$. In line with previous work on cross-modal retrieval, we also report mean average Precision at 10 (mAP10) and Median Rank (MedR) in our main results. We construct our testing set by randomly sampling a subset of 1000 (audio, text) pairs from our testing split. This is chosen to be consistent in size with other datasets for sentence-based audio retrieval [63, 64].

Results Table 1 shows the performance of MusCALL on the cross-modal retrieval task. We compare this to the baseline system for the *Language-Based Audio Retrieval* subtask of Task 6 in the 2022 DCASE Challenge, [2] trained and evaluated on our dataset. This is a simplified version of the approach proposed in [56] and consists of a pre-trained *word2vec* model [65] as the text encoder and a convolutional recurrent neural network as the audio encoder. Average pooling is used to obtain global representations for each modality from the output of the encoders. These are then jointly trained via a triplet ranking loss [66]. We also consider a variant of this baseline where we use our loss instead of the triplet ranking loss, to provide a closer comparison to our approach.

Our results show that MusCALL significantly outperforms the baseline on both text-to-audio and audio-to-text retrieval. Enhancing the baseline with our loss slightly reduces this margin, bringing a 14.2% and 60.7% average

Method	Prompt	Genre	Tagging	
		Acc.	ROC	PR
$\text{MusCALL}_{\text{BASE}}$	✗	55.5	**78.0**	28.3
$\text{MusCALL}_{\text{BASE}}$	✓	52.0	72.0	21.0
$\text{MusCALL}_{\text{SSL}}$	✗	58.2	**77.4**	**29.3**
$\text{MusCALL}_{\text{SSL}}$	✓	**62.0**	73.4	23.2

Table 2: **Zero-shot transfer results**. We report $\text{MusCALL}_{\text{BASE}}$ and $\text{MusCALL}_{\text{SSL}}$ accuracy on GTZAN (genre classification), and ROC-AUC and PR-AUC on MTAT (auto-tagging). *Prompt* indicates whether a template was used to wrap the class label.

improvement over the vanilla baseline for text-to-audio and audio-to-text respectively. However, the use of our contrastive loss alone does not account for the full difference, indicating that the design of our text and audio encoders and the use of linear projection layers, play a crucial role.

5.2 Zero-shot Transfer

By design, our cross-modal learning approach endows the model with the ability to interpret arbitrary text inputs. This powerful property can be exploited to perform new tasks based on textual descriptions via a transfer learning paradigm known in the literature as *zero-shot transfer* [33, 34, 67]. Similarly to zero-shot learning, zero-shot transfer aims to learn a model that can generalise to unseen classes or tasks without further training. But, in contrast to zero-shot learning, it somewhat relaxes the requirement that target classes must be completely unseen. Instead, the model is usually pre-trained in a task-agnostic fashion on large amounts of natural language text, and may be exposed to information relevant to the target tasks through this, although no supervised examples are provided.

We explore this paradigm in our work and investigate whether MusCALL exhibits zero-shot transfer capabilities on two tasks, genre classification and auto-tagging. We evaluate this on the most popular public datasets for these tasks, GTZAN [68] and MagnaTagATune (MTAT) [69]. Treating audio clips in each dataset as queries, we obtain classification predictions by considering the similarity scores between audio embeddings and text embeddings of the target labels, similarly to the procedure described for cross-modal retrieval in Section 5.1. Based on this, we calculate accuracy for GTZAN, and area under the receiver operating characteristic curve (ROC-AUC) and area under the precision-recall curve (PR-AUC) for the MTAT dataset.

In order to reduce the distribution shift between pre-training and downstream text input when doing zero-shot transfer, it is common practice to wrap the labels in templates. For example, the label "*rock*" may be wrapped in the sentence "*This is a rock song with electric guitars*", making it much closer to a typical caption encountered in training. Based on evidence that it can improve performance [33], we explore this in our evaluation by passing "*A* [LABEL] *track*" as the text input, but do not further tune the prompts to our model, leaving this for future work.

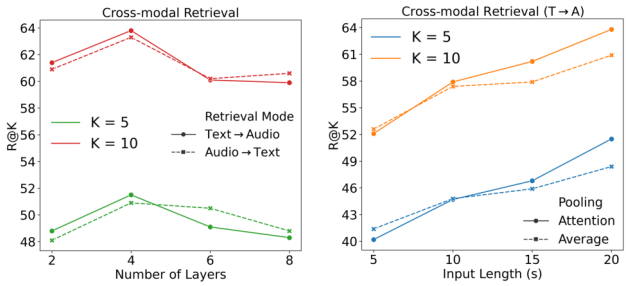

Figure 3: **The effect of varying** (left) the **depth** of the text encoder and (right) the **audio input length** on retrieval.

Results In Table 2 we compare zero-shot performance of two model variants, $\text{MusCALL}_{\text{BASE}}$ and $\text{MusCALL}_{\text{SSL}}$. We find that the self-supervised learning objective yields, on average, better performance, with a 5.4% improvement over $\text{MusCALL}_{\text{BASE}}$. This is not too surprising, as the SSL objective is designed to improve the representation quality of our audio branch and is therefore expected to have a positive effect on generalisation [70]. However, this improvement is not consistent across datasets and tasks, a result that may be attributed to different degrees of similarity between pre-training and downstream datasets, as found in prior work [71]. We also find that zero-shot performance is sensitive to the choice of text prompt. This confirms a well-known phenomenon reported in the literature [33, 72] and suggests that techniques such as prompt tuning and ensembling [33] may lead to further improvements.

Additionally, there are some important differences that should be considered when comparing $\text{MusCALL}_{\text{BASE}}$ and $\text{MusCALL}_{\text{SSL}}$, since the SSL module introduces more activations and overall learnable parameters. This has two implications: firstly, to offset the increased memory footprint while keeping the batch size unchanged and still satisfying our memory constraints, we reduce the size of the input audio to $10s$. We verify that this slightly degrades performance on cross-modal retrieval even in the absence of the SSL module, as shown in Figure 3. Assuming that this trend would be reflected in the zero-shot scenario, we conclude that $\text{MusCALL}_{\text{SSL}}$ would benefit from using longer audio clips. Secondly, the higher number of parameters makes $\text{MusCALL}_{\text{SSL}}$ prone to overfitting, a factor that we believe may also be limiting its performance.

6. ANALYSIS & DISCUSSION

We now discuss the qualitative characteristics of our model (Section 6.1) and examine the contributions of the main design choices through an ablation study (Section 6.2).

6.1 Qualitative Analysis

Similarity score distribution In Figure 4 (left) we show the kernel density estimation of the distributions of pairwise similarity scores in the joint embedding space for positive and negative pairs in our testing set. From this we can see that aligned pairs have distinctly higher scores compared to random ones, confirming that the model distinguishes positive and negative examples with a good level of confidence.

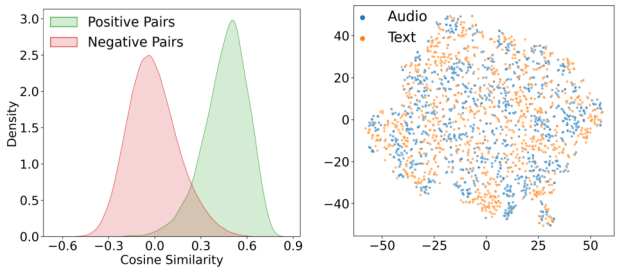

Figure 4: **Feature visualisation**. (Left) distributions of pair-wise similarity scores of aligned and non-aligned (audio, text) pairs in our testing set. (Right) t-SNE visualisation of audio and text features in the multimodal output space.

Feature visualisation Figure 4 (right) shows a t-SNE plot of audio and text embeddings in our testing set. We observe no separation between modalities in the output space, with representations of both audio and text inputs well mixed together, confirming that MusCALL learns to adequately map both input modalities to a common space.

Failure analysis In order to provide more context to our cross-modal retrieval results beyond metric-based evaluation, we also perform a qualitative error analysis by examining the relevance of the retrieved items in cases of incorrect retrieval. As highlighted in the examples in Table 3, in some cases, while the ground-truth item is not ranked first, MusCALL is still capable of retrieving audio tracks whose associated caption is semantically related to the query.

6.2 Ablation Study

The effect of data augmentations & random crop Table 4 shows that removing random cropping (RC) considerably degrades performance (-13.7% compared to $\text{MusCALL}_{\text{BASE}}$), while removing the audio augmentations (AA) only marginally alters results (-1.5%). When considering both together, we find that, in the absence of RC, the benefit of performing augmentations is amplified, and removing both has more drastic effect (-31.5%). This is expected, since both techniques effectively increase the variety of samples seen in training. To avoid costly hyperparameter tuning, we do not exhaustively explore audio transformations and their composition, and note that tailoring the AA pipeline, for example via additional frequency-domain transformations, may lead to better results.

The effect of loss weighting As also shown in Table 4, using our content-aware loss weighting (Section 3.2.1) results in comparable retrieval performance to our vanilla contrastive loss. To more closely observe the effect of using loss weighting, we compare the pairwise similarity distributions of positive and negative pairs produced by MusCALL with and without loss weighting (shown in the supplementary material). This reveals that similarity scores of positive pairs have lower variance and a higher mean when using loss weighting, suggesting that this technique nudges the learning process towards a better discrimination of positives and negatives, but not enough to produce significant improvements in the cross-modal retrieval task.

Query Text	Text of the Top-1 Audio
An atmospheric and introspective orchestral track featuring strings, piano, and synth.	*An inspirational and moody orchestral track featuring strings and choir.*
Deep chilled out space jazz with crisp beats and lush electronics.	*Jaunty swing featuring trumpet.*
Up tempo, pumping dance pop with female vocals.	*Quirky, fun, positive disco party music.*

Table 3: **Failure analysis** of text-to-audio retrieval.

LW	RC	AA	AP	Text → Audio		
				R@1	R@5	R@10
✗	✗	✗	✓	14.7	33.9	47.2
✗	✗	✓	✓	18.5	43.5	57.4
✗	✓	✓	✗	24.9	49.3	58.9
✗	✓	✗	✓	24.3	51.3	62.2
✗	✓	✓	✓	24.6	51.5	63.8
✓	✓	✓	✓	25.9	51.9	63.3

Table 4: **Ablations**: loss weighting (LW), random cropping (RC), audio augmentations (AA), attention pooling (AP).

The effect of attention pooling Our ablation study confirms that removing attention pooling hurts performance: on average, the Recall results drop by 4.9% compared to simple average pooling. We note that the advantage of using attention pooling becomes more pronounced as we increase the audio input length, as shown in Figure 3. This is particularly relevant in the music domain, since music signals exhibit structure over longer ranges compared to other types of audio signals like environmental sounds.

7. CONCLUSION

We presented MusCALL, a method for multimodal contrastive learning of audio-linguistic representations. By leveraging aligned (audio, text) pairs, MusCALL successfully learns to perform cross-modal retrieval, allowing to search for music via natural language queries and vice versa. Extending this multimodal alignment capability to the zero-shot setting, MusCALL can also be transferred to music classification tasks by simply providing target labels as text inputs. Through an extensive set of experiments, we validated the main design choices in our core approach and explored two variants. Through the first variant, we demonstrated the viability of using a text-based similarity metric to weigh the loss contribution of each negative sample, providing a starting point for improving multimodal contrastive learning on real-world music data. Through the second variant, we explored including a self-supervised objective to improve the audio representation quality. Both variants show promising results and provide opportunities for further research. Future work will focus on assessing their performance in more depth, particularly in the zero-shot scenario, including human evaluations alongside automatic metrics and considering a wider set of tasks.

8. ACKNOWLEDGEMENTS

This work was supported by UK Research and Innovation [grant number EP/S022694/1] and Universal Music Group. We would also like to thank The Alan Turing Institute for the support provided during the first author's time as an Enrichment Student.

ABSTRACT

We present MusAV, a new public benchmark dataset for comparative validation of arousal and valence (AV) regression models for audio-based music emotion recognition. To gather the ground truth, we rely on relative judgments instead of absolute values to simplify the manual annotation process and improve its consistency. We build MusAV by gathering comparative annotations of arousal and valence on pairs of tracks, using track audio previews and metadata from the Spotify API. The resulting dataset contains 2,092 track previews covering 1,404 genres, with pairwise relative AV judgments by 20 annotators and various subsets of the ground truth based on different levels of annotation agreement. We demonstrate the use of the dataset in an example study evaluating nine models for AV regression that we train based on state-of-the-art audio embeddings and three existing datasets of absolute AV annotations. The results on MusAV offer a view of the performance of the models complementary to the metrics obtained during training and provide insights into the impact of the considered datasets and embeddings on the generalization abilities of the models.

1. INTRODUCTION

Audio-based music emotion recognition is a popular task in music information retrieval (MIR) that has recently gained more presence in the context of industrial applications. It is relevant for building systems for navigation of music collections, music search, exploration, and recommendation, and diverse applications that can benefit from MIR, such as audio branding or music therapy.

There are two types of approaches to emotion recognition in MIR following research in music psychology and affective computing [1–3]. The categorical approach considers different discrete categories of emotions (or moods [1]) or their clusters [4, 5] separately. It relies on taxonomies of descriptive mood tags and is frequently addressed by research on music classification and autotagging [6–9]. In contrast, the dimensional approach proposes representations on a continuous scale for several dimensions [10], allowing for a direct comparison of different moods, which is convenient for many applications.

The dimensional approach is based on existing research in music psychology which proposes two-dimensional or three-dimensional representations, including *arousal* (energy and stimulation), *valence* (pleasantness and positivity), and *dominance* (potency and control) [11] or, alternatively, *depth* [12] or *tension* [13], with many representations inheriting from the circumplex model of emotion by Russell [14]. In general, the 2D arousal/valence (AV) representation is a common model widely adopted in affective computing in different domains including music.

Various MIR researchers have worked on building datasets of AV annotations of music and training machine learning models for their automatic regression from audio [10, 15–21]. These datasets have been created with different methodologies, music collections, and participating annotators. However, there is no common benchmark dataset that could be conveniently used to compare models proposed by researchers and trained on different datasets. Existing studies report model performances using dataset splits without validation of the trained models on external datasets, which has been found to be very informative in other music classification tasks [22–24], providing insights on the generalization abilities and preventing overoptimistic conclusions.

In this paper, we propose to establish a common dataset for complementary evaluation on external data. We describe our methodology for building such a dataset, taking into account music genre diversity, and using it for evaluation of AV regression models. In contrast to many previous studies, we use comparisons between pairs of songs as ground truth instead of absolute values (coordinates) within the 2D AV space to make our annotations easier to gather and potentially more reliable, as suggested by previous works on relative emotion annotation in music and other domains [25–28]. In addition, we apply loudness normalization to avoid bias in arousal annotations [29], which has not been considered in previous datasets. The proposed validation of AV emotion recognition models provides a complementary view on their performance giving an opportunity to estimate generalization capabilities

[1] Even though some researchers distinguish the terms "emotion" and "mood", with moods being longer-term perceptions of musical input, we will use both terms interchangeably in this paper for simplicity.

Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

of the models on a common ground truth.

Following this methodology, we build a dataset based on audio previews and metadata available via Spotify API and evaluate a selection of AV regression models based on state-of-the-art audio embeddings. We analyze annotation agreement, propose strategies for building refined subsets of the dataset with different levels of consistency of annotations, and discuss the performance of the AV models.

2. RELATED WORK

Music emotion recognition is challenging because of the biases in cultural background, generation, genre, and personality [2, 30–33]. Nevertheless, this task gathered research attention in MIR from early on [34,35] given potential applications. Table 1 summarizes public AV datasets previously used in research. They all contain music audio excerpts and crowdsourced explicit arousal/valence annotations (absolute values that characterize each track or comparisons of track pairs) except for the MuSe dataset.

2.1 AV datasets with absolute values

There is a considerable variety of approaches to AV regression [10, 36–38] based in different audio features, including MediaEval campaigns in 2013-2015 [39–42]. We highlight the three most commonly used datasets containing absolute value annotations:

- **EmoMusic** [17] has been presented for the MediaEval 2013 Emotion in Music Task [39]. It contains 744 full audio tracks as well as 45-second excerpts. All audio is sourced from Free Music Archive (FMA). The excerpts are manually annotated with AV values characterizing the overall feel of the tracks as well as dynamic AV values at different rates, additionally summarized over the segment length (mean and stdev).
- **DEAM** [16] contains 1,802 audio excerpts (58 full-length songs and 1,744 excerpts of 45 seconds). The audio comes from several sources including FMA, Jamendo, and the MedleyDB dataset. The dataset similarly contains the overall AV values and dynamic values at a one per second rate and their summary (mean and stdev). This dataset has been derived from EmoMusic and used for the MediaEval 2013-2015 Emotion in Music Task [42] and in more recent studies [43, 44].
- **MuSe** [20] provides track-level valence, arousal and dominance values derived from social tags associated with music tracks on Last.fm [2] by using a dictionary of emotional ratings of words [45]. The dataset includes annotations for 90,408 songs, however the audio is not directly available. Instead, the tracks are identified by metadata, including Spotify IDs for 61,630 tracks. Nevertheless, only 41,021 30-second audio previews are currently accessible via Spotify API. [3]

Importantly, the EmoMusic and DEAM datasets are limited in coverage and they do not represent a large variety of music available on commercial digital music platforms. The MuSe dataset has a significantly larger size and coverage, including 835 genres, achieved by sampling Last.fm using a diverse set of mood labels. Yet, its downside is that it is possibly noisy due to the tags-to-AV mapping. As a compromise, Panda et al. [37] propose to infer AV annotations from AllMusic [4] emotion tags, but they only use them to create a balanced annotation pool that is then manually validated. The resulting dataset (MER-TAFFC) contains 900 30-second track previews annotated by four AV emotion quadrants. In our work, we also follow an automated music preselection approach and prioritize large genre coverage while keeping the annotations manual. We can then compare AV regression models trained on EmoMusic, DEAM, and MuSe using our new dataset.

Dataset	# tracks	Type	Source
EmoMusic [17]	744 ft/exc	abs	MTurk
DEAM [16]	1,802 ft/exc	abs	MTurk
MuSe [20]	41,021 exc	abs	Last.fm tags
MER-TAFFC [37]	900 exc	quad	manual
CCMED-WCMED [46]	800 exc	rel	CrowdFlower
EMusic [26]	140 exc	rel	CrowdFlower
MusAV	2,092 exc	rel	manual

Table 1. Public music datasets for AV regression and the proposed MusAV dataset. ft: full tracks, exc: excerpts, abs: ranged absolute values, quad: quadrants, rel: relative annotations.

2.2 Relative annotations

Some researchers in affective computing highlighted the disadvantages of rating-based emotion annotation by absolute values and propose to use relative annotations [27,28]. In MIR this has been considered in few studies. Yang and Chen [25] propose to gather relative AV annotations and employ learning-to-rank algorithms to train models predicting absolute AV values. They discuss the limitations of absolute value rating-based annotations and show that relative annotations are significantly easier and have more within-subject and between-subject reliability. Their annotation experiment involved a corpus of 1,240 pop songs (30-second segments) and 99 annotators with an average of 4.3 annotators per song. However, they considered relative annotations only for valence and the audio for the dataset is not publicly available.

The idea of relative AV annotations has been further explored by Fan et al. for the case of experimental music [26] (the EMusic dataset) and classical music [46] (CCMED-WCMED). For the former dataset, they crowdsource pairwise track AV comparisons for 140 track segments from 9 genres by 823 annotators gathering up to three annotators per pair. The latter contains 800 track segments from Western and Chinese classical music with pairwise comparisons by 989 annotators. In addition, a similar study proposes relative ground truth for soundscape emotion recognition [47].

3. ANNOTATION APPROACH

We follow a methodology that allows to avoid some of the limitations related to subjective annotation of arousal and valence with absolute values and instead consider comparative annotations on pairs of music tracks [25, 26]. Our main motivations are the following:

- Many practical applications are concerned not with the absolute AV values of songs, but with rankings songs according to these values. In such cases, relative annotations are convenient to validate ranking performance.
- For annotators, pairwise comparisons can be easier to understand and make decisions. They might require less effort than annotating with ranges of continuous values or Likert scales, which have more cognitive load [25,48].
- There is evidence that relative annotations have higher between-subject and within-subject agreement [25, 27].
- There are simple strategies to refine annotations according to the agreement between different annotators.
- Model evaluation can be a simple comparison of the ground-truth ordering of two tracks with the ordering according to the predicted AV values for all track pairs.
- Depending on how the models are trained, different models might predict AV values within different value ranges, which should be accounted for when comparing the performance metrics such as RMSE. Relative comparisons on pairs of tracks allows using simple common metrics that are compatible with all models.

To collect the dataset ground truth, we need an annotation tool able to reproduce pairs of music excerpts and collect the user's input. Such a tool should address potential sources of bias and simplify and speed up the annotation process. We define several requisites to accomplish this:

- We are interested in relative judgements about a pair of tracks (A and B) that can be formulated as the following question: "Which song has more *music property X*". The following choices are considered: *A*, *B*, or *same*. To minimize potential biases toward any of the choices, none of them should be selected by default.
- It may be difficult to maintain consistency when answering non-factual questions. Therefore, we consider that the interface should display multiple pairs in the same *page* to give the user an opportunity to improve coherence of their annotations before submitting the page.
- Loudness has a large impact in music perception. Higher loudness correlates to higher perceived arousal [29]. To minimize this effect, the annotation tool should include loudness normalization. Previous studies that proposed interfaces for AV annotations [16,17,25,26] ignored this issue and did not include any normalization.

4. THE MUSAV DATASET

We created our dataset following the described methodology, using Spotify API as a source for music audio previews and genre metadata. Using Spotify allows us to access a wide range of music, while the 30-second previews it provides are sufficiently long to capture an overall perceived emotion with AV annotations.

4.1 Preparing the annotation pool

We collected a list of 5,716 genres from *everynoise.com* [5] which corresponds to the genre taxonomy of the Spotify API [6] and contains broad genres as well as specific subgenres. We then used the API's *Search* method to select random tracks for each genre. We generated multiple queries for each genre (using the genre tag, a wildcard search string starting with a random character, and a random market) and picked a random track from the list of the returned results for each query. This method allowed us to diversify music coverage and avoid popularity bias, downloading 17,574 track previews for 4,386 genres (up to 15 tracks per genre). All audio previews are 30-second long MP3 files with a 96 kbit/s bitrate. Each preview has a corresponding metadata file obtained with the API's *Get Track* method, including artist and album metadata and various audio analysis features.

We then analyzed the loudness of the audio previews to discard tracks with atypical levels, computing the integrated loudness in LUFS [49] of each track with the Essentia audio analysis library [50]. Based on the distribution of the obtained values, we kept tracks within the range between -20 and -5 LUFS, which represents the range of healthy loudness levels for the majority of mastered music. As a result, we reduced our pool to 15,979 tracks by 3,630 genres.

We organized the tracks into triplets with three pairwise comparisons each, allowing for additional inconsistency checks according to gathered relations within each triplet. We randomly assigned the tracks to two types of triplets: *genre-triplets* with all tracks sharing the same genre (one triplet per genre) and *global-triplets* containing tracks from various genres (the remaining tracks) to account for a use-case of distinguishing emotions within the same genre. All resulting 5,326 triplets contain unique tracks. We randomly split all generated triplets into annotation chunks, each one containing 100 triplets with 80% being global-triplets and 20% genre-triplets.

4.2 Annotation tool and process

We implemented a custom tool according to the requirements in Section 3. For each pairwise comparison (a pair), we used the wavsurfer-js [7] player to display a navigable representation of the waveforms. To prevent loudness bias, we normalize the songs to a common level of -20 LUFS. We computed the normalization factors from the LUFS values precomputed in the dataset preparation step, and converted them to linear gain units as expected by wavsurfer-js.

Our interface formulates two questions: "Which song has more arousal?" and "Which song has more va-

[5] https://everynoise.com

[6] https://developer.spotify.com/documentation/web-api/reference

[7] https://wavesurfer-js.org/

lence?". For both questions, the choices are *A*, *B*, or *same* arousal/valence. The tool shows a configurable number of pairs on each screen page (6 by default) and a submit button that stores the answers from the current page and renders the next one. We present the annotator with multiple pairs on the same page, as this can facilitate double-checking decisions made across pairs to minimize inconsistencies. Additionally, it simplifies navigation of the annotation interface, reducing the amount of necessary mouse movements and clicks. Finally, the tool has a page counter and displays each pair's ID to facilitate reporting any possible issues. The annotator outputs one JSON file per pair containing the answers to the two questions.

Figure 1 depicts the annotation tool. The source code for the annotation tool is publicly available online. [8] The tool is distributed as a Docker web application.

Due to the limitations on effort and availability of our annotators, we have proceeded with 7 annotation chunks which account to 2,100 tracks assigned to 700 triplets with 2,100 pairwise track comparisons. Overall, we gathered annotations from 20 participants, including authors' colleagues and students, with a background in music and technology. Each chunk was presented to three different annotators. Every annotator was given a single chunk, with an exception of one annotator who worked with two chunks. All annotators were instructed about the meaning of arousal and valence beforehand following their common definition [16, 42] and were asked to focus on perceived emotion [51]. Participants were aware of the subjectivity of the task and we encouraged to provide their subjective opinion. In total, we gathered 6,255 comparative arousal and valence judgments on pairs of tracks after discarding 15 pairs that the annotators reported having non-music tracks (speech) and duplicated tracks. These annotations involve 2,092 track previews by 1,404 genres.

4.3 Annotation agreement and consistency

By having multiple people annotate the same chunks of audio, we can measure the agreement between annotators. Computing ordinal Krippendorff's alpha, we obtained values of 0.48 for arousal and 0.39 for valence, which indicates a fair to moderate level of agreement, which is consistent with previous studies [26, 42, 46].

For building our ground truth for arousal and valence, we defined two types of agreement for pairwise comparisons of tracks by three different annotators. If all three annotators agreed on a pair of tracks with the same answer (*A-A-A*, *B-B-B*, or *same-same-same*) the annotations for this pair were considered to be in *full agreement*. If only two annotators agreed, we checked whether the third annotator was in a soft (e.g., *A-A-same*, *same-same-A*) or hard (*A-A-B* or *B-B-A*) disagreement. In the case of the former, we considered the annotations for the pair to be in *majority agreement*. Table 2 presents the agreement statistics for all gathered annotations.

In addition, we checked whether pairwise comparisons contradict each other within triplets (that is, whether they are geometrically inconsistent). For example, for three tracks X, Y, and Z forming a triplet, if $X > Y$ and $Y > Z$, but $X \leq Z$, such triplet and all its pairs are considered inconsistent. We considered triplets as consistent only if all constituent pairs had full or majority agreement in the annotations and no contradictions have been found.

Agreement	Arousal		Valence	
	# pairs	%	# pairs	%
FA+MA	1,448	69.4	1,341	64.3
FA	975	46.8	810	38.8
FA+MA, CT	738	35.4	606	29.1
FA, CT	519	24.9	381	18.3

Table 2. Number and percentage of annotated track pairs with different levels of annotator agreement and consistency for arousal and valence. FA+MA: pairs with full or majority agreement. FA: pairs with full agreement. CT: only pairs belonging to consistent triplets.

As a result, we generated different subsets of the annotations, with 69.4% and 64.3% of track pairs having at least some level of agreement and 24.9% and 18.3% passing the most strict conditions (pairs with full agreement, belonging to consistent triplets) for arousal and valence, accordingly.

Finally, as we had two types of triplets, we checked the effect of genre on the agreement rate: 67% and 61% of pairs in global-triplets had either full or majority agreement compared to 76% and 75% in the case of genre-triplets for arousal and valence, accordingly. This observation revealed that it was slightly easier to reach agreement on pairs of tracks coming from the same genre than from different genres.

4.4 Dataset contents

We provide the following contents as part of the dataset, available online: [9]

- Metadata for the entire annotation pool. [10] Each triplet is identified by a triplet ID and contains track Spotify IDs, triplet type (global-triplet or genre-triplet) and genre information.
- Split of the annotation pool into annotation chunks. [11]
- Raw comparative arousal and valence annotations on track pairs by anonymized annotators.
- Processed ground-truth annotations with different levels of agreement and consistency (full and major agreement with/without triplet consistency).
- Track audio previews and metadata gathered from the Spotify API for the annotated chunks. [12]
- Dataset metadata statistics (e.g., genre distribution).
- Scripts to reproduce the creation of the dataset.

[10] All annotation metadata is licensed under CC BY-NC-SA 4.0.

[11] It is possible to expand the dataset by annotating more chunks.

[12] Available under request for non-commercial scientific research purposes only. Any publication of results based on this data must cite Spotify API as the source of the data.

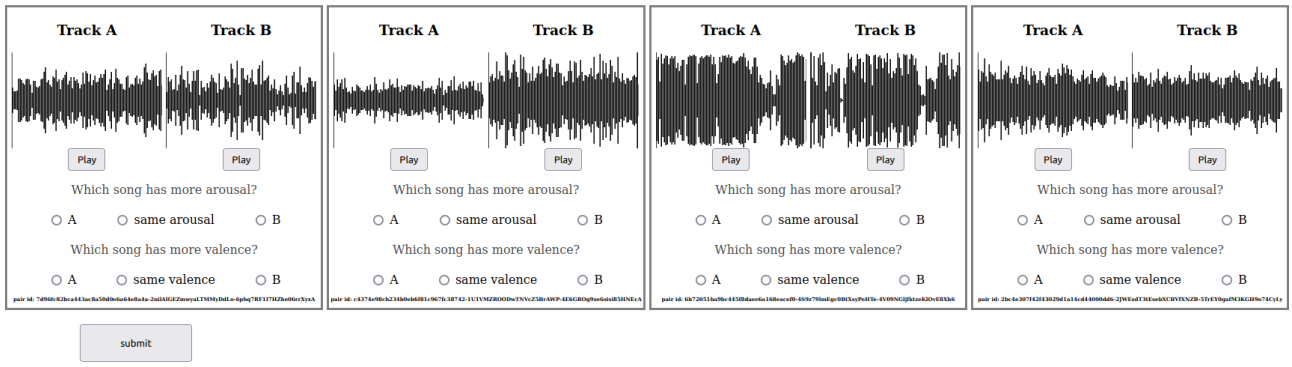

Figure 1. Screenshot of the annotation tool.

5. EXPERIMENTS

We demonstrate the dataset in use on the example of evaluating AV regression models based on audio embeddings.

5.1 Models

We created AV regression models based on three types of audio embeddings:

- **MusiCNN-MSD** (*musicnn*) is a music auto-tagging CNN with filter shapes motivated by music domain [52] trained on a subset of the Million Song Dataset. Its embedding layer has 200 units.
- **VGGish** (*vggish*) is a VGG architecture with an embedding layer of 128 units trained on audio from YouTube videos mapped to general purpose audio labels derived from their metadata [53]. The embeddings from this model were previously used for AV regression in combination with support vector regression [46].
- **EffNet-Discogs** (*effnet*) is an EfficientNet architecture trained to predict the music styles tags from Discogs. [13] The model produces 1280-dimensional embeddings and it is publicly available as part of Essentia models [54]. [14]

The embeddings are extracted on short one-, two-, and three-second audio excerpts for *vggish*, *effnet*, and *musicnn* models, accordingly. They are then used by the downstream regression models that we train. These models provide arousal-valence inference for each embedding vector, with a variable batch size with batch normalization. As Figure 2 depicts, we use a fully connected layer with a linear activation function, preceded by batch normalization and dropout. We also apply L1-L2 and L2 regularizers in the fully connected layer and dropout as regularization methods.

For training, we used three different datasets: DEAM, EmoMusic and MuSe, which we selected based on their music coverage as more appropriate for general use, with the goal to incorporate the resulting models as part of Essentia [24]. Each of them provides different audio excerpts (with 30-45 second duration) and arousal-valence values characterizing the overall emotion of each track. We extracted the embeddings with the pretrained models and used them as features. We followed a standard data splitting and loading strategy used in previous music classification publications [24]. To generate a train/test split stratified in terms of AV quadrants, we use Z-score normalization. However, we did not normalize the training data. The AV value range in all the datasets is from 1 to 9.

Figure 2. Arousal-valence backend model architecture.

Our models operate on short audio chunks and allow us to generate sequences of AV predictions over time with a new prediction every 1-3 seconds, depending on the receptive field of the embedding model used. Therefore, we compute the average of predictions on chunks to estimate the overall arousal/valence of a track.

In Table 3, we report Root Mean Square Error (RMSE) and Coefficient of Determination R^2 (R^2) commonly used for evaluation of regression models [17, 55, 56], obtained

	Arousal		Valence	
	R^2	RMSE	R^2	RMSE
deam-effnet	0.404	0.913	0.335	0.909
deam-musicnn	**0.417**	**0.894**	**0.400**	**0.818**
deam-vggish	0.396	0.963	0.344	0.963
emomusic-effnet	0.420	1.090	0.375	**0.948**
emomusic-musicnn	**0.451**	**1.030**	0.363	0.966
emomusic-vggish	0.429	1.037	**0.376**	0.973
muse-effnet	**0.143**	**1.148**	**0.089**	**1.581**
muse-musicnn	0.141	1.320	0.085	2.509
muse-vggish	**0.143**	**1.148**	0.085	1.584

Table 3. Evaluation metrics for the AV regression models on the held-out (testing) sets of the corresponding training datasets. The best values for each dataset are in bold.

Table 4. External validation results on the proposed MusAV dataset (the percentage of track pairs with a correctly predicted ordering). FA+MA: pairs with full or majority agreement. FA: pairs with full agreement. CT: only pairs belonging to consistent triplets. The highest values are marked in bold. The top three AV models are marked in gray.

on the datasets used for training the models.

5.2 External validation on MusAV

We used our new dataset to validate the performance of the models. To this end, we assessed whether the ground truth ordering of track pairs coincided with the ordering according to the AV values predicted by the models. In addition, we also evaluated arousal and valence estimations provided by Spotify API and computed from audio as an additional reference. [15] This reference possibly represents a common state of the art in industrial systems. We ensured that our external validation set is independent of the datasets used for training the models: EmoMusic and DEAM contain non-commercial music unavailable on Spotify, while the intersection with MuSe, for which we also used Spotify track previews, includes 24 tracks that we filtered out for our evaluation.

For simplicity, we discarded all ground-truth annotations marking two songs as equivalent (13% and 15% of the ground-truth pairs with full or majority agreement in the case of arousal and valence, respectively). Thus, we focused only on examples with clear difference in arousal or valence. Table 4 presents the accuracy of the models in terms of the percentage of track pairs with correct ordering. We report the results on different subsets of the AV ground truth to demonstrate various evaluation possibilities.

5.3 Discussion

Having a new common ground truth for all models, our external validation shows the impact of the training dataset and embeddings.

Remarkably, models trained on the EmoMusic dataset perform the best for both arousal and valence regression. This is surprising, given that this dataset is smaller and less diverse than DEAM, which was derived from EmoMusic. On the other side, models based on MuSe have the worst performance in the case of arousal. Even though MuSe is the largest dataset in terms of size and coverage of commercially-available music, it appears to be too noisy to be able to train efficient models for arousal. Notably, it is the only dataset out of three relying on user-generated tags instead of explicit AV annotations, and the employed process for mapping tags to AV values might be inherently noisier.

Second, given a dataset, the choice of embedding model also matters. For example, the *effnet* embeddings trained on a large music style dataset appear to be inefficient for emotion recognition. The models based on them are consistently worst in the case of arousal (with all three datasets used for training) and valence (with EmoMusic and MuSe used for training). In turn, our validation reveals high performance of the *vggish* embeddings in many cases, possibly due to their generalization ability which was previously evidenced in literature [24]. This observation contradicts the results obtained in the respective held-out sets, where it did not have a remarkable performance overall.

Finally, in our validation, some of the considered AV models have performance competitive with an industrial reference. Still, all of the considered models only achieve up to 90% accuracy for arousal and 81% for valence. This is in line with evidence that predicting valence (as well as its annotation) is generally considered more complex than arousal [17, 42].

6. CONCLUSIONS

We present a new public dataset of relative AV annotations for validation of audio-based AV models. To build it, we employ a methodology that maximizes coverage in terms of genres to gather our annotation pool and allows to assess consistency of annotations on triplets of songs. The dataset is based on audio previews from Spotify API which allows validating performance on diverse types of commercially-available music. As an example, we train and evaluate AV regression models based on three common AV datasets and three types of pretrained audio embeddings and show how such a benchmarking can provide valuable complementary information about model performances. The resulting pretrained models are publicly available as part of Essentia models.

[15] We consider the "energy" descriptor in the Spotify API as arousal.

7. ACKNOWLEDGEMENTS

This research was carried out under the project Musical AI - PID2019-111403GB-I00/AEI/10.13039/501100011033, funded by the Spanish Ministerio de Ciencia e Innovación and the Agencia Estatal de Investigación. We also thank Juan Sebastián Gómez Cañón for his suggestions and all participating annotators.

ABSTRACT

Structure is one of the most essential aspects of music, and music structure is commonly indicated through repetition. However, the nature of repetition and structure in music is still not well understood, especially in the context of music generation, and much remains to be explored with Music Information Retrieval (MIR) techniques. Analyses of two popular music datasets (Chinese and American) illustrate important music construction principles: (1) structure exists at multiple hierarchical levels, (2) songs use repetition and limited vocabulary so that individual songs do not follow general statistics of song collections, (3) structure interacts with rhythm, melody, harmony and predictability, and (4) over the course of a song, repetition is not random, but follows a general trend as revealed by cross-entropy. These and other findings offer challenges as well as opportunities for deep-learning music generation and suggest new formal music criteria and evaluation methods. Music from recent music generation systems is analyzed and compared to human-composed music in our datasets, often revealing striking differences from a structural perspective.

1. INTRODUCTION

Structure is fundamental to music, as seen in the focus on form and analysis in music theory [1–3], music segmentation [4–6], structure analysis [7–9] and chorus detection [10] in MIR research, and recently in the attention given to long-term dependencies in music sequence generation using deep learning techniques [11, 12]. As a basic indicator of music structure, repetition contains important music information. Music relies heavily on repetition to create internal references, coherence and structure.

Unfortunately, the nature of repetition and structure in music is still not well understood, and much remains to be explored with music information retrieval techniques. For example, while music theory may suggest that songs have distinctive motives, our work quantifies and generalizes this notion. We will use "structure" to refer broadly to organizing principles in music, which are generally hierarchical and include sections, phrases and various kinds of patterns. A primary generator of structure is repetition, which includes not just music content within repeat signs but also approximate repetitions at different time scales.

In music generation, many researchers rely on deep learning models to capture music structure and organizing principles implicitly from data. However, repetition, especially long-term repetition structure, does not seem to emerge automatically in deep music generation. Deep learning is a promising direction, but such research should include evaluations where we can assess the successes and failures of new approaches. Moreover, some may argue that we do not need deep learning models to learn prevalent repetitions in music: we can produce repetition simply by generating phrases to the desired length and pasting them into a template. However, we will see that phrase structure, song structure, and other elements of music are intertwined, making this simple approach unable to reproduce characteristics of actual songs. Thus, we need a better understanding of repetition if we want machines to compose or even just listen to music in a more human way.

We aim to use formal models to explore music repetition and structure. By characterizing structural information in music, we can discover new principles of music organization and propose new challenges and evaluation strategies for music information retrieval and music generation.

An essential aspect of repetition structure is hierarchy. We use objective data analysis to support the existence and significance of multiple levels of hierarchy in popular music. We also present a number of results that show strong interactions between structure and pitch, rhythm, harmony, entropy and cross-entropy. Simply stated, structure can help predict pitch (or rhythm, harmony, etc.) and pitch (or rhythm, harmony, etc.) can help predict structure. These findings, in turn, challenge and inform research on deep learning to model hierarchical music structure.

Another important effect of repetition is that song-specific vocabulary of rhythm and pitch patterns is limited relative to what would be expected from the entire dataset. This vocabulary serves both to unify multiple phrases within a song and distinguish songs from others.

The main contribution of this work is a better understanding of the nature of repetition in popular music. We will see that repetition exists in many forms and at different levels of hierarchy. We offer ways to quantify music repetition structure, especially as it relates to pitch and

Dannenberg, "What is missing in deep music generation? A study of repetition and structure in popular music", in *Proc. of the 23rd Int. Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

rhythm, often by measuring entropy or cross-entropy. We also reveal striking differences from a structural perspective through case studies on recent deep music generation models. These and other findings offer challenges as well as opportunities for deep-learning music generation and suggest new formal music criteria and evaluation methods.

After describing related work in the next section, we discuss music repetition and structure in Section 3, how it relates to deep music generation in Section 4, and we present conclusions in Section 5.

2. RELATED WORK

Repetition is a key element of music structure. Repetition is one of the three commonly used principles for segmenting music, along with novelty at segment boundaries and homogeneity within segments [7]. People have developed a variety of segmentation and section detection methods based on repetition with acoustic features [4, 10]. Repetition becomes especially useful in segmenting symbolic music or lead sheet representations where timbre and texture may be lacking [13].

Repetition also plays an important role in music expectation and prediction [14, 15]. Studies of repetition and structure are common in Music Psychology [16]. For example, listening experiments with reordered Classical and Popular music have shown that listeners are rather insensitive to restructuring, but these results are subtle and somewhat ambiguous [17]. Music form and structure, including repetition, is also a major focus of Music Theory [1,18,19].

There are many deep learning models for music generation [11, 20–23], however, capturing repetition and long-term dependencies in music still remains a challenge. One mainstream approach is to model distribution of music via an intermediate representation (embedding), such as Variational Auto-Encoders (VAE) [20,24], Generative Adversarial Networks (GANs) [25] and Contrastive Learning [24, 26]. Due to their fixed-length representation and short-length output, it is difficult to exhibit long-term structure. Another popular trend is to use sequential models such as LSTMs and Transformers [11, 22, 27] to generate longer music sequences, but they still struggle to generate repetition and coherent structure on long-term time scales. Some recent work introduces explicit structure planning for music generation, which shows that using structure information leads to better musicality [12, 28, 29].

Current evaluation methods for music generation rarely consider repetition and structure. Deep music generation systems [11,30] use objective metrics such as negative log-likelihood, cross-entropy and prediction accuracy to compare generated music with ground-truth human-composed music. But these metrics do not precisely correspond to human perception and are not reliable for musicality. Another trend is using domain-knowledge [31] and musical features [32–35] such as pitch class, pitch intervals, and rhythm density to evaluate music statistically. However, most of them ignore even short patterns, and none evaluate music structure. In contrast, we offer quantitative and objective methods to evaluate music repetition and structure.

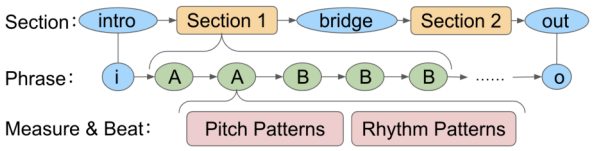

Figure 1: Structure hierarchy in pop music.

Figure 2: Repeated motives in a phrase in *Yankee Doodle*.

3. REPETITION AND STRUCTURE IN MUSIC

We are interested in three main problems concerning repetition and structure in music: (a) How are repetition and structure organized hierarchically? (b) How do different levels of structure interplay with other music elements? (c) How does repetition play out over time?

Unlike traditional music theory with case-by-case human analysis, we explore these problems in a data-driven approach. For training and testing, we use a Chinese pop song dataset POP909 [36], which has 909 pop song performances in MIDI, and an American pop song dataset PDSA [37], in MusicXML, which has 348 American pop songs originating from 1580 to 1924. We use only songs in 4/4 time to simplify analysis.

3.1 Repetition and Structure Hierarchy

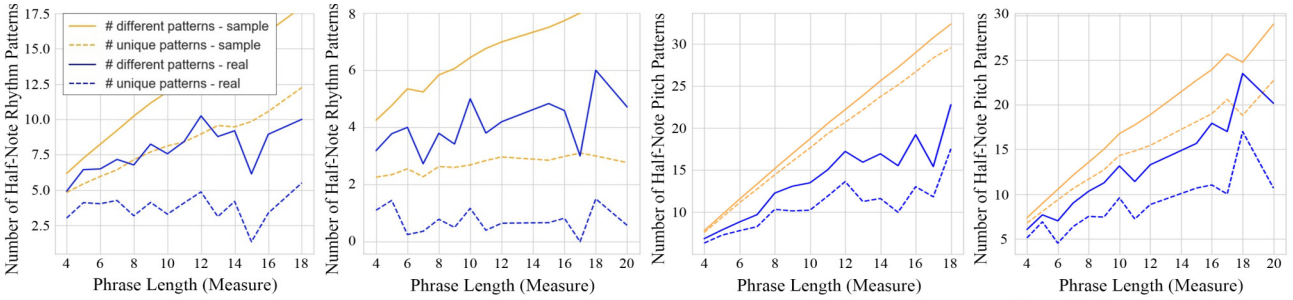
Music structure is hierarchical. It contains multiple levels of repetitions, ranging from low-level pitch and rhythm motives (patterns) to higher-level phrases (analogous to sentences) and sections (analogous to paragraphs). We describe these in more detail and use statistical and machine learning findings in the data to explore their significance.

3.1.1 Phrases and Sections

Researchers [13] found two levels of structure in POP909: *sections* and *phrases*. Phrases were identified by searching (automatically) for approximate repetitions of sequences of 4 or more measures. Non-unique phrases (those that match other phrases) often occur in sequences such as "AABBB" in Figure 1 called *sections*, which are by definition separated by non-repeated or non-melodic phrases. For example, Figure 1 has an intro, two sections connected by a bridge transition, and an outro, which is a typical pop song structure. Here "A" can be a verse, and "B" can be a chorus phrase. These phrase and section levels of structure were found to be predictive of aspects of pitch, rhythm and harmony, which shows that these two levels have significance for composition, probably for perceptual reasons.

3.1.2 Repetition Below the Phrase Level

There is at least another level of repetition below phrases (Figure 1). For example, in the first 8-measure phrase of the chorus in *Yankee Doodle* (Figure 2), the first and second half repeat elements of rhythm and interval. The colored boxes show repeated rhythm patterns, and the red lines point out repeated pitch contours. We want to assess whether this kind of repetition is common.



(a) POP909 phrases – rhythm pattern (b) PDSA phrases – rhythm pattern (c) POP909 phrases – pitch pattern (d) PDSA phrases – pitch pattern

Figure 3: Average number of different patterns (solid) and unique patterns (dashed) within a phrase vs. phrase length. (a)(b) are patterns of half-note melody note onset, (c)(d) are half-note pitch patterns. Blue lines are real phrases in the dataset. Orange lines are sampled phrases constructed by choosing each pattern at random from the entire dataset distribution.

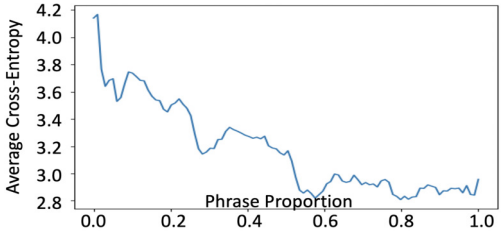


Figure 4: Average cross-entropy of diatonic pitch predictions over time within a phrase in POP909, using variable-order Markov models.

We extract the phrase-level structure in PDSA using the algorithm in [13], and use human-labeled structure in [13] for POP909. We study rhythm patterns by segmenting melody sequences into half-note onset patterns. PDSA has 54 different half-note patterns, while POP909 has all 128 possible patterns (onsets are quantized to 16th notes, and we assume an initial onset).

We claim that phrases have a limited vocabulary of onset patterns and therefore much repetition. This will of course be true necessarily if the entire dataset has a very limited vocabulary, so as a baseline for comparison, we construct random phrases by sampling half-note onset patterns from the entire dataset distribution. For POP909 songs, Figure 3(a) shows the average number of different onset patterns in phrases of different lengths (solid lines) and also the average number of patterns that occur only once in the phrase (dashed lines). This allows us to evaluate whether patterns within phrases (blue) have similar distributions to those of the entire dataset (orange). A similar graph for PDSA songs is shown in Figure 3(b). The analysis of pitch patterns is similar. Figure 3(c)(d) presents counts of melodic pitch patterns analogous to the onset pattern counts. Again, we see that real song phrases have a limited vocabulary compared to phrases assembled from random half-note units representing the entire dataset, and fewer real phrases go unrepeated.

If repetition of small patterns is frequent, variable-order Markov models [38, 39] can make good song-specific online predictions by updating the model at each element of the observed sequence. Conceptually, a variable-order Markov model estimates separate Markov chains of order 0 to N based on observed state (e.g., pitch) transitions. When data is too sparse to use a higher order, the model falls back (iteratively) to the next lower order. Repetitions of different lengths are readily learned, thus prediction accuracy indicates repetition significance. Figure 4 shows the average cross-entropy for pitch prediction over the length of all phrases, with phrase length normalized to 1. The clear downward trend shows the extent to which internal repetition enables better prediction.

In summary, we find abundant evidence for repetition within phrases:

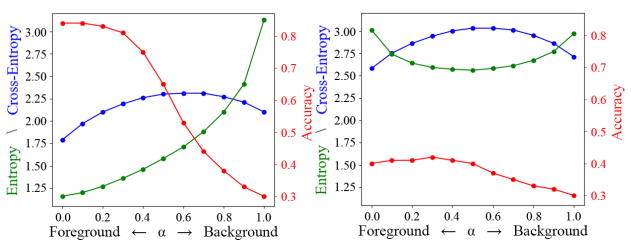
- Compared to sampling onset patterns at random from the POP909 distribution, real phrases have fewer distinct onset patterns, and more onset patterns are repeated in the phrase (Fig 3(a)). Same trend occurs in PDSA (Fig 3(b)), whose phrases contain even fewer distinct onset patterns.
- Rhythm patterns show a clear repetition structure within phrases. Considering each measure as a rhythm pattern, in PDSA, 7% of phrases have the same rhythm pattern in every measure, 28% have a repetition structure in one of the forms: "abab," "aabbaabb," "aba," or "abababa."
- The vocabulary of pitch patterns within a song or phrase is also very limited compared to the whole dataset, implying pitch sequence repetitions within the phrase level.
- The cross-entropy of predicting pitches decreases over time in a phrase, suggesting within-phrase repetition.

3.1.3 Song-Specific Vocabulary and Common Patterns

Motives and patterns below the phrase level create a song-specific vocabulary and have a long-term dependency throughout the whole piece. For example, in Beethoven's Symphony No.5, the first movement begins with a distinctive four-note "short-short-short-long" (the famous "Fate Motive"). It repeats everywhere throughout the piece, and Beethoven arranged it logically to unify the entire work.

We chose variable-order Markov models to further explore patterns because (a) it is easy to tune the weights between models trained on different data, (b) models can learn different lengths of pattern repetition. The following results show 1) song-specific vocabulary is critical in prediction, 2) there is long-term dependency between phrases.

To see the effects of song-specific vocabulary and context, we compare the results of variable-order Markov models predicting pitch trained on many other songs (background model), versus training on the same song after removing a short segment to be predicted (foreground model). Predictions are a linear combination of the back-



(a) Including duplicated phrases in foreground training

(b) Hold out repeated phrases in foreground training

Figure 5: Average entropy, cross-entropy and accuracy of predicting the first eight diatonic pitches in each phrase, tuning between foreground and background in POP909.

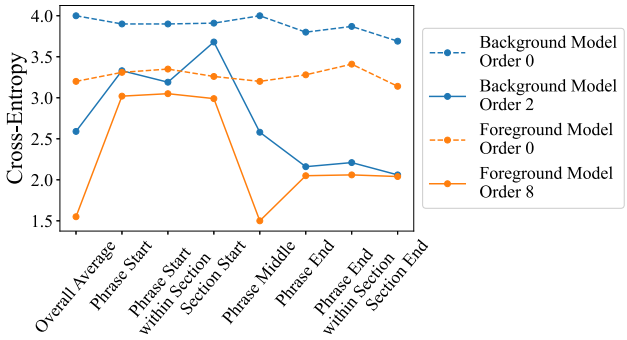


Figure 6: Average cross-entropy on diatonic pitches at different structure level positions in POP909 dataset predicted by background and foreground variable Markov models.

ground and foreground models. Figure 5(a) shows that the pure foreground model always obtains the best results. One possible reason is that phrase-level repetition in the foreground allows memorization. Thus, we removed all the duplicated or similar phrases in the foreground training and tested only on the first eight notes in each phrase (without updating the model) to eliminate both the effects of phrase-level repetitions and within-phrase motive repetitions. With almost no information from the repeated phrase, we might expect little information within a song to help predict pitches. However, Figure 5(b) indicates that we obtain the best prediction accuracy when incorporating 70% foreground and 30% background information. Since duplicate phrases have been removed and the first eight notes involve little within-phrase repetition, the results show that there must be a song-specific vocabulary or context that repeats across different phrases throughout the song, but not across the database (otherwise background would work better).

3.2 Structural Influence

Can repetition structure be considered orthogonal to melody, harmony and rhythm generation? If so, we can simply generate music note-by-note, ignoring structure, and then impose structure by repeating generated sequences. However, if there is significant interaction between structure and other facets of music, then structure is an integral part of music analysis, music modeling, and music generation. Our findings show the latter is the case.

Previous work has found systematic interactions between repetition structure and three facets of music: melody, rhythm and harmony, with interactions at both the phrase level and the section level [13]. For example, chords at the ends of phrases differ from chords in the middle of phrases. Furthermore, final chords in sections differ significantly from final chords in phrases that are not at the ends of sections. This does not mean that "good music" must reflect a structural hierarchy, but at least this finding offers insight into how music generation might be improved, and it raises questions for further study.

In this work, we have also explored confidence and surprise in music construction to better understand the role of different levels of structure in music. In Figure 6, we trained on the entire dataset (background model) of melody pitch sequences, holding out test songs; and also trained on single songs (foreground model), holding out all phrase repetitions to eliminate prediction by memorizing phrases, and holding out eight notes at a time for testing. Only order 0 (histogram) and the best-performing order maxima (2 and 8, respectively) are shown. As seen in the previous section, the foreground model predictions are better by 1 bit on average, indicating more repetition within songs (foreground) than across songs (background).

Even though the Markov models have no positional encoding or conditions, we can still see a dramatic difference in predictability at different structure positions (Figure 6). For example, using the background model, cross-entropy at the start of sections is over 3.5 (bits), while other phrase starts are about 3.2, and for most notes (phrase middle), cross-entropy is only 2.6. Using the foreground model, we see a different pattern, but predictability still varies substantially according to position in the structure.

3.3 Repetition and Structure Over Time

Music is not repeated randomly. After seeing different levels of hierarchy in Section 3.1, we ask: Is there a schema for repetition? How does repetition play out over time?

Huron suggests that if music is to manipulate prediction through repetition, it makes sense to repeat some of the music early on [14]. This affords immediate pleasure from successful prediction rather than delaying until all novel material is exhausted. POP909 supports this hypothesis: More than 50% of the phrases repeat immediately, and almost all phrases repeat within a quarter of the song.

In Section 3.1, we have seen that most rhythmic and melodic patterns in a phrase are repetitions. At the song level as well, using the phrase repetition labels in POP909, we found that for 79% of songs, 15% to 35% of their duration consists of new material and the rest is repetition.

Returning to our consideration of structure over time: How does surprise vary with structure? We might expect less surprise at the ends of sections to give a sense of completion or resolution. Figure 7 Left shows a histogram percentage of phrase-level repetition over the course of a song. We see a relatively low repetition rate in the first 1/10 of the song. The repetition rate sharply increases as we progress to the first 1/5 of the song because, after introducing the initial materials, most songs repeat them. There is a notice-

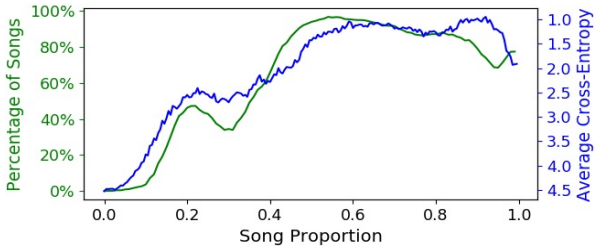

Figure 7: **Left** (green): Percentage of POP909 songs that have phrase repetitions at different song locations. **Right** (blue): Average prediction cross-entropy using variable-order Markov models on diatonic pitches in POP909 songs over time, and note the y-axis is inverted.

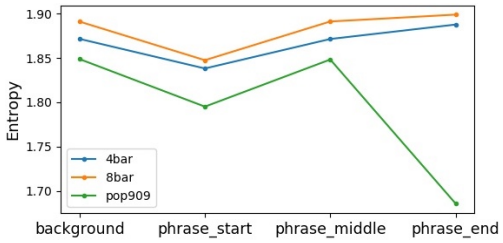

Figure 8: Entropy of pitch scale degree distribution at different phrase positions, comparing generated 4-bar and 8-bar phrases from VAE with real phrases in POP909.

able drop around the quarter-way point where many songs introduce new material. In the second half, almost everything is a repetition or variation of what came in the first half. Finally, the graph shows novel material is often introduced near the end. In Figure 7 Right, we use the variable-order Markov model to calculate the average cross-entropy over time on melody pitches. To show the correspondence, we flip the vertical cross-entropy axis. Note the similarity between the trends in repetition and cross-entropy.

From these results, it is clear that repetition is not random but follows a plan in which novelty is revealed, presumably to enhance the enjoyment or effect of the music. This is perhaps surprising because other research shows that music can be substantially rearranged without destroying positive impressions [40]. Whether this organization matters to listeners or simply reflects composers' intentions requires further research.

4. IMPLICATIONS FOR DEEP MUSIC GENERATION

One application of our studies is to gain insight into deep learning models for music generation. We can apply the analyses from Section 3 to melodies generated from deep learning models. Through these case studies, we can characterize repetition and structure from deep music generation and compare to human-composed songs. To be clear, we are not claiming that any particular structure is *necessary* or even *good*. Our goal is to illuminate possibilities and better understand both real and generated music. We then discuss our results and point out new directions and ideas for future work in deep music generation.

4.1 Lack of Repetition and Structure

We studied repetition and structure in deep learning generated melodies to answer three questions: 1) do melodies have multiple levels of repetition and structure? 2) do they have song-specific vocabulary and common patterns? 3) how does cross-entropy vary over time? We used two deep music generation models: One is a VAE model using representation learning [24], chosen because it uses contrastive learning to generate longer sequences (8 bars) than other VAE models. The other model is Music Transformer [11].

4.1.1 Do deep melodies have multiple levels of structure?

We want to know if deep-learning-generated music has multiple levels of structure and whether any structure is reflected in pitch and rhythm. Unfortunately, most deep learning models can generate only a limited length: VAEs and GANs usually have a fixed length from 2 to 8 bars, about the length of just one phrase. Sequential models like Transformer and LSTM can generate longer sequences, but we cannot find any salient repetition comparable to repeated phrases by listening or by automated analysis. These differences from popular songs are striking.

Thus, the only thing we can do is to test on short generated sequences, consider them as a phrase, and see if they have phrase structure. We tested the 4 bar and 8 bar generated phrases from a VAE model [24] and used 1000 examples of each duration. Figure 8 shows that there is no significant differences between the entropy of pitch scale degree distributions at the start of phrases, middle of phrases and end of phrases, but we see significant differences in the real POP909 phrases. Also, the probabilities of different pitches at different phrase-level positions only change slightly in the analyzed outputs. For example, the probability of seeing the tonic at phrase end is 35% in real POP909 phrases, while at the other positions it is around 20%. The probability of seeing the tonic in VAE output is in the range of 20% to 21% for all positions.

4.1.2 Do deep melodies have song-specific vocabulary and common patterns?

Following the logic in Figure 3, we count the rhythm (melody note onset) patterns for whole songs from Music Transformer and from POP909 itself. We trained the Music Transformer on 80% of songs in POP909, using 10% for validation and 10% for testing. We initialized the generation with the first 2 to 6 bars of the test songs, but did not count the initialization bars as part of the generated melody. To calculate the song length, we use the total length of melodic phrases, omitting measures that are empty or have long rests.

In Figure 9, we see that transformer-generated results have a much higher rhythm vocabulary compared to real songs. Many people have observed that deep-learning-generated music has many outlier notes and patterns that appear once and sound like mistakes. Here we see that transformer-generated melodies have a higher number of unique rhythm patterns compared to real songs, which might explain the sense of too many outliers.

We also analyzed half-note pitch patterns in 4-bar and 8-bar phrases from the PDSA, from random pitch patterns drawn from the entire PDSA distribution, and for the VAE

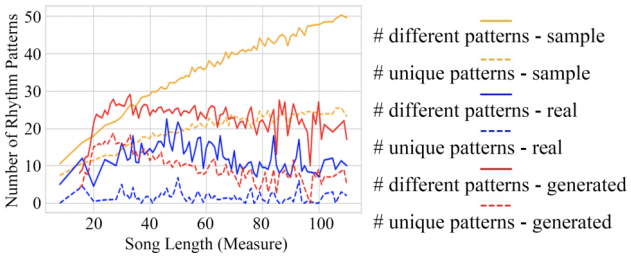

Figure 9: Analysis of note onset pattern vocabulary from randomly sampled POP909 patterns (yellow), Music Transformer songs (red), and POP909 songs (blue) as a function of song length. Solid lines are the total number of different patterns, and dashed lines are the number of unique (not repeated) patterns.

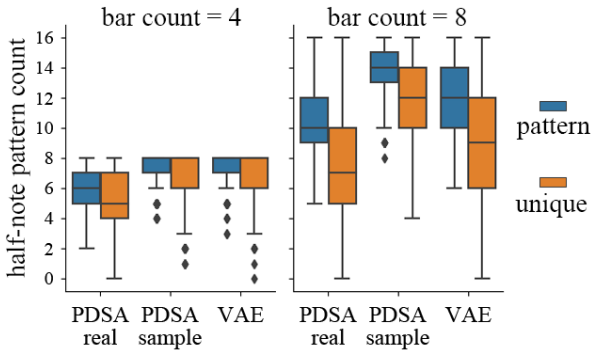

Figure 10: Comparison of half-note pitch pattern counts in PDSA phrases, randomly sampled PDSA pattern phrases, and phrases from VAE. The y-axis counts the number of different patterns (blue) or number of unique (not repeated) patterns (orange) found in 4 or 8 bars. The VAE generated patterns are significantly more than the patterns in the real PDSA dataset, with p-value less than 10^{-5}.

model [24] (see Figure 10). Vocabulary is more limited in PDSA phrases compared to the random patterns and VAE patterns. The VAE pattern counts are closer to those of synthetic phrases and thus may lack some of the coherence, redundancy, and predictability of PDSA.

4.1.3 Entropy over time

We also compared trends in cross-entropy of the pitch sequence over the course of songs from POP909 (Figure 7 blue) and Music Transformer (Figure 11). Although both exhibit an overall cross-entropy decrease over the course of the phrase, there are important differences. POP909 cross-entropy increases at around 20% of the song length, probably due to the introduction of novel and contrasting patterns, and also around the end. POP909's average cross-entropy is greater than one bit per note except for a small region around 90% of song length, while Music Transformer is below one on average for the last 30% of the song, suggesting overly predictable sequences.

4.2 Discussion and New Directions

Rather than learning and reproducing general statistics of datasets, we need to learn how songs strategically diverge from background or stylistic norms to create interest, surprise, and individuality. It is particularly interesting that

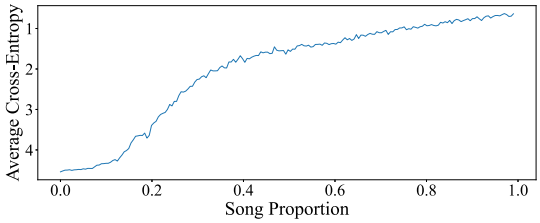

Figure 11: Average prediction cross-entropy using Markov models on diatonic pitches over time in 910 generated music pieces from music transformer, y-axis inverted.

phrases can be better predicted by relatively short phrases within the same song than by large amounts of training data from other songs. It seems plausible that songs of the same artist or same sub-genre may be more predictive than songs in general. Our findings also reinforce previous findings that using structure in MusicFrameworks [12] results in better human evaluations.

Examples in Section 4.1 suggest that we can compare generated music to real music using measures of structure, repetition and entropy. Matching these measures is not guaranteed to make music "better," but we should not simply ignore clear objective differences. We would at least expect differences to be small when the task is to imitate a style or genre. We can also speculate that these measures are relevant to listener preferences even if they do not tell a complete story.

Although we have focused on popular music, repetition and hierarchical structure seem to be ubiquitous in music. Pop music, with its nearly exact repetitions, seems easier to study than Classical music where we might expect more variation, development and modulation, which make repetition less obvious. We are encouraged by our results using variable-order Markov models on pitch sequences. These studies reveal much more information than we expected and do not rely on finding wholly duplicated measures, which we used to extract phrases and sections. Perhaps this approach will be of use in Classical and other music.

5. CONCLUSION

It should be no surprise that structure, repetition, pitch, rhythm, harmony and entropy are all strongly connected and interdependent. We have offered new ways to explore these connections objectively, using a data-driven approach without relying on subjective human analyses.

Among our findings are that within-song and within-phrase vocabulary and repetition are not a reflection of more general background statistics from a collection of songs. Instead, songs and phrases gain "individuality" through more repetition and smaller vocabulary. This has important implications for machine learning and music generation systems.

There are clear differences between measurements of real songs and those of many music generation systems, suggesting that there are important gaps to fill through new research. We hope that this work will inspire further research in the roles played by repetition and structure in music as well as methods to learn repetition and structure.

6. ACKNOWLEDGEMENT

We would like to thank Ziyue Piao and Ying Yee Wong for their assistance in the early stage.

ABSTRACT

Music emotion recognition has been a growing field of research motivated by the wealth of information that these labels express. Recognition of emotions highlights music's social and psychological functions, extending traditional applications such as style recognition or content similarity. Once musical data are intrinsically multi-modal, exploring this characteristic is usually beneficial. However, building a structure that incorporates different modalities in a unique space to represent the songs is challenging. Integrating information from related instances by learning heterogeneous graph-based representations has achieved state-of-the-art results in multiple tasks. This paper proposes structuring musical features over a heterogeneous network and learning a multi-modal representation using Graph Convolutional Networks with features extracted from audio and lyrics as inputs to handle the music emotion recognition tasks. We show that the proposed learning approach resulted in a representation with greater power to discriminate emotion labels. Moreover, our heterogeneous graph neural network classifier outperforms related works for music emotion recognition.

1. INTRODUCTION

Music is intrinsically connected to human emotions. At the same time that a songwriter expresses emotions in the composed songs, we can use music's emotional information to characterize the listener's moments and feelings. Music emotion recognition (MER) is a task that highlights social and psychological functions comprised by recordings, extending traditional applications in the area of music information retrieval [1]. According to the literature, mapping the spectrum of emotions can be done by analyzing the values in arousal and valence domains [2]. Besides, the emotions can be represented by labels that indicate negative, positive, and neutral values of arousal and valence and labels that point to emotional expressions, such as happiness, anger, or satisfaction [3]. Each label may be defined according to the significance of valence and arousal simultaneously, as illustrated in Figure 1. The MER task aims to use a musical representation to estimate these significances or predict discretized labels.

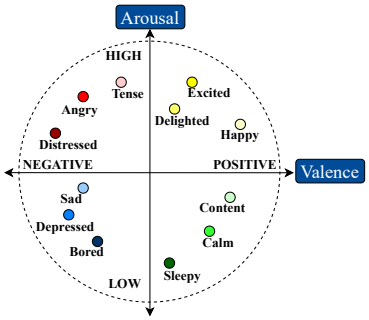

Figure 1: Emotions mapped in the arousal and valence domains.

Textual information is the most used data type in tasks involving emotion labels [4]. When emotion recognition is performed on music data, lyrics are commonly used as input [5, 6]. However, some studies emphasize the importance of acoustic features for the same task [7]. The fact that both modalities complement musical perception is well-known [8–10]. However, there is no consensual approach for incorporating multiple modalities into a unified representation.

Defining the structure to deal with different data types, such as text and audio, is a preliminary step to generate a unified multi-modal representation of musical data. Building this structure is an open problem in the literature. Techniques based on feature fusion are the most explored approach in the literature [11, 12]. Fusion of features can be performed by simply concatenating text and audio features or even learning embeddings via multimodal deep learning. However, these existing methods have limitations regarding incomplete modalities, deal with modalities of different dimensionality, and the interpretability of the generated representations [13].

Heterogeneous networks are a well-known representation for manipulating multiple modalities of unstructured data [14, 15]. This resource has been explored due to the ability to map data on graphs, representing connections between objects (nodes) through edges. Therefore, this process produces a graph that can be used as input in Graph

Neural Network models [16]. Structuring data on heterogeneous networks has been widely studied in varied data such as text and images [17,18], but there are still few studies for musical data.

This work introduces a novel model for music emotion recognition that uses a heterogeneous network to structure audio and lyrics features and build a new multi-modal graph-based representation of musical data using the graph convolutional network (GCN). Our proposed model, described in detail in Sec. 3, uses content-based features (audio descriptors) together with features extracted from lyrics (embeddings from the language model). The music graph topology is based on relations defined by cluster information from audio e textual metadata. Some music nodes have labels with emotional information. Therefore, the proposed structure is composed of a heterogeneous network, and GCN can predict the emotion of unlabeled music nodes.

We apply a network regularization framework to propagate and refine information between neighboring nodes from different modalities. The matrix resulting from this regularization, along with the graph connections, is used as input for training our GCN. In this embedding space, music with similar emotions are close to each other, while dissimilar ones are further apart.

To evaluate our approach, we used the publicly available dataset PMEmo [19], which has 794 songs represented by audio descriptors and lyrics with annotations for arousal and valence domains. We measured the relevance of the learning process of a multi-modal graph-based representation for MER. Our proposal was compared with two different methods and other works from the literature that reproduced a similar experiment.

Our method was able to obtain a meaningful embedding representation that unifies different audio and text music features across the heterogeneous network. In addition to the heterogeneous network enabling interpretability of the relationships between text and audio features, our method outperforms other existing methods for music emotion recognition tasks.

2. RELATED WORK

The construction of methods to learn representations for unstructured data aims to reduce the work for features extraction and selection to describe the data and make learning algorithms less dependent on these processes [20]. Learning a representation for musical data involves manipulating features obtained by multiple modalities and projected in different spaces [21, 22].

Learning to represent music to recognize the comprised emotion involves exploring different features [1, 23]. We can observe most applications using the lyrics to represent the music [5, 6, 24] justified by the direct association we can make with the meaning of words and emotion labels. However, we have evidence that acoustic features also contain information that characterizes emotions [11,12,25]. In summary, there is no consensus on representing music using multiple modalities for the MER task, although we note that audio and lyrics features are relevant.

Recent work about music representation learning has explored strategies based on deep neural networks, such as early and late fusion [26, 27] and evaluating combinations between different input features [13]. This strategy advances and presents successful results that justify the representation learning process. However, there is a demand for approaches that explain the semantic complementarity existing between the features that justify the obtained results [28]. We explore the heterogeneous network resources to embed multiples music features and explicit the latent relationships among nodes, similar to [29, 30]. Moreover, we learn a graph-based representation that concentrates information from related music.

The complementarity between distinct features in musical perception justifies the motivation to build a multimodal representation [31]. For the emotion recognition problem, [7] describes what semantic information exists in various acoustic features and which emotions each feature can emphasize. We note that lyrics are also associated with emotions and must be used for the recognition task [32]. Therefore, we aim to build a multi-modal representation that integrates features obtained through the audio and lyrics and compares its performance against unimodal scenarios.

The construction of multi-modal embeddings requires that distinct features be mapped in a unified space. Graph-based methods have been applied in recent years when nodes and edges have different types [33]. We can exploit the relationships between neighboring nodes to build an embedding space that aggregates information from the node features even in different spaces. Significant advances are observed in multi-modal and unstructured data applications [34].

For musical data, [35] explores the task of similarity between artists. Authors use data previously structured to create the graph and apply it in GCN to build music embeddings with acoustic characteristics and tags. Finally, the embeddings are used to predict links to new artists. In contrast, [36] introduces a proposal of graph-based representation learning with the graph being constructed from a co-occurrence matrix obtained by the presence of pairs of songs in playlists.

Our proposal aims to create a heterogeneous network with multiple musical features and connect nodes that share cluster information. This network produces the features input for GCN to build a multi-modal representation and handle the music emotion recognition task. Our learned representation does not depend on previous information to structure the graph. Although we do not extend the approach to the multi-task scenario, it can be easily adapted for different tasks, maintaining the same heterogeneous network.

3. MODELLING

Our goal is to recognize emotions present in songs, such as a classification problem $Y = f(X)$, where Y represents the set of emotion labels, X represents the songs, and $f(.)$

denotes the function responsible for predicting emotions from a multi-modal musical representation given as input.

The proposed method for handling the MER is divided into three steps. The first step is to construct a heterogeneous network to structure songs in nodes and organize the acoustic and lyrics features available in the PMEmo dataset into different layers and build the relationships. Then, in sequence, we regulate the network to propagate information between nodes of different layers and explore the semantic complementarity between features of both modalities. Finally, we use the regularized network as input our multi-modal network embedding method using Graph Convolutional Network (GCN). The generated embeddings are also used by GCN to classify the emotion of the songs.

3.1 Heterogeneous network to structure music data

Musical data are intrinsically multi-modal, formed by features semantically complementary. Therefore, building a representation that incorporates multiple features demands manipulating modalities organized in different spaces. In this sense, heterogeneous networks offer resources for structuring data as nodes, with each modality projected on a layer and forming relationships between nodes for information sharing.

Mapping unstructured data on graphs has been gaining attention in the literature, motivated by the success of GNN-based learning models. For musical data, [37, 38] proposes to build a graph relating nodes from a distance function where nearby nodes are connected, while [39] assumes that all nodes are connected by adding weights in the edges, and as the works aforementioned [35, 36] that employing existing information to create a graph structure. We propose constructing the graph topology by using clusters for each modality as network nodes. Thus, we model the relationships between music, audio and texts from the cluster labels for each modality. Figure 2 illustrates this process, where songs are initially clustered according to their audio features. In this work, we use the k-means algorithm; however, the modeling is not dependent on a specific clustering algorithm. Then both clusters and songs are considered network nodes. The links indicate association between songs and clusters formed with audio features. This process is repeated for textual features, thereby allowing to obtain a heterogeneous network with three layers as shown in Figure 3.

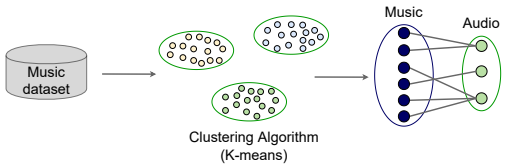

Figure 2: Illustration of mapping songs and respective audio features in a bipartite graph using clustering. This process is repeated for text features to generate the proposed heterogeneous network.

The heterogeneous network is formally defined as $N = (O, R, W)$, where O represents the set of objects, R represents the relationships and W represents the weights. Let $o_i \in O$ as the notation for an object, $r\_o\_i, o\_j = (o_i, o_j) \in R$ indicates whether there is a connection between the objects o_i and o_j, where the weight of r_{o_i,o_j} is given by w_{o_i,o_j} with $w \in W$. Currently, our propose use binaries relationships, $w_{o_i,o_j} \in \{0, 1\}$, for example, if a music node o_i is associated to a cluster with textual information, or audio information, o_j.

The benchmark dataset used has textual and acoustic features so that the set of objects $O = \{O_M \cup O_A \cup O_T\}$ is organizing each feature modality in the heterogeneous network proposed for musical data. O_M are objects representing each music in the dataset, O_A are objects representing acoustic features formed by audio descriptors, and O_T are objects representing textual features extracted from the lyrics.

3.2 Network regularization

In the proposed heterogeneous network, the objects $o \in O$ have one or more initial features vectors. For example, an object $o_m \in O_M$ that represents a music might contain an acoustic feature vector $x_{o_m}^{(A)} \in \mathbb{R}^{d_A}$, as well as a textual feature vector $x_{o_m}^{(T)} \in \mathbb{R}^{d_T}$. The vectors are in their respective spaces $\mathbb{R}^{d_A}$ (e.g. melspectrogram or chromagram) and $\mathbb{R}^{d_T}$ (e.g. word2vec or BERT). However, objects in sets O_A and O_T exclusively have the initial features of their modalities. Still, we highlight that objects in O_M may contain absent modalities, such as missing lyrics for some musics. Thus, inspired by the concept of embedding propagation from networks [40], we integrate a regularization framework capable of propagating information between objects of different modalities according to the network topology.

The regularization process exploits the network topology to propagate information between objects to complement missing information and adjust existing features according to the object label. The process is represented in Figure 3. The music is the input data, where each feature modality composes a layer in the heterogeneous network. Objects in the central layer are in O_M and are connected to objects of other types, having their feature vectors. The objects in O_A contain audio descriptors, and objects in O_T contain lyrics features. When finish regularization process, all objects will have feature vectors from objects of different modalities.

The proposed method to perform the network regularization is an instance of label propagation methods [41]. This step aims to propagate the object's features, assuming two constraints: neighboring objects must have similar features; the final feature vector must be similar to the initial features for objects. Formally, network regularization can be associated with a representation learning problem. We define as learning a mapping function $f : o_i \rightarrow \mathbf{z}_{o_i} \in \mathbb{R}^d$, where $\mathbf{z}_{o_i}$ is the learned vector of object $o_i \in O$ in network $N(O, R, W)$. The equation 1 defines the function to be minimized to learn the new space $\mathbf{Z} \in \mathbb{R}^d$, in which all

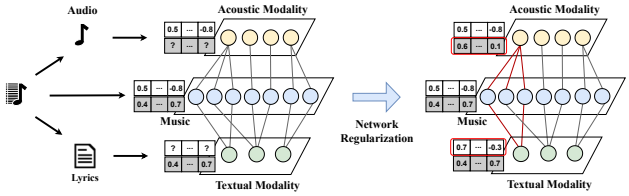

Figure 3: The heterogeneous network regularization aims to fill in missing modalities in objects. Objects on the central layer have relationships with objects on other layers. After regularization, all nodes receive information from neighbors nodes (highlights in red) with different modalities from the network topology.

heterogeneous network objects are mapped.

$$Q(\mathbf{Z}) = \frac{1}{2} \sum_{o_m \in O_M} \sum_{o_a \in O_A} w_{o_m,o_a} (\mathbf{z}_{o_m} - \mathbf{z}_{o_a})^2 + \frac{1}{2} \sum_{o_m \in O_M} \sum_{o_t \in O_T} w_{o_m,o_t} (\mathbf{z}_{o_m} - \mathbf{z}_{o_t})^2 + \mu \sum_{o_i \in O_X} (\mathbf{z}_{o_i} - \mathbf{x}_{o_i})^2 \quad (1)$$

The two initials terms of the regularization function are responsible for computing the proximity between the feature vectors for each pair of related objects in the network, indicating the weight of the relationship between the objects. The last term is responsible for computing the distance between the features of objects that had initial features, O_X, and the features learned in the space $\mathbf{Z}$. The parameter μ determines the level of preservation in the initial features. The high value indicates the more preservation of the features, while low values allow adjusting the features according to the network topology. The Equation (1) is applied for each modality, textual and acoustic. Therefore, at the end of the regularization process, we obtained Z_{audio} and Z_{text} for all nodes in the network. Finally, we concatenate both spaces, $Z_{\oplus} = Z_{audio} \oplus Z_{text}$.

3.3 Graph Convolutional Networks

The general idea of graph learning methods is to iteratively update object representations, combining them with representations of their neighbors. In this context, initially, the objects are represented by $Z_{\oplus}$ resulting from the regularization. The neighboring nodes are obtained from the heterogeneous network N, indicated by an adjacency matrix A. In particular, we used a GCN to learn the final representation and handle the MER task. The representation obtained by the GCN is represented by the matrix $F \in R^{T \times D}$, where T is the number of nodes and D is the dimension of the new unified space learned. In general, a GCN can be described according to Equation 2,

$$H^{(l+1)} = f(H^{(l)}, A) = \alpha(AH^{(l)}W^{(l)}) \quad (2)$$

where $H^{(0)} = X$, l, represents the current layer, A represents the adjacency matrix, $W^{(l)}$ represents the weight in l-th layer in a neural network, and $\alpha(.,.)$ defines the activation function. The layer $H^{(l+1)} = H^{(L)} = U$ contains the new learned space by GCN.

We pre-process the adjacency matrix A in the GCN. First, we need to add self-loops on each node to consider its features in the learning process. Then, we add A to identity matrix I, which result in $\hat{A}$. In addition, we normalize A to maintain the representation vectors scale in each layer. We did the matrix normalization by multiplying A with D^{-1}, where D indicates a diagonal matrix formed by the degrees of each node in the network, or A by $D^{-\frac{1}{2}}$, for symmetric normalization. Thus, the adjacency matrix used in the GCN is defined by Equation 3,

$$\hat{A} = D^{-\frac{1}{2}} S D^{-\frac{1}{2}} \quad (3)$$

where $S = A + I$, I represents the identity matrix, and $D_{ii} = \sum_j S_{ij}$ indicates the node degree.

The proposed GCN architecture comprises three graph convolutional layers combined with a hyperbolic tangent activation function. The dimensionality of vector input for each layer is indicated by the previous layer's output. The first layer receives the learned matrix $Z_{\oplus}$ to produce vectors with 512, 256, and 128 dimensions in next layers. Furthermore, we computed a softmax cross-entropy as the last layer to indicate the probability that each music is associated with emotion labels. Finally, we train the networks using the ADAM optimizer with a learning rate of 0.0001 and 3000 epochs.

4. EXPERIMENTS

Our experiments aim to evaluate the construction of a heterogeneous network to structure musical data and learn and evaluate a multi-modal graph-based representation in the music emotion recognition task. The k parameter defines the number of clusters used to connect objects in the heterogeneous network. This parameter is the main target of the analysis during network construction. The number of clusters allows us to create new connections between objects that initially have different labels, exploit regularization to propagate information and refine their representations.

We evaluated the representation learned with the GCN by comparing using two classifiers that utilize as input the representations formed by features provided in the dataset, including combinations between them. Finally, our results are relationships with similar works of literature. In all evaluation scenarios, our proposal presented the best results.

4.1 Dataset and features

The PMEmo is a popular music dataset with emotional annotations as a benchmark in music emotion retrieval and recognition [19]. PMEmo dataset containing emotion annotations of 794 songs in arousal and valence domains with audio and lyrics features. For acoustic features, PMEmo has a pre-computed vector composed of audio descriptors, which represent the music chorus information. In addition,

there are the lyrics and a source code for textual features to pre-process it and build the feature vector based on Bag-of-Words (BoW).

In addition to the representations of each modality, the authors of the PMEmo dataset [19] also presented competitive approaches that explore emotion classification based on fusion features, which were explored for comparison with our proposed method.

Besides these two representations, we build another textual feature on the lyrics using a pre-trained language model based on BERT models [1] fine-tuned to sentence similarity tasks, to have a more robust representation than the BoW. The model uses a triplet network structure to produce lyrics embeddings. Thus, we explored five strategies to represent the music that varies between isolated features and concatenation between them, as indicated in the PMEmo baseline scenario: `Audio`, `Bert`, `BoW`, `Audio+BoW`, `Audio+Bert`. Therefore, we have resources to build uni-modal and multi-modal scenarios to evaluate the emotion recognition task.

We have discretized the annotations in arousal and valence domains to transform the values in the labels, according to the works [42, 43]. First, we remove instances with missing information, and normalize the values of both domains with a range between 1 and 9. So, we assign the labels according to the values. An instance is negative if the normalized value is < 4.5; neutral if value $>= 4.5$ and < 5.5; or positive if value $>= 5.5$. The table 1 summarize the number of instances distributed for each label, as well as the dimensionality for all feature vectors.

Feature size	
Audio	6373
Bert	512
Bert	7670

Instances in each label		
	Arousal	Valence
Negative	151	145
Neutral	100	96
Positive	354	364
Total	605	

Table 1: Summary of dataset properties

4.2 Experimental setup

The representation learning with a GCN is done through a transductive process, where we need to know the complete dataset. As our goal is to recognize the emotions present in the music, we divided the dataset into stratified ten folds and masked the labels in test folds. As comparison approaches, we reproduce another transductive classification method based on label propagation (LPA). The instance labels in the test set are changed during the learning process and must converge to the original labels. We also reproduce an inductive scenario using a multilayer perceptron classifier (MLP). In this scenario, the test set is unknown, and the labels are predicted according to patterns learned during training [2]. In both scenarios, the features were normalized for each split according to train and test folds.

We evaluated a variation in the number of clusters that structure the objects represented by acoustic and textual features such that $k \in \{3, 7, 13, 20, 30\}$. The smallest value represents the original number of labels, while the largest value is defined by $\sqrt{N}$, where N indicates the samples in the dataset. We assume the hypothesis that by increasing the number of clusters, we can relate objects in the network with similar content but do not share the same label or objects that share a label and can be associated with objects with more similar content.

4.3 Results and discussions

We reported the mean and standard deviation for the F1-score and Accuracy metrics for each musical data representation strategy for the three evaluated methods. We refer to our representation as MRLGCN, an acronym for Music Representation Learning using GCN. Emotion labels are commonly explored in conjunction with text-based representations, so acoustic features are proposed to complement the representation. We can notice in Figure 4 that representations that concatenate both features do not lead to performance improvement. Observing the performance obtained by our approach, we can highlight the relevance of a learning process to incorporate the information of the different features.

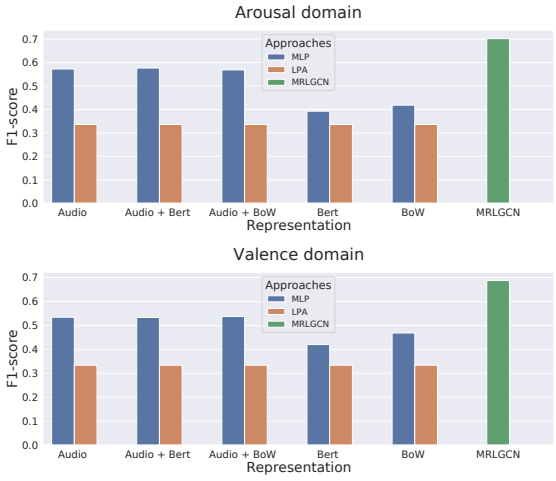

Figure 4: In the uni-modal scenario, textual features are more associated with emotion labels than acoustic features. In the multi-modal scenario, concatenating acoustic and lyrics features did not result in a more efficient representation, showing that exploring the semantic complementarity demands more robust strategies. Our representation presented the best result in both domains, evidencing the presence of relevant information in all the features used.

Figure 5 shows the results obtained by our method when the number k of clusters varies. We can notice that the performance of MRLGCN increases when k increases. It validates the hypothesis that we have objects with similar content that must be related, even those that do not share labels. Although it shows an upward trend, it is expected

[1] https://huggingface.co/sentence-transformers/distiluse-base-multilingual-cased-v1

[2] The LPA and MLP algorithms used are implementations available in the sklearn library using default parameters.

that the performance stabilizes and decreases after a certain k. This behavior is explained by the appearance of disconnected graphs that influence the regularization of the network, affecting the propagation of information between objects.

Clusters	F1-score		Accuracy	
	μ	σ	μ	σ
3	0.4530	0.096	0.6421	0.050
7	0.5231	0.087	0.6701	0.051
13	0.6010	0.107	0.7224	0.059
20	0.6612	0.120	0.7589	0.073
30	0.7018	0.131	0.7833	0.084

(a) Arousal domain

Clusters	F1-score		Accuracy	
	μ	σ	μ	σ
3	0.4820	0.089	0.6659	0.055
7	0.5300	0.099	0.6945	0.062
13	0.6095	0.127	0.7386	0.079
20	0.6399	0.137	0.7564	0.078
30	0.6873	0.151	0.7842	0.095

(b) Valence domain

Table 2: Results obtained with average (μ) and standard deviation (σ) for F1-score and accuracy metrics for each k value.

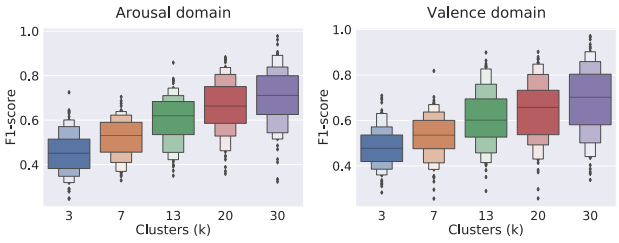

Figure 5: Performance in arousal and valence domains according to increase k value. The variation in the number of clusters highlights that the contents of the objects have similar relationships that may not be presented only by the label information.

Due to the unbalanced data distribution, we report a confusion matrix for each k to validate that the values presented for both metrics result from a learning process without bias towards the majority label. We can see that the increase in the metrics shown in Table 2 is accompanied by a proportional increase in the percentage of correct predictions for three labels, as seen in Figure 6.

5. CONCLUDING REMARKS

This work presents a new proposal to structure musical data using heterogeneous networks and build a graph-based multi-modal representation using Graph Convolutional Network to handle music emotion recognition tasks. We map acoustic and textual features as objects in different layers on a heterogeneous network, using cluster information to build relationships among objects, and insert a network regularization framework to propagate information between objects of other modalities. The embeddings

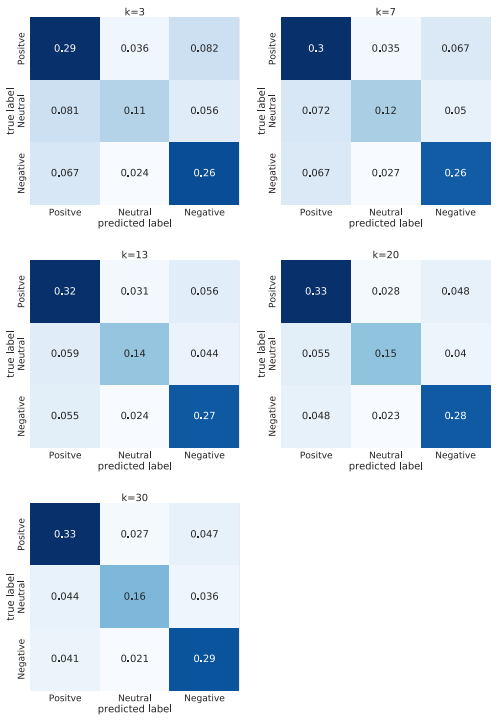

Figure 6: We highlighted the behavior of balanced growth of correct predictions across all labels, without bias for the majority label. This matrix evidences the learning process during the increase in the number of clusters.

resulting are used as input for GCN to learn a new music representation, with application in music emotion recognition task. Our proposal presented superior results in all evaluation scenarios and an significant improvement ratio concerning works in the literature. The results reinforce the applicability of graph-based representations in unstructured and multi-modal data.

Our proposal can be seen as a strategy that exploits a welcome trade-off for musical data representation. First, heterogeneous networks show explicit relationships between audio and text features and facilitate interpretability. Second, a GCN-based deep neural network learns embeddings that map the heterogeneous network into a promising representation for music emotion recognition.

In future work, we want to add other features as layers in the heterogeneous network and propose the inclusion of an importance matrix during representation learning. We will define criteria for determining optimal parameters for building the heterogeneous network and GCN architecture. In addition, we want to identify semantic relevance for each feature, measure the discriminative capacity's impact on learned representation, and evaluate the effect of the regularization step, like an ablation study. Finally, we can integrate the regularization process and GCN in an end-to-end framework for emotion music classification. The source code, datasets, and heterogeneous networks used in this paper are publicly available at `https://github.com/AngeloMendes/Heterogeneous-Graph-Neural-Network-for-Music-Emotion-Recognition`.

Papers - Session VI

AND WHAT IF TWO MUSICAL VERSIONS DON'T SHARE MELODY, HARMONY, RHYTHM, OR LYRICS ?

ABSTRACT

Version identification (VI) has seen substantial progress over the past few years. On the one hand, the introduction of the metric learning paradigm has favored the emergence of scalable yet accurate VI systems. On the other hand, using features focusing on specific aspects of musical pieces, such as melody, harmony, or lyrics, yielded interpretable and promising performances. In this work, we build upon these recent advances and propose a metric learning-based system systematically leveraging four dimensions commonly admitted to convey musical similarity between versions: melodic line, harmonic structure, rhythmic patterns, and lyrics. We describe our deliberately simple model architecture, and we show in particular that an approximated representation of the lyrics is an efficient proxy to discriminate between versions and non-versions. We then describe how these features complement each other and yield new state-of-the-art performances on two publicly available datasets. We finally suggest that a VI system using a combination of melodic, harmonic, rhythmic and lyrics features could theoretically reach the optimal performances obtainable on these datasets.

1. INTRODUCTION

The version identification (VI) problem has received much attention over the last two decades. Pioneering works showed promising accuracy on small audio datasets, but remained difficult to scale to larger modern audio corpora. The recent introduction of data-driven approaches based on neural networks led to significant progress towards accurate yet scalable VI systems [1].

Different paradigms are currently active: one approach considers VI as a classification task, and intends to classify versions into the same class [2], while another approach formulates VI as a metric learning problem, and intends to minimize (resp. maximize) a distance between versions (resp. non-versions) [3, 4]. Recent works have also proposed a combination of both [5]. Metric learning or classification approaches seem to yield similar performances, as it has been observed for other MIR applications [6]. These systems also differ according to a perhaps more important aspect: their input feature. Some use a generic audio representation, such as the Constant-Q transform [7], and rely on the expressivity of the network to disentangle relevant musical features. Others use specialized features, such as the melodic line, the harmonic structure and/or the lyrics, and rely on input data to discriminate between versions and non-versions [3, 4, 8, 9].

In this work, we pursue in the direction of a metric-based approach using specialized features. We build upon the system described in [8], conserving its principle and architecture, and explore the use of new input features. The reason is motivated by three practical considerations: firstly, the metric learning approach yields a very compact representation of audio (its embedding), which can be conveniently stored, indexed and queried in very large databases. Secondly, the embedding space and the musical similarity measure that is obtained for each different specialized features is meaningful from a musical perspective, and can be reused for other purposes, e.g. playlist generation. Thirdly, the use of specialized features requires smaller models that are faster to train and less energy consuming than larger architectures [10].

It can reasonably be assumed that different versions of the same musical work share at least one of these four features: the melodic line, the harmonic structure, the rhythmic patterns and sometimes the lyrics. The role of melody and harmony in version similarity has been thoroughly investigated [8]. The role of the lyrics has also been studied recently, albeit not from a metric learning perspective [9].

In this work, we present a systematic study of the contribution of these four features to version similarity, and describe a metric learning-based system combining all of them. We show that this combination provides new state-of-the-art performances on two publicly available datasets. We also show that an oracle using these feature embeddings nearly achieves the maximum theoretical performances on these datasets, suggesting that design of future VI systems reaching these performances may be possible.

The rest of this paper is organized as follows: we briefly review the previous studies inspiring our current work (Section 2). We then describe how we extracted rhythmic and lyrics features, and our metric learning-based architecture (Section 3). We present our experiments, discuss our results (Section 4), and illustrate them with some examples (Section 5). We conclude this paper with our future work.

2. RELATED WORK

In this section, we present a brief overview of the main concepts that inspired our present work.

2.1 Metric learning

Learning a similarity metric that generalizes to unseen examples is a common objective in machine learning. The goal is to learn how to map the data of interest into a compact representation (its embedding), and to minimize (resp. maximize) the distance between the embeddings of similar (resp. dissimilar) examples. Various MIR applications rely on a concept of musical similarity, e.g. music classification [11], music recommendation [12], or VI systems [1], among many others. Musical similarity between two tracks is typically evaluated first deriving an intermediate feature representation from the audio waveform and then computing a distance between feature pairs.

In the past few years, metric learning has proven its efficiency to build scalable yet accurate VI systems. These modern architectures typically rely on a CNN-based model trained with a triplet loss [13] to embed the musical information contained in the input feature into a single vector embedding that can be rapidly compared via Euclidean distance computation. However, these different systems have made different choices regarding their input features: for instance, Doras et al. [3] used a melodic line representation, Yesiler et al. [4] used a harmonic structure representation, and Du et al. [5] used a more generic CQT. The choice between specialized or generic features seems to have a non-negligible impact on the required size of the models (the former uses a 5-layers CNN, while the latter uses a ResNet50).

In this work, we choose the first alternative, and we propose to explore other specialized features beside melody and harmony, in particular the rhythmic and lyrics features.

2.2 Rhythm patterns detection

Musical similarity based on rhythmic patterns has long been investigated in MIR research, e.g. for audio retrieval [14] or music classification [15]. With the purpose of analysis of musical style and recognition of musical genres, Pampalk et al. introduced the fluctuation patterns (FP), representing rhythmic patterns in different frequency bands, and their evolution over time [16]. The basic assumption is that similar songs exhibit similar characteristic rhythmic patterns, and that comparing FP between tracks shall give enough information about their similarity or dissimilarity from a genre or mood perspective. We propose here to extend this idea to VI context, and to use the fluctuation patterns to discriminate versions from non-versions.

In practice, the FP is obtained computing the audio Mel spectrogram, summing up the high Mel bands to highlight the low frequencies and performing a second STFT in each mel band along the time axis. This results in a 3-dimensional matrix with axes corresponding to the the Mel bands, the frequency modulation and the time. The frequency modulation axis therefore represents the periodicity of the loudness in the corresponding Mel band: for example, a drum kick playing at 120 bpm will be represented here with a frequency modulation at 2 Hz in the low frequency bands. Finally, a perceptual filter is applied on each frequency modulation band. This filter is supposed to highlight the frequency modulations most perceived by the human ear ; for example, a frequency modulation at 4 Hz gives a more intense feeling of fluctuation strength. The 3-dimensional matrix is then averaged along the frequency axis, resulting in a representation of the variations of the frequency modulation over time.

One of the FP limitation is the use of a linear scale to represent periodicities. This was addressed by Pohle et al., who used a log scale to represent frequency modulations [17]. The advantage is that the same onset structure played at different tempi will have all its activations shifted by the same amount along the frequency modulation axis. Another way to achieve this tempo invariance is to compute periodicities with a Constant-Q transform (CQT) instead of a STFT [18].

2.3 Lyrics recognition

In automatic speech recognition (ASR), the traditional approach relies on a language model and an acoustic model, typically implemented as a Hidden Markov Model, possibly coupled with a neural network [19]. An alternative approach consists in implementing both language and acoustic models as a single neural network, trained in an end-to-end fashion with a Connectionist Temporal Classification (CTC) loss [20]. CTC-based models outputs the probability distribution of symbols at each time frame, which can be decoded into the most likely sequence of symbols via classical beam search. This approach has become very popular since fully convolutional end-to-end architectures have achieved performances comparable to those of the hybrid architectures [21].

Although singing voice has many obvious differences with speech, automatic lyrics recognition (ALR) or alignment (ALA) systems are usually directly inspired by ASR applications. Moreover, the recent introduction of large lyrics annotated audio datasets, such as Dali [22], has fostered the development of new ALR systems, whether they are based on the traditional [23] or end-to-end [24] architectures. While the former seems to yield better results [25], the latter has the advantage of its simplicity, both at training and inference time.

However, very few attempts have been made to use lyrics to assess audio track similarity. It was proposed to improve a query-by-humming system [26], but to the best of our knowlege, only Vaglio et al. proposed the use of lyrics for version identification [9]. They used an existing ALR system to extract lyrics from the audio, and estimate track similarity via a string matching algorithm. However, the comparison cost of such algorithm quickly becomes prohibitive when querying large modern corpora, and limits the scalability of this approach.

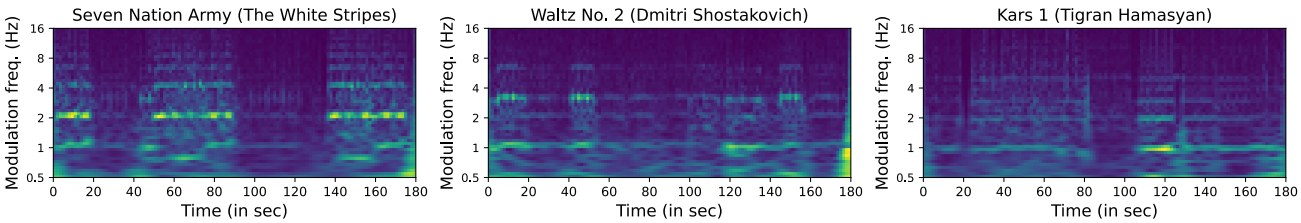

Figure 1: Examples of the Constant Q Fluctuation Patterns (CQFP).

3. PROPOSED METHOD

In this section, we describe and motivate our design choices. We first present how we extracted our rhythmic and lyrics features, and publicly release our datasets [1] . We then present our metric learning-based VI model.

3.1 Rhythmic features

Our assumption is that the FP representation described in Section 2.2 displays both the local rhythmic patterns along the frequency modulation axis, as well the global rhythmic evolution of the piece over time. We therefore propose to use this representation as our rhythmic feature for version identification. However, we introduce a CQT to compute the periodicities, and to achieve tempo invariance along the frequency modulation dimension. We choose as minimum frequency for the CQT 0.5 Hz (i.e. 30 bpm which we assume would be the tempo of the slowest tracks), and to cover up to 5 octaves i.e. 16Hz (960 bpm) with 10 bins per octave to get all the rhythmic subtleties. We kept the same other parameters as in the original implementation [16].

As an illustration, Figure 1 represents the CQ-FP obtained for different tracks with characteristic time signature. The first example has a 4/4 time signature, and clearly displays a rhythmic pattern present around 2 Hz (~120 bpm), as well as another periodicity around 4 Hz, which corresponds to a clear binary rhythm. The second example has a 3/4 time signature, and the rhythm of a waltz appears clearly: one beat at 1 Hz (60 bpm) and another at about 3 Hz. Finally, the third example has a 5/4 time signature (irregular), and we find this characteristic by observing bands at 1, 2 and 3 Hz. It can also be observed on each example that our rhythmic feature also represents the global structure of the piece over time, which is probably another relevant aspect in a VI context. Finally, as the modulation frequency dimension has a constant Q-factor, a change in tempo would not change the spacing between activations.

3.2 Lyrics features

We argue that accurate lyrics recognition is not required for version identification, and that identifying only a few common words, or even a few common character sequences, between tracks shall be sufficient to determine whether they are versions or not. We thus implemented a deliberately simple fully convolutional ALR system inspired by recent ASR system [21, 27].

[1] https://ircam-anasynth.github.io/papers/2022/abrassart

Model It is an 8-layers 2D-CNN with 3x3 kernels. Max-pooling 2x2 is applied on the first 2 layers to decrease time and frequency dimensions, and max-pooling 1x2 is applied on the next 6 layers only for frequency dimension. The first layer has 64 filters, doubled at each layer up to 512. A dropout with rate 0.3 is applied.

Inputs/outputs We use no pre-processing on the audio (no data augmentation, no voice separation). As classically done in ASR, we use 40 band Mel-spectrogram with 10ms timeframes as input feature. The model outputs a posteriorgram corresponding to the log-probabilities of the 'a...z' letters, the space symbol and the CTC blank symbol, i.e. 28 bins in total. An output example is shown Figure 2.

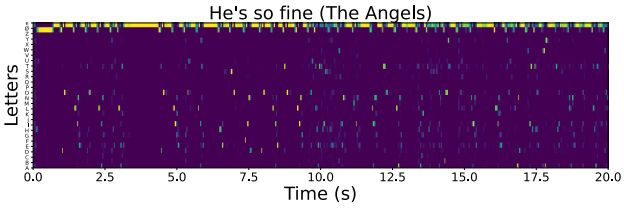

Figure 2: A posteriorgram obtained for 20 sec. of audio.

Training and inference The model is trained on the Dali dataset, which provide 12k+ polyphonic audio with lyrics annotations at the word level. We used audio chunks of 10 seconds, and used a CTC loss with Adam optimizer to train the model to align between audio and text. We evaluated its performances on a distinct Dali test subset using a greedy beam search decoding with no language model, and achieved a modest Character Error Rate (CER) of 0.496.

3.3 Convolutional architecture

The same simple architecture (with different configurations) has shown its ability to capture relevant melodic or harmonic similarity between versions [3,4]. It consists in a plain 5-layers Convolutional Neural Network (CNN), encoding each input feature using time and frequency max-pooling, while increasing the number of filters at each layer. The CNN output feeds a gated temporal attention mechanism [28], which was found to help the model to focus on relevant portions of the input features. We refer the reader to our previous work [8] for implementation details.

In this work, we keep the exact same generic architecture, and propose two new configurations to process also the rhythmic and lyrics features. We summarize the configuration used for each of the four features in Table 1.

Features	Melodic [3]						Harmonic [4]						Rhythmic						Lyrics					
Layers	n	k	ks	p	ps	d	n	k	ks	p	ps	d	n	k	ks	p	ps	d	n	k	ks	p	ps	d
1	64	3x3	1x1	2x2	2x2	0.0	256	180x12	1x1	1x12	1x1	0.0	64	3x20	1x1	1x2	1x2	0.4	64	10	1	5	2	0.3
2	128	3x3	1x1	2x2	2x2	0.1	256	5x1	1x1	1x1	1x1	0.0	128	3x3	1x1	1x2	1x2	0.3	128	10	1	5	2	0.2
3	256	3x3	1x1	2x2	2x2	0.1	256	5x1	1x1	1x1	1x1*	0.0	256	3x3	1x1	1x2	1x2	0.2	256	10	1	5	2	0.1
4	512	3x3	1x1	2x2	2x2	0.2	512	5x1	1x1	1x1	1x1	0.0	512	3x3	1x1	1x2	1x2	0.1	512	10	1	5	2	0.1
5	1024	3x3	1x1	2x2	2x2	0.3	512	5x1	1x1	1x1	1x1*	0.0	1024	3x3	1x1	1x2	1x2	0.0	1024	10	1	5	2	0.0

Table 1: Configuration of the 5-layers CNN used for the features. n : number of filters, k : kernel size, ks : kernel stride, p : pool size, ps : pool stride, d : dropout. 1st dimension is time, 2d dimension is frequency. Convolutions are "same" for Me, Rh and Ly, and "valid" for Ha. *Ha uses dilation rate of 20 and 13 along time dimension on 3^{rd} and 5^{th} layers respectively.

Rhythmic features Given the tempo invariance on the periodicity dimension explained in Section 3.1, the first layer has a 20 bins kernel on this axis to capture all patterns within 2 octaves (for instance quarter, eight and sixteenth notes). All other layers have 3x3 kernel with max-pooling of size 2 on the periodicity axis.

Lyrics features We conducted various experiments to find the best kernel size to apply to the lyrics. It appeared that a rather short receptive field of 10 bins yield the best results. We kept it for all layers, with a mean-pooling of size 5.

Finally, a dense layer applied after the temporal attention block outputs a 512 bins embeddings, L2-normalized so that each track becomes a point on the surface of the unit hypersphere, bounding the distance between 2 points within the [0,2] interval.

3.4 Embedding concatenation

In this work, we investigated only a late embedding fusion scheme, which simply consists in concatenating each feature embedding, and to L2-normalize the concatenated result. It is straightforward to show that the distance between a pair of normalized concatenation of n feature embeddings is the quadratic mean of the n distances between each feature embedding pair. All feature combination scores in Section 4 have been obtained using this method.

The practical advantage of this simple concatenated embedding is twofold: it remains easy to store and to query in an large index, and the lookup can be done for some specific feature combinations only (zero masking the unwanted feature embeddings).

4. EXPERIMENT AND RESULTS

In this section, we present our experimental setup and results. For brevity, we will denote melodic, harmonic, rhythmic and lyrics features by their abbreviations Me, Ha, Rh, and Ly, respectively.

4.1 Experimental setup

We use the exact same protocol as in our previous work [8].

Training We trained our four models on the publicly available dataset SHS_{5+} [1], which contains ~62k covers of ~7.5k works. We used the provided features for Me and Ha, and extracted Rh and Ly from the audio, as described in sections 3.1 and 3.2. We used a semi-hard triplet loss, using an Adam optimizer, an initial learning rate of $1e^{-4}$ and a batch size of 64. All other details are replicated from [8].

Test We tested our four models on SHS_{4-} [1], containing ~50k covers of ~20k works. We also retrained models on $SHS_{5+/4-}$ and tested on Da-Tacos [2], containing 13k covers of 1k works and 2k confusing tracks [29]. As some samples overlap between Da-Tacos, SHS_{4-} and Dali, we made sure that none of these samples were used for scoring the models, as done in [5].

For each feature, we used the corresponding trained model to compute each track embedding, and computed their pairwise distance matrix. For feature combinations, distance matrix is computed using the quadratic mean of each feature distance matrix, as described in Section 3.4.

4.2 Results

We summarize in Table 2 the performances obtained on SHS_{4-} and Da-Tacos by our models, reporting the metrics classically used for VI: Mean Average Precison (MAP), mean number of correct answers in the first 10 (MT@10) and mean rank of first correct answer (MR1).

Train set	SHS_{5+}			Pruned $SHS_{5+/4-}$		
Test set	Pruned SHS_{4-}			Pruned Da-Tacos		
Input feature	MAP	MT@10	MR1	MAP	MT@10	MR1
Me	0.427	0.822	1131	0.363	4.064	97
Ha	0.538	1.003	982	**0.488**	**5.256**	**63**
Rh	0.099	0.231	2921	0.055	0.689	244
Ly	**0.672**	**1.190**	**968**	0.393	4.596	199
Me+Ha	0.693	1.256	453	**0.626**	**6.668**	**32**
Me+Ha+Ly	**0.800**	**1.396**	291	0.602	6.480	33
Me+Ha+Rh	0.688	1.250	413	0.557	5.994	33
Me+Ha+Rh+Ly	0.785	1.378	**286**	0.560	6.054	33
Me+Ha (O)	0.879	1.521	97	0.837	8.709	4
Me+Ha+Rh (O)	0.939	1.607	21	0.905	9.303	**1**
Me+Ha+Ly (O)	**0.963**	**1.637**	**14**	**0.918**	**9.398**	**1**
Me+Ha+Rh+Ly (O)	**0.978**	**1.658**	**4**	**0.951**	**9.657**	**1**

Table 2: Performance metrics obtained on SHS_{4-} and Da-Tacos for input features and their combinations. O=oracle

We first examine the performances of each single feature. Me and Ha results are in line with our previous work [8].

Rhythmic features The performances obtained using Rh are clearly lower, which suggests that our rhythm feature is not providing relevant VI information, or that the rhythm patterns themselves are not specific enough to discriminate between versions and non-versions. As a consequence, adding Rh degrades our Me+Ha baseline. This is not entirely surprising, as many non-versions might exhibit similar rhythmic patterns (we will however see in Section 4.3 and Section 5 that Rh can be relevant in some cases).

[2] https://github.com/MTG/da-tacos

Lyrics features In contrast, the use of lyrics clearly outperforms the other features on SHS_{4-}. This confirms that versions often share the same lyrics, and that even a very inaccurate ALR system can be beneficial to VI. The combination Me+Ha+Ly improves by more than 10% the Me+Ha performances, which will be explained in Section 5.1.

On Da-Tacos, we observe much less clear-cut results. As already noticed by Vaglio et al. [30], Da-Tacos has about 20% of instrumental songs. A closer look to our results shows that these songs typically produce false positives. Following Vaglio et al., we pruned the instrumental songs from Da-Tacos, and recomputed the results for Ly, obtaining MAP=0.674, MT@10=5.931 and MR1=59, which is consistent with the values obtained for SHS_{4-}.

4.3 Oracle results

We also present in Table 2 the results obtained by an oracle. This oracle only considers the best performing feature to compute each pairwise distance: for each pair of tracks, it only uses the feature embeddings yielding the lowest (resp. highest) distance for versions (resp. non-versions).

Interestingly, it appears that the performances of an oracle using three or four features approaches the theoretical optimal values on our two datasets. This is particularly clear with the Me+Ha+Ly and Me+Ha+Rh+Ly combinations: the MAP tends to 1.0, i.e. most versions have been ranked in the first answers for each query. The MR1 also tends to 1, i.e. first answer is correct for most queries. The MT@10 also tends to the theoretical optimal values (in SHS_{4-}, each track has 2, 3 or 4 versions, and its optimal MT@10=1.695, while in Da-Tacos, each track has 0 or 12 versions, and its optimal MT@10=10).

The Figure 3 displays the contribution of each feature to the oracle score, i.e. which feature is the most relevant to determine if two tracks are versions ("Positive pairs") or non-versions ("Negative pairs").

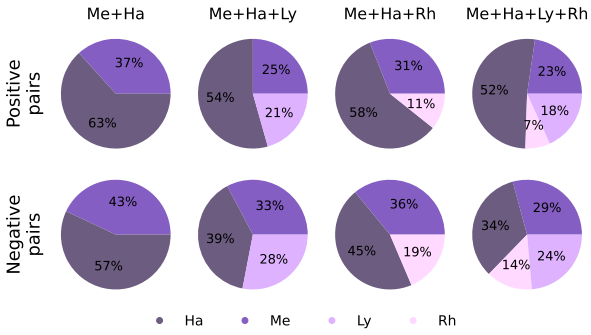

Figure 3: Most relevant feature proportions to identify positive and negative pairs on SHS_{4-}.

It appears that Ha is usually the most efficient feature to discriminate between versions or non-versions. However, both Me and Ly contribute importantly to identification (e.g. resp. 25% and 21% of the positive pairs, 33% and 28% of the negative pairs in the Me+Ha+Ly combination). Finally, and even though Rh alone yields poor results, its contribution is not negligible when combined with other features (e.g. 14% of the negative pairs in the Me+Ha+Rh+Ly combination).

4.4 Comparison with state-of-the-art

Performances obtained by recent VI systems are summarized in Table 3 (second column indicates the embedding size used by each system).

Our system using Me+Ha+Ly improves the state-of-the-art on SHS_{4-} and on Da-Tacos (without instrumentals).

Test set		SHS_{4-}			Da-Tacos		
Model	Emb.	MAP	MT@10	MR1	MAP	MT@10	MR1
Doras et al. [8]	512	0.660	1.080	657	0.635	6.744	30
Vaglio et al. [30]	n/a	n/a	n/a	n/a	0.804*	n/a	n/a
Du et al. [5]	1536	n/a	n/a	n/a	**0.791**	n/a	**19.2**
Me+Ha+Ly (ours)	1536	**0.800**	**1.396**	**291**	**0.818***	**7.205***	**16***
					0.602	6.480	33

5. QUALITATIVE ANALYSIS

In this section, we illustrate qualitatively the previous quantitative results. We encourage readers to listen to the audio samples available on the paper companion website [1] as part of reading the paper.

5.1 Ly vs. Me+Ha examples

We intend here to illustrate how Ly improves the Me+Ha system. Figure 4 plots the distance obtained for Me+Ha and Ly between randomly sampled positive (green) and negative (red) pairs.

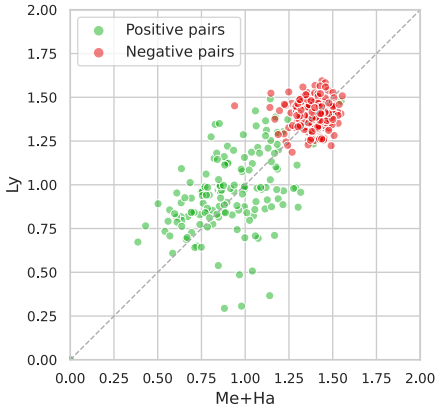

Figure 4: Pairwise distances for Me+Ha vs. Ly (500 pairs from SHS_{4-}).

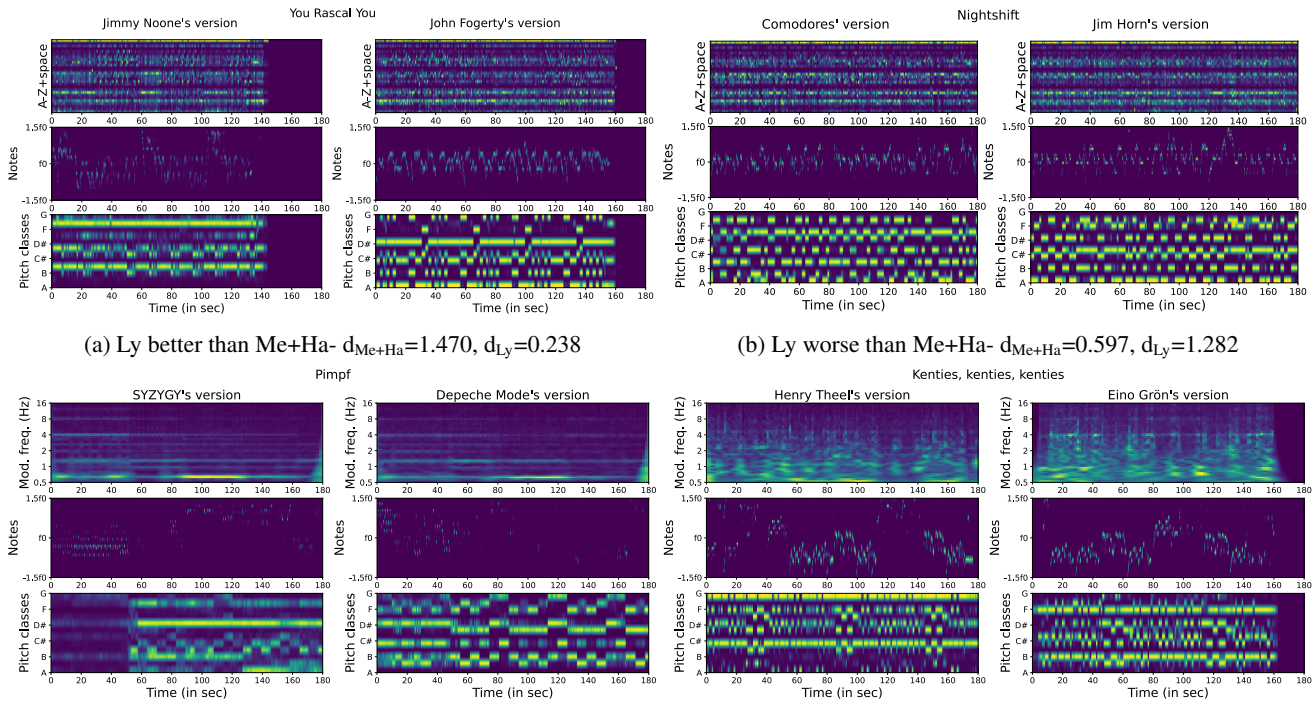
This plot confirms that Me+Ha and Ly are complementary, as already seen in Section 4.3. The dots situated away from the diagonal correspond to track pairs scored correctly by Me+Ha and incorrectly by Ly (or vice-versa). As certain features yield better results for certain songs, their combination will statistically improve the results, as we will now illustrate with some contrasted examples.

Ly > Me+Ha There are many versions whose musical style, melody and harmony differ greatly from the original, and where only the lyrics can help to identify them. This is illustrated on Figure 5(a), which shows that the Jimmy Noone's and John Fogerty's versions of "You Rascal You" are very different musically while the lyrics exhibit enough similarity to be correctly identified.



(a) Ly better than Me+Ha- d_{Me+Ha}=1.470, d_{Ly}=0.238

(b) Ly worse than Me+Ha- d_{Me+Ha}=0.597, d_{Ly}=1.282

(c) Rh better than Me+Ha - d_{Me+Ha}=1.084, d_{Rh}=0.459

(d) Rh worse than Me+Ha - d_{Me+Ha}=0.498, d_{Rh}=1.380

Figure 5: Examples for rhythm and lyrics : Rh > Me+Ha 5(c), Rh < Me+Ha 5(d), Ly > Me+Ha 5(a) and Ly < Me+Ha 5(b)

It also appears that our approximated ALR system is efficient for different languages. For instance, the versions of Asta Kask and of The Hep Stars of the song "I natt jag drömde", are very different in melody and harmony (d_{Me+Ha}=1.448) while the lyrics remain similar (d_{Ly}=0.342), despite the fact that the lyrics are in Swedish.

Ly < Me+Ha As already mentioned, using Ly will yield wrong results in presence of instrumental version (i.e. no lyrics). In the example shown in Figure 5(b), the version of "Nightshift" by the Commodores has lyrics while the one of Jim Horn's does not. We noticed that the system sometimes considers lead instruments as voices. However, this Ly false negative is correctly caught by the Me+Ha.

5.2 Rh vs. Me+Ha examples

Although less obvious than for Ly, combining Rh and Me+Ha also appears to be complementary in some cases.

Rh > Me+Ha Even though Rh yields poor performances in general, there are cases where it is the only feature available to identify versions. This is illustrated on Figure 5(c), which shows the Rh, Me and Ha features for two versions of "Pimpf". In this song, the melody is almost non-existent, and the harmony is very different between both versions. Only a few bass notes in the middle are salient enough to identify the song, and this short bassline appears similarly on the two FP features.

Rh might also be a good discriminating feature in other cases, e.g. for live concert versions. One version of "Mama's Little Baby" is recorded in studio while the other is a concert filmed from the audience. The Me+Ha distance between these versions is high (d_{Me+Ha}=1.329) because of the bad live recording quality. But, the drums are distinguishable enough to find similarity (d_{Rh}=0.714).

Rh < Me+Ha But Rh often yields wrong results. This is illustrated on Figure 5(d), which shows the features of two versions of "Kenties kenties kenties". Although melody and harmony are similar, the rhythm is very different, and the use of Rh produces a false negative.

6. CONCLUSION

It was shown previously that VI systems combining melody and harmony yields promising performances. In this paper, we proposed to consider also rhythmic and lyrics features to improve these results further. We showed that an existing rhythmic feature commonly used for genre classification is only helpful in a few cases, such as live version identification. But we also showed that an approximate lyrics representation can improve the performances of existing melody and harmony-based systems. We explained these results by the fact that detecting correctly only a few character sequences appears to be enough to distinguish versions and non-versions. We showed that our system combining these features establishes new state-of-the-art on two public datasets. More importantly, we indicated that these feature combinations provide enough information to approach the theoretical optimal performances obtainable on these datasets.

In our future work, we will investigate a more elaborated fusion scheme in order to train our model to behave as an oracle: our objective is to teach the system how to choose between available features to pick only the most relevant one for each pair of tracks. This might answer the question of whether the concept of musical version can be reduced to its melodic, harmonic, rhythmic, and lyrics dimensions.

7. ACKNOWLEGMENTS

Authors would like to thank the anonymous reviewers for their helpful comments, and for suggesting the Figure 3.

ABSTRACT

Notable progress in music source separation has been achieved using multi-branch networks that operate on both temporal and spectral domains. However, such networks tend to be complex and heavy-weighted. In this work, we tackle the task of singing voice extraction from polyphonic music signals in an end-to-end manner using an approach inspired by the training and sampling process of denoising diffusion models. We perform unconditional signal modelling to gradually convert an input mixture signal to the corresponding singing voice or accompaniment. We use fewer parameters than the state-of-the-art models while operating on the waveform domain, bypassing the phase estimation problem. More concisely, we train a non-causal WaveNet using a diffusion-inspired strategy while improving the said network for singing voice extraction and obtaining performance comparable to the end-to-end state-of-the-art on MUSDB18. We further report results on a non-MUSDB-overlapping version of MedleyDB and the multi-track audio of Saraga Carnatic showing good generalization, and run perceptual tests of our approach. Code, models, and audio examples are made available. [1]

1. INTRODUCTION

Singing voice extraction, which involves separating the vocal source from music recording mixtures, has received a lot of attention from the Audio Signal Processing (ASP) and Music Information Retrieval (MIR) communities in the recent years. The problem can be modelled in the waveform domain [1–4], the frequency domain [5–7], or a combination of both [8–10]. In general, spectrogram-based approaches have been more popular despite having to deal with the problem of the complex phase, usually leading to artifacts or unnaturalness of the separated sources. Within the Music Demixing Challenge (MDX) framed in ISMIR 2021 [11], diverse submissions achieved state-of-the-art source separation performance, in the majority of cases being multi-branch networks combining features from both time and frequency domains [8–10], proposing therefore solutions to account for the problem with the phase. Nonetheless, these models tend to be heavy-weighted and include engineered strategies to improve the predicted outputs.

While the problem of source separation has been shown to be challenging on the waveform domain, promising results have been reported [2, 3, 12], opening the door for the development of models that bypass the problem with the complex phase. However, as the performance improves, the model size and complexity accordingly grow.

In this work we propose a training and sampling strategy inspired on the recently emerged denoising diffusion models [13] to perform end-to-end singing voice extraction. Denoising diffusion models are a novel class of generative models theoretically grounded in the non-equilibrium statistical physics that can gradually convert one distribution into another using a Markov chain [14], while learning to perform the reverse process. More concisely, numerous works use diffusion models to convert a signal from a particular data distribution to a simple one (e.g. isotropic Gaussian noise) by gradually adding samples of the said simple distribution. Subsequently, the model is trained to reverse the perturbation process and generate data samples of the original distribution using the easily tractable noise as input [15–17]. Diffusion models have recently emerged as a versatile and high-performance method for data generation, outperforming classical generative approaches for the task of image generation [13]. In the fields of ASP and MIR, diffusion models have also shown promising performance for speech synthesis [16, 18], speech restoration and enhancement [13, 15, 19–21], audio super-resolution [22], singing voice synthesis [23], and symbolic music generation [24]. Despite that, the literature does not include many attempts to use diffusion models for source separation, being [25], to the best of our knowledge, the only attempt.

Despite the use of deterministic signals as diffusion perturbation in place of Gaussian noise has shown promising results in reverting different arbitrary types of image noise and performing image morphing [26], to the best of our knowledge, no exploration of this idea in the audio domain has been reported to date. In this work, we build on top of DiffWave, a versatile diffusion model for speech synthesis [16] that is based on a non-causal WaveNet architecture that has been previously used for music source separation [12]. We introduce an end-to-end approach to model

the task of singing voice extraction as a diffusion-alike process, by converting between two audio data distributions that share similar content, in this case the singing voice and the corresponding mixture. We propose to use a deterministic diffusion perturbation, a music mixture, to gradually transform its corresponding isolated singing voice into the mixture while learning to conduct the reverse process at inference. Given the formulation of the diffusion process, we train a model that learns to estimate the perturbation at different ratios. Subsequently, we leverage from the parametrization of the reverse process of diffusion models to chain these estimations and sample, given an input mixture, improved vocal source separation in terms of artifacts and interferences compared to the vanilla trained network.

2. METHOD

2.1 Diffusion process

We assume that the waveform-domain signal corresponding to the mixture m is the sum of the singing voice v and the accompaniment a, such as: $m = v + a$. Our goal is to estimate v given m. In the following sections we formalize our method by relating it with the diffusion theory in the literature. In Figure 1 we display the two main steps of our method: the diffusion and the reverse process.

Diffusion. The diffusion process assumes perturbing the training data with different scales of noise iteratively following a Markov chain [13]:

$$q(x_1, ..., x_T|x_0) = \prod_{t=1}^{T} q(x_t|x_{t-1}) \tag{1}$$

The input signal x_0 is gradually perturbed by incrementally adding a particular signal in small T diffusion steps. This process results into a latent variable x_T of same distribution of the perturbation. The standard diffusion schema, introduced in [13] and subsequently used in most of the diffusion research, perturbs x_0 with random Gaussian noise, therefore x_T is an isotropic Gaussian noise distribution. In our case, the input signal x_0 is initialized with the isolated singing voice v, and perturbed by incrementally adding the mixture m. This results in x_T being a mixture-alike signal, containing both voice and accompaniment. Therefore, $q(x_t|x_{t-1})$ in Eq. 1 is an operation to add a small amount of perturbation m to the given signal x_{t-1}, moving to the next diffusion step x_t. We use m as perturbation to account for the formal diffusion design in [13], in which the latent variable x_T is expected to belong to the same data distribution as the perturbing noise. The level of perturbation at each diffusion step is controlled by β_t, which is a small positive coefficient within a fixed noise schedule denoted β. That said, using the parametrization proposed in [13], we can compute any given diffusion step using:

$$q(x_t|x_0) = \sqrt{\bar{\alpha}_t}x_0 + \sqrt{1 - \bar{\alpha}_t}m \tag{2}$$

where $\alpha_t = 1 - \beta_t$ and $\bar{\alpha}_t = \prod_{s=1}^{t} \alpha_s$. Note also that the most common inference input of a singing voice extraction model – which in our case is x_T – is a mixture. Given Eq. 2, the perturbation is a mixture m to ensure $x_T \approx m$, otherwise the said condition may not be given.

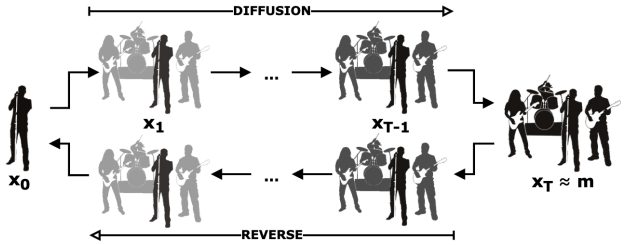

Figure 1. Overview of our diffusion-inspired training approach for the case of singing voice extraction.

Modelling musical signals using a mixture of Gaussian functions has been previously explored in [27]. Note also that architectures similar to DiffWave have been already used to model mixture, accompaniment, and vocal signals [12, 28] (for further detail see Section 2.2).

Reverse process. The reverse process aims at iteratively reverting the perturbation added by the diffusion:

$$p_\theta(x_0, ..., x_{T-1}|m) = \prod_{t=1}^{T} p_\theta(x_{t-1}|x_t) \tag{3}$$

We propose to parameterize the variable $p_\theta(x_{t-1}|x_t)$ as $\left(x_t - \frac{1-\alpha_t}{\sqrt{1-\bar{\alpha}_t}}\epsilon(x_t, t)\right)\frac{1}{\sqrt{\alpha_t}}$, being $\epsilon(x_t, t)$ the perturbation estimated by the model at a given diffusion step t. This parametrization is leveraged from the diffusion sampling process in [13]. However, we remove the deviation parameter from the original parametrization, which in our deterministic noise case yields worse predictions. This process can be seen as an iterative refinement of the latent variable x_T to convert it to x_0, in our case to iteratively transform an input mixture to its corresponding singing voice source.

Training. The training objective of the original diffusion process is to maximize the log likelihood of: $p_\theta(x_0) = \int p_\theta(x_0, ..., x_{T-1}|x_T)p_{latent}(x_T)dx_{1:T}$ [13], considering stochastic noise as perturbation. Since in this context it is not possible to calculate the said integral, in the literature this problem is approached by maximizing its variational lower bound (ELBO) [13]. The reader is referred to [16], for a detailed development of this maximization. In our case, relying on the ELBO is not required given the deterministic perturbation. Therefore, by using pairs of (x_t, x_0) [13], and referring to Eq. 2, we are able to effectively optimize the model with parameters θ using the following objective [13]:

$$L(\theta) = \left\|\epsilon - \epsilon_\theta(\sqrt{\bar{\alpha}_t}x_0 + \sqrt{1 - \bar{\alpha}_t}m, t))\right\|^2 \tag{4}$$

where ϵ is the target or true perturbation, whereas ϵ_θ is the perturbation the model estimates based on $\bar{\alpha}, t$, the mixture m and the input x_0. In the case of extracting the singing voice, we use the accompaniment a instead of mixture m as the target corresponding to ϵ. Therefore, we do not include the voice into the target of the training process, thus we alleviate the loss of vocal quality that may occur after several reverse steps.

Noise schedule. Choosing the noise schedule β has been found to be crucial for the performance of diffusion models [13] [2] and in fact, efforts have been done to learn said variable instead of defining it manually [29]. In our scenario, we require a schedule β that accounts for the proposed diffusion-inspired approach, in which x_0 is expected to be predominant in the completely perturbed signal x_T. Moreover, our perturbation m is the mixture corresponding to x_0, thus x_0 is contained in the perturbation, which may lead to an abnormally over-loud source in the completely diffused x_T. Ultimately, the inference input is a mixture, therefore we propose to use a schedule that produces a latent variable x_T as close as possible to an actual mixture.

Our noise schedule is defined by $\beta_0 = 1^{-4}$, $\beta_T = 0.2$, and $T = 20$, being 20 a reliable option for audio as found in [16]. This noise schedule produces $q(x_T|x_0) \approx m$, and we denote it β_{20}. Note that the closer β_T to 1, we should expect a more aggressive transformation, leading to less interference at the expense of losing quality of the estimated source. Recent diffusion-based works in the audio domain successfully model their task using 4–8 steps [21]. To study the effect of the number of diffusion steps and explore the feasibility of modelling the task with less computational expense, we experiment with a new schedule β_8, which is defined by $\beta_0 = 1^{-4}$, $\beta_T = 0.5$, and $T = 8$.

Accompaniment estimation. To perform accompaniment estimation we initialize x_0 to be the musical accompaniment a, while the singing voice v is the target ϵ for training in Eq. 4, and we adjust β. Since usually the accompaniment is a mixture of multiple sources, and the singing voice – now the perturbation – is normally predominant, we may increase the number of diffusion steps to 100 in the schedule and experiment with a more granular reverse process. The other parameters remain unchanged.

2.2 Network details

We propose to use the unconditional vanilla DiffWave to learn the reverse process [16]. Although recent works in music separation propose various improvements with regards to the architectures used, in this work we focus on exploring a novel diffusion-inspired process for source separation. At the same time, we aim at improving a smaller model that has been previously applied for source separation using our diffusion-inspired training and sampling method, while leaving the improvements on the network, or using a different architecture, as future work. Nonetheless, we consider the versatility and light weight of the entire method an advantage. Note that within the scope of this paper, we perform monaural source separation.

Architecture. The DiffWave architecture is based on a modified WaveNet [30] extended with bidirectional dilated convolution modules (Bi-DilConv), aiming at removing the autoregressive generation constraint so that the model is non-causal and the reverse process is done in T steps. The said Bi-DilConv modules have been previously applied for the problem of music source separation [12, 28]. The used non-causal WaveNet consists of a stack of L residual layers, which are equally grouped into N blocks. Therefore, each block includes L/N layers with skip-connections as the original WaveNet. A Bi-DilConv module with kernel-size 3 is included in each layer. The size of the dilation, initialized at 1, is doubled at each layer of a block: $[1, 2, 4, 8, ..., 2^{L/N} - 1]$. Before going through the stacked blocks, the input is projected using a 1D convolutional layer of C channels of features. Similarly to the original WaveNet, the output is obtained by summing the skip connections of all the residual blocks. For our experiments we configure the WaveNet architecture with $L = 30$, $N = 10$, and $C = 64$, which in [16] is found to effectively work while preserving the light weight of the architecture.

Diffusion step embedding. Since the training process is based on optimizing Eq. 4 given a pair (x_t, x_0), we need to input the diffusion step t to the model. We use a 128-dimension encoding vector for each t [16], defined as [31]:

$$t_{embed} = \Big[sin\left(10^{\frac{0*F}{S-1}}t\right),\ ...,\ sin\left(10^{\frac{(S-1)*f}{S-1}}t\right),\\ cos\left(10^{\frac{0*F}{S-1}}t\right),\ ...,\ cos\left(10^{\frac{(S-1)*F}{S-1}}t\right)\Big] \quad (5)$$

where F is the embedding factor and S is half the embedding size. Note that F and S are pre-defined and fixed hyperparameters, which in our experimentation are set to $F = 4$ and $S = 64$. Next, the embedded diffusion step is passed through three dense layers, the first two having size $S * 2$, while the latter maps the latent embedding into the C channels the input is projected to, therefore we can add the embedding to the input of each residual layer.

Conditioning. Using a vocoder paradigm, diffusion-based approaches for audio modelling usually use conditioning to guide the signal generation, providing clues to obtain a particular desired output. Audio-related diffusion works in the literature propose to guide the signal generation using, for instance, mel-spectrogram [16, 32] or linguistic features [33]. We do not condition our network for three reasons: **(1)** Conditioning our vocal extraction model, for instance on the mel-spectrogram of the target vocal signal, would probably improve the output quality, however the task of source separation assumes that data of this kind is not available at inference, **(2)** Our latent variable x_T is not an isotropic Gaussian but a known mixture recording containing the target signal, therefore it serves as a conditioner to guide the transformation towards the isolated singing voice, **(3)** We reduce the model size.

2.3 Post-processing

To account for a possible over-increase of the signal amplitude during the reverse process, the output of said process is clamped to the amplitude levels of the input mixture.

During the iterative signal transformation at inference we may generate audio content and artifacts not contained in the original vocal signal. Although not perceptually significant, these artifacts are heavily penalized by objective evaluation metrics [34]. Moreover, the iterative nature of the algorithm may accumulate several of the said artifacts

[2] Despite being aware that our perturbation is a deterministic signal instead of stochastic noise, we still use the term noise schedule in this work for easier understanding in relation with cited works.

in the final prediction. As an optional step, we use the multichannel Wiener filter to improve our separation, a well-known process used in numerous source separation works [35]. We use the Python version in `norbert` [36].

Since our model operates in an end-to-end manner, we use the following procedure to apply the Wiener filtering. Let $\hat{v}$ be an estimated vocal source and $\hat{a}$ the corresponding estimated musical accompaniment. The inputs of the Wiener process are the Short-Time Fourier Transform (STFT) of the input mixture m, and the magnitude STFT of both $\hat{v}$ and $\hat{a}$ estimates. The outputs of the Wiener process are the filtered complex spectrograms for $\hat{v}$ and $\hat{a}$. We take the magnitude of said spectrograms and combine it with the corresponding phases $\phi(\hat{v})$ and $\phi(\hat{a})$ that our proposed model estimates. In that sense, we do not use the Wiener filtering to estimate the phase as typically done for spectrogram-based approaches that cannot estimate such complex target, but refine our estimation using the Expectation-Maximization algorithm [37] to make sure that the predicted signal is contained in the input mixture.

3. RELATION WITH PREVIOUS WORK

The literature on waveform-based singing voice extraction is mainly based on encoder/decoder architectures, with the non-causal adaptation of WaveNet [12, 30] as the only exception. Wave-U-Net [3] is an autoencoder inspired by its spectrogram-based counterpart U-Net [7], while ConvTas-Net [2, 4] estimates prediction masks in the mid-point of the network. The leading model is Demucs, now available in two versions v1 [1] and v2 [2], which is also a convolutional autoencoder with a bidirectional LSTM in the bottleneck. There is a growing tendency on the size of the above-mentioned models, while all use similar, standard training procedures. In contrast, we focus on the training strategy and propose a diffusion-inspired approach for a light-weight model. Building on top of DiffWave, we train a non-causal WaveNet very similar to the one used for music source separation [30], differing only on the number of residual layers, the output projection (since WaveNet in [30] estimates multiple targets while in DiffWave the target is only the added perturbation by the diffusion process), and the additional diffusion step embedding.

Our work has common aspects with [39], in which a novel training strategy is built on top of Demucs (v2) by modelling and learning the dependencies between target sources, and adding an iterative refinement at the output using a Gibbs sampling process. Contrastingly, we use a diffusion-inspired algorithm to train a smaller baseline model for source separation, not to directly estimate the target sources but to gradually transform a mixture signal into its corresponding singing voice.

The literature of diffusion-related approaches for music source separation is scarce. In [25], an improved reverse process based on Langevin dynamics is proposed and applied to several autoregressive models, including WaveNet, which shows competitive performance on separating the vocals from a piano accompaniment. However no experiments on MUSDB18 [40] are reported.

4. EXPERIMENTS

4.1 Experimental setup

We include the following models in our experiments: **(1)** Singing voice extraction model with different noise schedules: β_{20} and β_8 and β_1, **(2)** Singing voice extraction model with β_{20} and Wiener filtering, using the accompaniment obtained by subtracting the estimated vocals $\hat{v}$ from the input mixture m, **(3)** Accompaniment extraction model with β_{100}, **(4)** Combination of singing voice extraction model with β_{20} and accompaniment extraction model with β_{100} using Wiener filtering. For the experiments we use ADAM optimizer with learning rate of 2^{-4} and batch size of 8. The models are first trained for 200k steps and next, we keep training while evaluating the performance using BSS Eval [41] repeatedly when ≈ 500 training steps are completed, storing the model that performs the best on the validation set, until 500k steps.

We use the MUSDB18 dataset [40] for training. The accompaniment is computed as the linear sum of the *bass*, *drums*, and *other* sources as represented in the dataset. To train the models we first split the tracks in MUSDB18 in chunks of 4 seconds to optimize the training process and obtain more variate data batches along the training steps. We do not disregard the unvoiced samples, aiming at improving the estimation on vocal silences [28].

For a comparison with the state-of-the-art, our models are evaluated on the test set of MUSDB18, using the standardized metrics for source separation (Signal-to-Distortion Ratio or SDR, Signal-to-Interference Ratio or SIR, and Signal-to-Artifact Ratio or SAR) [42]. We use the BSS Eval implementation and the evaluation setup from the SiSEC challenge [41], using window and hop sizes of 1 second, and subsequently computing the median over all the 1-second estimations of each song. We finally report the median over the entire MUSDB18 testing tracks. We compare our approach with the waveform-based state-of-the-art: WaveNet, Wave-U-Net, ConvTas-Net and Demucs v1 and v2. We report the metrics that the best versions of these methods obtain on the testing set of MUSDB18 [41]. For WaveNet we consider the best performing configuration in [28], and for ConvTas-Net the music source separation version proposed in [2].

Being aware of the possible biases that might occur if training and evaluating on data from the same distribution, even if the splits are properly differentiated, we consider two additional testing sets: (1) A non-MUSDB-overlapping version of MedleyDB [43], in which we remove the 46 overlapping tracks between MedleyDB and MUSDB18 [44] disregarding also the tracks from shared artists between the two even if the track is not present in both, and (2) A manually-cleaned subset of the multi-track audio of the Saraga Carnatic dataset [45] (ground-truth accompaniment is not available). The track list of both datasets is made available in the accompanying repository.

The objective metrics in [41] are not always correlated with the scores from perceptual evaluations of music source separation [46]. However, perceptual tests are

			Singing Voice			Accompaniment

Table 1. Performance comparison between our model and the waveform-based state-of-the-art. Metrics in dB.

time-consuming and expensive to conduct. We run a perceptual evaluation of the vocal separation for four models: Wavenet (again the best model in [28]), Wave-U-Net (the best model in [3] for monaural separation), Demucs (the v2 model for stereo mixture and 4 sources), and our best model (combining both vocal and accompaniment extraction models using Wiener). We reiterate the experiment in [28] with the same 5 songs (10 second excerpts) and including now our model and Demucs v2. [3]

In this perceptual experiment we follow a double-blind multi-stimulus experimental design with a hidden reference. Similarly to [28], participants are asked to assess the global quality of vocal separation taking into account the suppression of other sources and the lack of distortion, rating the stimuli on scale from 1 to 5, with 1 being *very intrusive interferences from other sources and degraded audio*, and 5 being *unnoticeable interferences from other sources and not degraded audio*. In contrast to [28], the order of the songs is randomized, so that the final rating does not depend on a predefined ordering. In addition, we include the ground-truth vocal stem as a hidden reference along the other stimuli corresponding to the vocal separation of the four models being tested. This hidden reference is used as a control stimuli to filter-out participants that have not performed the training stage, have not understood the task, or do not have sufficient expertise. The participants are asked to calibrate the volume using a tone burst. Then, they perform a training stage where detailed instructions and three audio examples from the same song are presented: the reference mixture, the ground-truth vocal stem and a poor quality separation using a model not included in our test. We use the webMUSHRA framework [47] to implement the experimental design in an online test.

4.2 Objective evaluation

In Table 1 we compare the performance of our approach with the waveform-domain state-of-the-art models. No metrics on accompaniment separation and SIR/SAR for vocals are reported for Demucs and ConvTas-Net since these target to *vocals, bass, drums and other*. We observe that our vocal extraction model outperforms WaveNet (note that DiffWave is based on WaveNet), Wave-U-Net, and Demucs v1 in terms of SDR, the latter by a slight difference. Our model provides notable improvement on SAR, which is translated into an output with less artifacts. When combining our vocal and accompaniment extraction models through Wiener filter we obtain closer performance to ConvTas-Net, while Demucs v2 is still leading on SDR $\approx$ $0.8dB$ above. While iteratively transforming an input mixture, for instance, to the corresponding singing voice, incorrectly estimated accompaniment that is not recognised in the subsequent reverse steps may accumulate in the final prediction. Although the said interferences might not be audible at naked ear, these are penalized by the metrics. The Wiener filtering provides notable improvement on that issue, as especially noted in the SIR and also in the perceptual evaluation in Section 4.3, albeit the source quality is slightly compromised. Finally, note that we use fewer parameters, enhancing the portability and reproducibility of our approach.

The β_1 singing extraction model, which directly estimates the perturbation by transforming the input mixture in a single run, scores similar than the baseline WaveNet, however we observe a notable decrease of SIR, while SAR improves. This may be given the transformation nature of our approach, which removes the perturbation from the target source instead of directly estimating the source. The β_8 model scores similar than β_{20}, however the SIR decreases while SAR is maintained. While adding more steps provides improved interference removal, no notable negative effect is observed in the quality of the estimated source. Nonetheless, if the computational expense is prioritized, the β_8 model may be used for an optimized inference since the measured performance drop in our experiments is not dramatic. In fact, both models predict faster than real-time on a TITAN Xp GPU. For accompaniment separation, using β_{100} provides better predictions. However, as observed for vocals, we may be also capable of modelling this task using less steps, with no significant performance drop.

		MUSDB18			MedleyDB			Saraga Carnatic
Model for singing voice	**Model weight**	**SDR**	**SIR**	**SAR**	**SDR**	**SIR**	**SAR**	**SDR**
Ours (vocal, β_{20}, no Wiener)	$\approx$ 26MB	5.59	10.78	8.89	4.86	8.87	9.06	4.11
Wave-U-Net [3]	$\approx$ 117MB	4.97	13.98	4.41	1.61	7.47	4.50	2.13
Demucs (v2) [2]	$\approx$ 1GB	6.84	-	-	6.01	-	-	6.12

Table 2. Performance comparison of our baseline model and state-of-the-art on additional test datasets. Metrics in dB.

In Table 2 we evaluate our baseline β_{20} singing voice extraction model (with no post-processing) on the two additional testing datasets presented in Section 4.1. We perform the same evaluation procedure for Wave-U-Net and Demucs v2, comparing how the three models generalize to the testing datasets, using the performance on MUSDB18 – which is also the training dataset for the three – as reference. Our model and Demucs v2 show good generalization to MedleyDB, both getting a similar and small performance drop. Contrastingly, the Wave-U-Net performance is negatively affected in terms of both SDR and SIR. A similar scenario is observed in the Carnatic Music experiment. While Wave-U-Net generalization is again compromised, our model and Demucs v2 are decently able to maintain the performance, the latter being less affected by the change of domain. Similarly to what observed in the MUSDB18 experiment, Demucs v2 predictions include less artifacts, especially in the high-frequency range, being reflected in the metrics as such. Audio examples of this experiment are available in the accompanying repository.

We analyse the behaviour of the β_{20} singing voice model along the steps in the reverse process. We observe that the SIR (interf.) notably increases along the steps, at a compromise of a much less steeply SAR (artifacts) decrease. Namely, as we iteratively transform the signal from mixture to singing voice, we remove the accompaniment while trying to maintain the quality of the singing voice, relying on the model trained with our diffusion-inspired strategy to estimate the perturbation at each step while alleviating the additional interferences incorrectly generated during the reverse process. We note that given the parametrization of the reverse process, stronger transformation is performed in the first steps (1 to 5 for β_{20}), while the rest of the steps refine the final estimation. For that reason, fair or good performance – relatively to the overall track difficulty – on the first step normally leads to enhanced final output, while bad initial performance may even be further degraded through the reverse process.

4.3 Perceptual evaluation

In total 40 people participated in our experiment, 4 of them being excluded because they scored the ground-truth stimuli lower than a separation stimuli. We compute Mean Opinion Score (MOS) by averaging the ratings for all songs and all participants. The results in terms of MOS are presented in Figure 2. Note that Ground-truth is not reaching 5, meaning that the test includes difficult cases with distorted vocals or large unvoiced segments. We observe that the 95% Confidence Interval for our model is very similar to Demucs and notably higher than both Wave-U-Net and especially WaveNet, a very similar architecture to the instance we have trained using our diffusion-inspired strategy. Such test suggests that the predictions made by our approach may include artifacts or interferences that affect negatively the standardized metrics but are not perceivable at naked ear. This test may be extended in future to separately study the perceivable distortion and interference.

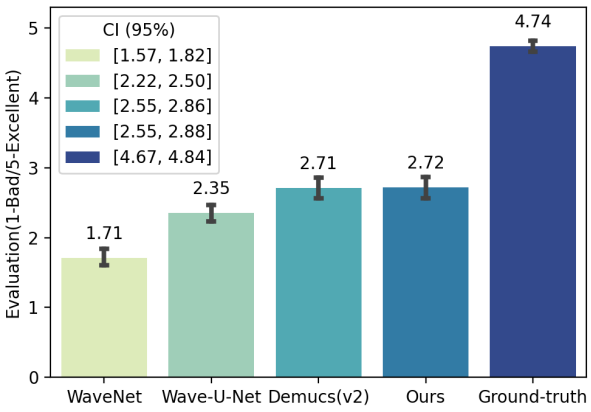

Figure 2. Perceptual evaluation report for the waveform-based state-of-the-art models and ours

5. CONCLUSIONS

In this paper we leverage from the denoising diffusion algorithm to propose a training and sampling strategy for singing voice extraction. The model trained using our approach learns to gradually transform a mixture into its corresponding vocal source or accompaniment, achieving comparable performance to the waveform-based state-of-the-art on MUSDB18. In addition, we evaluate how our approach generalizes to other testing sets, showing decent generalization to these out-of-domain data. We also run a perceptual test in which our approach scores similar than Demucs v2 and outperforms the others. Our approach operates on an architecture similar to WaveNet and obtains better objective and perceptual evaluation. This work has a broad future outlook. For the next steps, we look at separating other sources and supporting stereo. We also look at extending the approach, for instance, by using a different or improved network to learn the reverse process, focusing on U-Nets which are the leading architecture music source separation. We may also consider conditioning, the key element of diffusion-based approaches in the literature. Finally, our diffusion-inspired reverse parametrization may be further improved to better refine the predictions.

6. ACKNOWLEDGEMENTS

This work was carried out under the projects Musical AI - PID2019-111403GB-I00/AEI/10.13039/501100011033 and NextCore - RTC2019-007248-7 funded by the Spanish Ministerio de Ciencia, Innovación y Universidades (MCIU) and the Agencia Estatal de Investigación (AEI). We would like to thank the 40 participants that took the perceptual test for this work.

ABSTRACT

Machine learning techniques have proved useful for classifying and analyzing audio content. However, recent methods typically rely on abstract and high-dimensional representations that are difficult to interpret. Inspired by transformation-invariant approaches developed for image and 3D data, we propose an audio identification model based on learnable spectral prototypes. Equipped with dedicated transformation networks, these prototypes can be used to cluster and classify input audio samples from large collections of sounds. Our model can be trained with or without supervision and reaches state-of-the-art results for speaker and instrument identification, while remaining easily interpretable. The code is available at: https://github.com/romainloiseau/a-model-you-can-hear

1. INTRODUCTION

The emergence of deep learning approaches dedicated to audio analysis has led to significant performance improvements [1, 2]. Although these methods take sound excerpts as input, they typically rely on high-dimensional latent spaces, making the interpretation of their decisions difficult and limiting the insights gained on the considered data. Furthermore, such methods typically require large corpora of annotated sounds for supervision. We take a different approach, inspired by the recent Deep Transformation-Invariant (DTI) clustering [3] framework which learns prototypes in input space to analyze images or 3D point clouds [4]. Each prototype is associated with a set of transformations (*e.g.* rotations or morphological transformations) learned in the manner of Spatial Transformation Networks [5]. The DTI clustering model optimizes a reconstruction loss and associates each input with the prototype that provides the best reconstruction. We propose adapting this approach to the audio domain. The prototypes become log-scaled, Mel-frequency spectrograms, and their associated learnable transformations correspond to plausible sound alterations. We also introduce an additional loss based on cross-entropy in the supervised setting, which we demonstrate can boost the classification accuracy while preserving some interpretability.

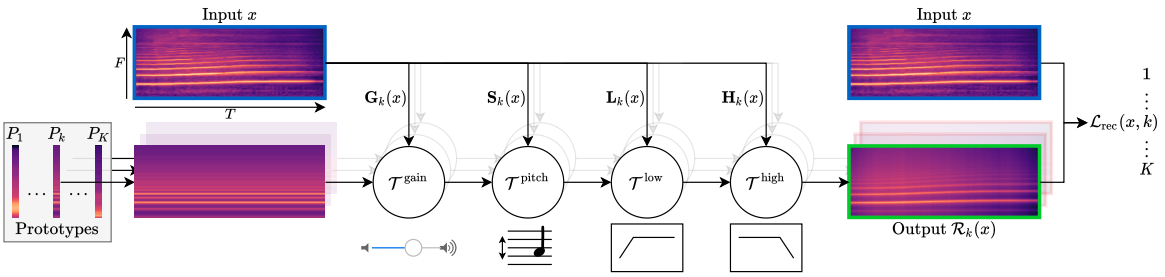

Figure 2: **Method overview.** Given an **input sound**, we predict for each prototype a *gain*, a *pitch* shift, as well as *low* and *high frequency filters* at each timestamp to generate the **output**. Prototypes and transformations are learned jointly using a reconstruction loss in either a supervised or unsupervised setting.

ing individual tones achieve appreciable precision, support vector machines operating on spectro-temporal sound representations can reach almost perfect accuracy. Similarly to supervised classification of instruments that play individual notes that could be considered solved [9, 10], speaker identification is mostly handled by convolutional and/or recurrent neural networks [11], which achieve almost perfect performances [12]. However, these models rely on complex and abstract latent representations that are not easily interpretable and cannot be visualized as spectrograms or heard in the audio domain.

Prototype-Based Methods. Auto-Encoders [13, 14] learn a compact latent representation of an input sample and are trained using a reconstruction loss. Using regularizations and constraints, the latent space can be adjusted for various tasks, such as classification [15]. However, the learned features remain largely non-interpretable and abstract. Inspired by the literature on images [16], the authors of [17] propose to generate prototypes in the latent space and analyze their similarity to the encoded input samples using a frequency-dependent measure. Although the latent prototypes can be decoded into input space, their role in class prediction remains obfuscated, as all similarities are mixed with a learned linear layer.

Transformation-Invariant Modeling. Deep transformation-invariant clustering [3] learns explicit prototypes in input space. Each prototype is equipped with dedicated transformation networks, allowing a small set of prototypes to faithfully represent a collection of samples. The resulting models can be used for downstream tasks such as classification [3], few-shot segmentation [4], and even multi-object instance discovery [18]. Jaderberg *et al*. [5] also proposes learning differentiable transformations in the input space, and feed the transformed data to a classification network. We propose to extend these ideas to the audio domain by learning prototypical log-Mel spectrograms along with adapted transformations.

3. METHOD

We consider a set of N audio clips $x_1, \cdots, x_N \in \mathbb{R}^{F \times T}$, each characterized by their log-Mel spectrogram with T time steps and a spectral resolution of F bins. The samples are annotated with class labels $y_1, \cdots, y_N \in \mathcal{Y}$ with $\mathcal{Y}$ a given class set $\{1, \cdots, K\}$. Our goal is to learn an interpretable model that can perform classification and clustering for the audio sample collection $x_1, \cdots, x_N$. Our model is based on prototypical spectrograms equipped with spectral transformation networks, which we present in Sec. 3.1. We propose an unsupervised training scheme in Sec. 3.2, and a supervised setting in Sec. 3.3. Finally, we provide details on parameterization and training of the model in Sec. 3.4.

3.1 Sound Reconstruction Model

Our model consists of K prototypes $P_k \in \mathbb{R}^F$ directly interpretable in the spectral domain, each equipped with a set of dedicated transformation networks (See Figure 2). Both prototypes and networks are jointly trained to reconstruct input samples. We can then use the reconstruction error as a measure of the compatibility between a sample and a given prototype.

Spectral Transformations Model. Even a single instrument or speaker cannot be meaningfully characterized by a single sound. In fact, they are typically capable of producing a rich and varied set of sounds. We propose equipping each prototype with a set of transformation networks that learn to change specific characteristics of the prototype, such as its amplitude and pitch, so that it can faithfully approximate a wide variety of samples. This also allows the prototypes to learn more subtle audio attributes, such as timbre or intonations.

Transformation networks associated to each prototype P_k take as input an audio sample $x \in \mathbb{R}^{F \times T}$ as input and predicts a spectral transformation for each time step t in $[1, T]$. For each prototype k, we propose a set of transformations specifically designed for the audio domain, illustrated in Figure 3:

• *Amplification.* Given an audio sample x, we predict a gain $\mathbf{G}_k(x) \in \mathbb{R}^T$ for all time step t. The transformation $\mathcal{T}_g^{\text{gain}}(m)$ adds the gain g to all frequencies of a log-Mel spectrogram $m \in \mathbb{R}^F$.

• *Pitch Shifting.* We map an audio sample x to a pitch shift $\mathbf{S}_k(x) \in \mathbb{R}^T$ for all time step t. The transformation $\mathcal{T}_s^{\text{pitch}}(m)$ shifts the log-Mel spectrogram $m \in \mathbb{R}^F$ by s.

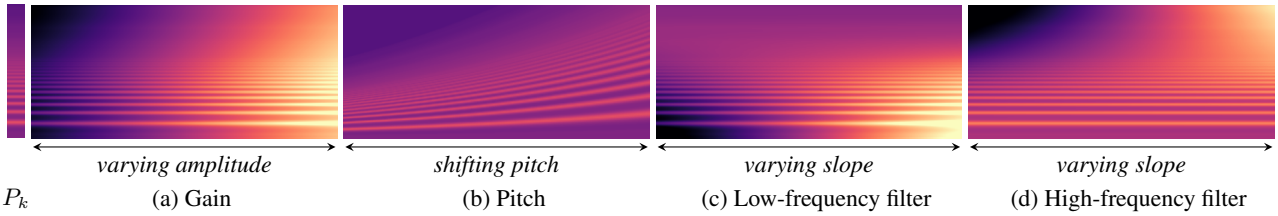

Figure 3: **Spectral Transformations.** Our proposed transformations learn to alter the gain (a), pitch (b) and frequency support (c,d) of a given prototype spectrogram P_k.

We use linear interpolation for handling non-integer shifts.

• *High- and Low-Frequency Filter.* Given an audio sample x, we define for each time t an affine low-frequency filter $\mathbf{L}_k(x)[t] \in \mathbf{R}^F$ by predicting its slope and cutoff frequency. Similarly, we predict a high-frequency filter $\mathbf{H}_k(x)[t] \in \mathbb{R}^F$. The transformations $\mathcal{T}_L^{\text{low}}$ and $\mathcal{T}_H^{\text{high}}$ simply add the corresponding filters L and H to a log-Mel spectrogram.

These transformations can be written as follows for a log-Mel spectrogram $m \in \mathbb{R}^F$ and a mel-frequency $f \in [1, F]$:

$$\mathcal{T}_g^{\text{gain}}(m)[f] = m[f] + g \tag{1}$$
$$\mathcal{T}_s^{\text{pitch}}(m)[f] = m[\Phi(f, s)] \tag{2}$$
$$\mathcal{T}_L^{\text{low}}(m)[f] = m[f] + L[f] \tag{3}$$
$$\mathcal{T}_H^{\text{high}}(m)[f] = m[f] + H[f], \tag{4}$$

with $\Phi(f, s) = A \log_{10}\left(1 + s\left(10^{f/A} - 1\right)\right)$ the mel-aware pitch shifting, with $A = 2595$ [19]. Our transformations have links with moment matching methods [20, 21]. In fact, modulating the amplitude, pitch, and spectral support of spectrograms is similar to matching the moment of zeroth order (amplitude gain), first order (pitch shift), and second order (frequency filters).

Reconstruction Model. For each prototype k and each time step t, we successively apply the gain, pitch shift, low-pass, and high-pass transformations in this specific order. The resulting reconstruction $\mathcal{R}_k(x)$ of an input sound x by a prototype P_k is defined as follows:

$$\mathcal{R}_k(x)[t] = \mathcal{T}^{\text{high}}_{\mathbf{H}_k(x)[t]} \circ \mathcal{T}^{\text{low}}_{\mathbf{L}_k(x)[t]} \circ \mathcal{T}^{\text{pitch}}_{\mathbf{S}_k(x)[t]} \circ \mathcal{T}^{\text{gain}}_{\mathbf{G}_k(x)[t]}(P_k), \tag{5}$$

where $\mathcal{R}_k(x)[t]$ denotes the t-th timestamp of the reconstruction, and $\circ$ denotes the composition of transformations. Note that the chosen transformations are constrained and limited on purpose, as we want each prototype to represent a restricted and consistent set of audio samples.

We measure the quality of the reconstruction $\mathcal{R}_k(x)$ of an input sample x by the k-th prototype as the spectro-temporal average of their ℓ_2 distance:

$$\mathcal{L}_{\text{rec}}(x, k) = \frac{1}{T} \sum_{t=1}^{T} \|x[t] - \mathcal{R}_k(x)[t]\|^2 . \tag{6}$$

Note that since this function is differentiable and continuous, it can be used as a loss function to train prototypes and transformation networks as defined in the next sections.

3.2 Unsupervised Training

We propose an unsupervised learning scheme in which we do not have access to labels $y_1, \cdots, y_N$ during training. Our goal is to cluster the samples $x_1, \cdots, x_N$ into meaningful groups of sounds that can be well approximated by the same prototype spectrogram and its associated transformations. We can train our model by minimizing the following loss:

$$\mathcal{L}_{\text{clustering}} = \sum_{n=1}^{N} \min_{k=1}^{K} \mathcal{L}_{\text{rec}}(x_n, k) . \tag{7}$$

This loss is the sum of the reconstruction errors with optimal cluster assignment and is a classical clustering objective used by K-means-based methods.

3.3 Supervised Training

In the supervised setting, each prototype and associated transformation networks are dedicated to a class and trained to reconstruct the samples from this class only. Once trained, the model predicts for an input x the class of the prototype with the best reconstruction.

To promote better class discrimination, we propose a dual reconstruction-prediction objective. We associate each input x with a probabilistic class prediction defined as the softmax of the negative reconstruction error between prototypes. For an input x of label y, we define the prediction loss $\mathcal{L}_{\text{ce}}$:

$$\mathcal{L}_{\text{ce}}(x, y) = -\log\left(\frac{\exp\left(-\beta \mathcal{L}_{\text{rec}}(x, y)\right)}{\sum_{k=1}^{K} \exp\left(-\beta \mathcal{L}_{\text{rec}}(x, k)\right)}\right), \tag{8}$$

where β is a learnable parameter. This loss encourages each prototype to specialize in reconstructing the samples of its associated class. To train our network, we use a weighted sum of both losses:

$$\mathcal{L}_{\text{classif}} = \sum_{n=1}^{N} \mathcal{L}_{\text{rec}}(x_n, y_n) + \lambda_{\text{ce}} \mathcal{L}_{\text{ce}}(x_n, y_n) , \tag{9}$$

with λ_{ce} an hyperparameter set to 0.01.

3.4 Parameterization and Training Details

Architecture. We implement the functions $\mathbf{G}_k$, $\mathbf{S}_k$, $\mathbf{L}_k$ and $\mathbf{H}_k$ as U-Net style neural networks [23] operating on

the log-Mel spectrograms $x \in \mathbb{R}^{T \times F}$. To save parameters, all networks share the same encoder, defined as a sequence of 2-dimensional spectro-temporal convolutions and pooling operations. This encoder produces a sequence of feature maps $z_0, \cdots, z_R$ with decreasing temporal and spectral resolutions $T/2^r \times F/2^r$. The spectral dimension of these maps is then collapsed using learned pooling operations: $\tilde{z}_r$ is of resolution $T/2^r$. Each decoder is then defined as a sequence of 1-dimensional temporal convolutions and unpooling operations. The spectral maps $\tilde{z}_0, \cdots, \tilde{z}_R$ are used through skip-connections in the decoders. The prototypes $P_1, \cdots, P_K$ and the inverse temperature β are directly trainable parameters of the model.

Curriculum Learning. We ensure the stability of our model by gradually increasing its complexity along the training procedure. First, we learn the raw prototypes without any transformation. Once the training loss does not decrease for 10 straight epochs, we add the gain transformation. We then add the pitch shift and spectral filters successively following the same procedure.

Implementation details. We use the ADAM [24] optimizer with a learning rate of 10^{-4}, and a weight decay of 10^{-6} for the transformation networks and 0 for β and the prototypes. Our model has 545k parameters with $K = 128$ prototypes. For comparison, the reconstruction model proposed by Zinemanas *et al*. [17] has 1.8M parameters.

4. EXPERIMENTS

We evaluate our approach in both supervised and unsupervised settings and on two datasets.

Datasets. We consider the following datasets:

• **SOL [6,7].** This dataset contains 24 450 samples of individual notes played with various playing techniques by 33 different instruments and sampled at 44.1kHz. We evaluate instrument classification.

• **Librispeech [8].** This 1000-hour corpus contains English speech sampled at 16kHz. We selected the 128 predominant speakers from the `train-clean-360` set. We evaluate the classification of speaker.

For both datasets, we randomly selected 70% of the clips for training, 10% for validation, and 20% for testing. We always use as many prototypes as the number of classes in the dataset.

Metrics. To assess the quality of classification models, we report the following metrics:

• *Overall Accuracy (OA).* Percentage of input samples correctly classified by our model, *i.e*., best reconstructed by the prototype assigned to their true class.

• *Average Accuracy (AA).* Average of the classwise accuracy, computed across classes without weights.

• *Reconstruction error ($\mathcal{L}_{rec}$).* To assess the quality of the reconstruction, we also report the reconstruction error $\mathcal{L}_{\text{rec}}$.

Methods trained in the unsupervised setting cluster the

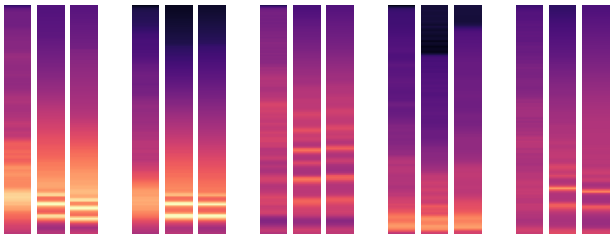

Figure 4: **Learned Meaningful Prototypes.** Comparison between the average spectrogram from one class (left), and the prototypes learned in the supervised setting without (middle) and with (right) cross-entropy loss. Our model can learn spectral representations that are crisper and more discriminative than a simple average.

audio samples instead of classifying them. We associate each cluster with the majority class of its assigned training samples. We can then predict for each test sample the class of its best-fitting cluster, allowing us to compute all the classification metrics.

Baselines. To put the performance of our method in context, we trained different baselines:

• *Classification.* We trained a temporal convolutional network to classify log-Mel spectrograms. We supervise this network with the cross-entropy on the labels. This network, which does not provide a reconstruction error, is called *Direct Classification*. We also evaluated the APNet [17] approach on our datasets. However, this method is limited in its interpretability, as it relies on latent prototypes and uses a fully connected layer to classify samples based on their similarity to the prototypes.

• *Clustering.* We trained a two-dimensional convolutional autoencoder without skip-connections to reconstruct log-Mel spectrograms. We supervised this network with the ℓ_2 norm between the input and the reconstruction. We then use K-means [22] on the innermost feature maps to cluster the samples. We also use K-means directly on the predicted similarities between feature maps and APNet prototypes [17]. Note this last approach requires to first train APNet in a supervised setting.

4.1 Quantitative Results

Reconstruction. As can be seen in Table 1, each successive addition of a transformation decreases the reconstruction error $\mathcal{L}_{\text{rec}}$ and improves the accuracy of classification. This shows that the curriculum training scheme allows our model to learn insightful and complementary spectral transformations. Supervised with the cross-entropy loss, our model reaches high accuracy, at the cost of a slightly higher reconstruction error. In fact, the additional objective not only encourages the reconstruction models $\mathcal{R}_k$ to provide a good reconstruction for the samples of their assigned class, but also a worse reconstruction for other classes.

Finally, we see that while adding frequency-filters yields better reconstruction, they hurt classification performance on SOL [6, 7] in the unsupervised setting. We hypothesize that the filters makes the transformation too expressive, reducing the specificities of the prototypes.

Clustering. As shown in Table 2, our method performs well compared to the baselines. For SOL, our method is affected by the class imbalance between samples, but still produces competitive results. In particular, note that our approach does not need any labels during training, in contrast to the APNet-based approach [17]. For LibriSpeech, our method produces convincing clustering results for speaker identification.

Classification. As shown in Table 3, our method reaches almost perfect precision for both datasets. While APNet [17] reaches better reconstruction scores, this method learns powerful transformations in an abstract latent space. This leads to a model that is more expressive but less interpretable. In contrast, we restrict the scope of the spectral transformations so that a prototype relates in a meaningful way to the samples that it reconstructs well. Yet, our model is still capable of producing faithful reconstructions, which would be suitable for audio generation tasks.

4.2 Interpretability

As shown in Figure 5, our model learns to reconstruct complex input samples (*e.g.* different notes, techniques, or voices) by automatically adjusting the amplitude, pitch, and spectral support of spectral prototypes. As seen on Figure 4 and Figure 1, these prototypes capture rich spectral characteristics such as timbre, and can be interpreted as an "acoustical fingerprint". Furthermore, as the prototypes are given in the spectral domain, they can be easily played and analyzed. Audio examples featuring the learned prototypes are provided in the supplementary materials.

In Figure 6, we represent the reconstruction of sounds played by various instrument with different prototypes. While the reconstructions are clearly more faithful when using the instruments' dedicated prototype, this opens the perspective for further MIR application such as interpretable timbre transfer.

5. CONCLUSION

We presented a novel approach to audio understanding by representing large collections of audio clips with few spectral prototypes equipped with learned transformation networks. Our model produces concise, expressive, and interpretable representations of raw audio excerpts that can be used to obtain state-of-the-art results for audio classification and clustering tasks.

ABSTRACT

Many previous works in recent years have explored various forms of music generation. These works have focused on generating either raw audio waveforms or symbolic music. In this work, we explore the feasibility of generating sheet music images, which is often the primary form in which musical compositions are notated for other musicians. Using the PrIMuS dataset as a testbed, we explore five different sequence-based approaches for generating lines of sheet music: generating sequences of (a) pixel columns, (b) image patches, (c) visual word tokens, (d) semantic tokens, and (e) XML-based tags. We show sample generated images, discuss the practical challenges and problems with each approach, and give our recommendation on the most promising paths to explore in the future.

1. INTRODUCTION

This work explores the feasibility of generating music in the form of sheet music images. Below, we provide a brief overview of recent work in the area of music generation, motivate the problem of generating sheet music images, and describe five sequence-based approaches that we will explore in this study. Our main goal is to identify the practical challenges and problems with each of the five approaches and to provide a recommendation on the most promising paths to explore in the future.

Music generation has been an active research topic of interest to the MIR community in recent years. Many recent works in this area fall into one or more of the following three research thrusts. The first research thrust is controllable music generation, in which a user can control certain aspects of the music generation process. Some examples of this include providing a template from which variations can be generated [1] [2], providing a video to which a suitable background music track is generated [3], specifying lyrics for the generated song [4], or disentangling different characteristics of music like style & melody [5], pitch & rhythm [6] [7], or structure & content [8]. A second research thrust is generating music with realistic short-term and long-term structure. Most recent works achieve this by representing music as a sequence of discrete tokens and using Transformer-based architectures to learn long-term dependencies. Some prominent examples of this include OpenAI's Jukebox model [4] and Google Magenta's Music Transformer model [9] [10]. Other works focus on encoding music in a way that allows the generated music to exhibit appropriate metrical structure at the beat, bar, and phrase levels [11]. A third research thrust is to generate music in different contexts and musical representations. Some examples include multi-part music [12], multi-track music [13] [14] [15] [16], guitar tabs [17], and jazz lead sheets [18]. Much of this work focuses on how to encode different music representations or different aspects of music (like pitch, duration, velocity, and timing [11]) in a form that is suitable for training with a Transformer model.

This work falls into the last group and explores music generation in a different musical representation: sheet music images. To the best of our knowledge, this is the first systematic study of generating sheet music images.

Why generate music in the form of sheet music images? We present four reasons. First, sheet music is the predominant medium by which compositions are shared in many genres of music. If a piece of music is intended to be a composition (as opposed to a demo for an academic research paper), the expectation is that the composition will be in the form of sheet music. Second, sheet music contains important musical information that is not contained in MIDI files (which is the most common symbolic music representation). For example, musical symbols in the sheet music like bar lines, rests, note ties, phrasing markings, sharps and flats, and key changes may not appear in a generated MIDI file in any explicit way. Third, generating sheet music cleanly decouples the musical composition and expressive performance aspects of music, allowing us to focus exclusively on the composition problem. Fourth, there is an abundance of sheet music data (>650k scores) available to the research community through the International Music Score Library Project (IMSLP) [19]. For the above reasons, we believe that studying the generation of sheet music images is an interesting and relevant problem.

Our goal is to explore the feasibility of generating sheet music. As an initial step, we focus on the specific task of generating monophonic incipit images, which are short snippets of sheet music that are used to identify a musical work. Using the PrIMuS dataset [20] as a testbed, we explore five different sequence-based approaches for generating incipits: (a) generating sequences of pixel columns, (b) generating sequences of image patches, (c) generating sequences of visual word tokens, (d) generating sequences

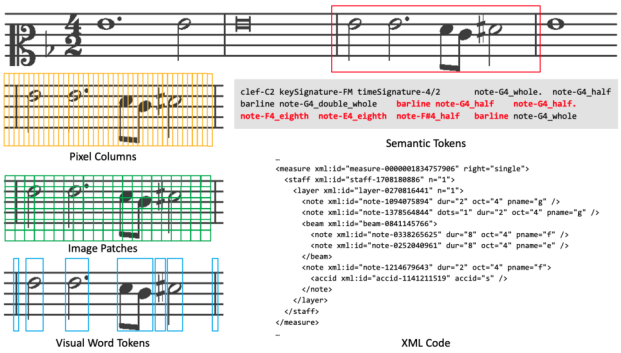

Figure 1. An example incipit from the PrIMuS dataset (top). We explore five different ways to generate sheet music: generating pixel columns, image patches, visual word tokens, semantic tokens, and XML code.

of semantic tokens, and (e) generating MEI code, an XML-based sheet music representation. For each of these five approaches, we train GPT-2 [21] and AWD-LSTM [22] language models, generate example incipits, and characterize the main challenges and problems with each approach.

2. SYSTEM DESCRIPTIONS

In this section we describe five different sequence-based approaches for generating a monophonic incipit image. All five approaches use language models to generate sequences of tokens, but they differ in the way that the tokens are constructed or defined.

2.1 Generating Pixel Columns

The first approach is to generate sequences of pixel columns. This is done in five steps, which are described in the following five paragraphs.

The first step is to standardize the incipits. The raw incipits in the PrIMuS dataset have variable height and width, so it is necessary to standardize the height of the incipit. This is done by selecting a fixed height for all incipits, ensuring that the five staff lines are vertically centered in the resulting image. This ensures that the staff lines appear in the same vertical pixel positions in each image. After the standardization, the images have a fixed height but variable width.

The second step is to convert pixel columns to words. Here, we interpret each standardized image as a sequence of words, where each word corresponds to a single pixel column. We convert pixel columns to words by simply binarizing the (grayscale) pixel values and interpreting each column's binary representation as a word.

The third step is to train a language model on the word sequences. This can be done in a self-supervised manner by predicting the next word in a sequence. We ran experiments with two different language models: (a) the AWD-LSTM model [22], which is a 3-layer LSTM model that incorporates multiple forms of dropout and (b) the GPT-2 small model [21], which is a 6-layer Transformer decoder model. We use the implementation of AWD-LSTM from the fastai [23] library and the implementation of GPT-2 from the huggingface [24] library. We use the default recommended vocabulary size in each respective library (GPT-2 small 30k, AWD-LSTM 60k), and map infrequently occurring words to a special unknown word token <unk>.

The fourth step is to generate new word sequences given a starting seed sequence. We do this by generating a new token at each time step and using the generated token as input to the next time step. For AWD-LSTM, we sample from the softmax distribution with a temperature of 0.8 (default in fastai). For GPT-2, we use top $K = 50$ sampling (default in huggingface).

The fifth step is to render the generated word sequence as an image. Since each word is a binary string of 0's and 1's corresponding to a single pixel column, we simply concatenate the generated words in a matrix and directly render it as a black-and-white image.

2.2 Generating Image Patches

The second approach is to generate sequences of image patches. This is done in five steps, which are described in the following five paragraphs.

The first step is to standardize the incipits. This is done in the same manner as described in Section 2.1 above.

The second step is to convert image patches to words. Figure 1 shows a graphical illustration of this process for a single measure (green squares at left). Instead of using pixel columns as words, we can instead use 15×15 square image patches as words. This allows individual words to retain context in both the vertical and horizontal dimensions, rather than only along the vertical dimension. This approach has been shown to work effectively for image classification in the Vision Transformer model [25]. After breaking the incipit image into square patches, we form a sequence by considering patches from top to bottom and from left to right. Each image patch is binarized and interpreted as a single word.

The third step is to train a language model on the word sequences. This is done in the same manner as before. We tried training both with and without special <col> tokens indicating the end of each column of patches but found that including the <col> tokens did not help.

The fourth step is to generate new word sequences given a starting seed sequence. We generate a sequence of words autoregressively as described previously.

The fifth step is to render the generated word sequence as an image. Each word is a binary string of length $15 \times 15 = 225$ and can be directly reshaped into a binary image patch. The image patches are assembled in the same rasterized order to generate the incipit image.

2.3 Generating Visual Word Tokens

The third approach is to generate sequences of visual word tokens. This is done in five steps, which are described in the following five paragraphs.

The first step is to standardize the incipits. This is done in the same manner as described in Section 2.1.

Figure 2. Visual word tokens. The top two rows show some of the most common visual word tokens, and the bottom two rows show a random selection of words in the vocabulary.

The second step is to tokenize each standardized incipit into a sequence of visual word tokens. This can be done by identifying pixel columns that only contain empty staff lines, and then interpreting these pixel columns as a separator (similar to tokenizing text based on whitespace). Figure 1 shows an example of this process for a single measure (bottom left). With the PrIMuS dataset, there are only a few unique "empty" pixel columns, but with other sheet music data one could train a simple model to identify empty pixel columns. Note that this process yields visual word tokens that span the entire height of the incipit and have variable width. The top two rows of Figure 2 show some of the most common visual word tokens, and the bottom two rows show a random selection of other visual word tokens in the vocabulary. One benefit of this approach is that entire symbols (e.g. clef signs) are interpreted as a single word, which allows the model to focus on modeling sequences of symbols rather than on rendering common symbols correctly. We found it helpful to impose a minimum separator width to avoid splitting certain symbols (like single whole notes) into two parts.

The third step is to train a language model on the visual word token sequences. This is done in the same manner as described in Section 2.1. The separator pixel columns are removed from the data and do not appear in training.

The fourth step is to generate new word sequences given a starting seed sequence. We generate a sequence of visual word tokens autoregressively as described in Section 2.1.

The fifth step is to render the generated visual word token sequence as an image. For simplicity, we simply concatenate the visual word tokens side by side and insert a fixed-width separator between each visual word token.

2.4 Generating Semantic Tokens

The fourth approach is to generate a sequence of semantic tokens. This is done in four steps, which are described in the next four paragraphs.

The first step is to represent each incipit as a sequence of semantic tokens. In the original PrIMuS dataset [20], the creators introduce a language for encoding musical symbols in a way that captures semantically meaningful information. Figure 1 shows an example incipit (top) and its corresponding sequence of semantic tokens (gray colored box on right). We tokenize by symbol and by symbol characteristics, so that a string "note-E4_eighth rest-eighth" would be converted into the sequence "note E4 eighth rest eighth". After tokenizing in this manner, there are 279 unique words across the PrIMuS dataset.

The second step is to train a language model on the semantic token sequences. This is done in the same manner as described in Section 2.1.

The third step is to generate new word sequences given a starting seed sequence. We generate semantic word tokens autoregressively as described in Section 2.1.

The fourth step is to render the generated semantic token sequence as an image. We first convert the semantic token sequence into Plaine and Easie [26] code using a relatively simple set of rules and logic. We then render the Plaine and Easie code as an image using Verovio [27].

2.5 Generating XML Code

The fifth approach is to generate MEI [28] code, which is a way of encoding music notation in XML form. This is done in four steps, which are described in the following four paragraphs.

The first step is to preprocess the MEI representation into a sequence of words. Figure 1 shows a portion of the MEI representation (bottom right) that encodes the measure highlighted in red (top right). To simplify the data, we filter out information that is not needed for the engraving process, such as headers, footers, and XML identifiers. We also insert spaces to keep conceptually distinct tokens separate. For example, a tag "<staff n='1'>" would be tokenized into the sequence "<staff", "n=", "'1'", and ">". Tokenizing the MEI representations in this manner, we get a vocabulary of 769 words across the PrIMuS dataset.

The second step is to train a language model on the MEI token sequences. This is done in the same manner as described in Section 2.1.

The third step is to generate new word sequences given a starting seed sequence. We generate a sequence of MEI tokens autoregressively until a closing </music> tag is generated. Note that, unlike the previous four methods, we cannot directly control the width of the generated incipit since the nested XML tags need to be properly closed.

The fourth step is to render the generated MEI representation as an image using Verovio. Note that the generated MEI code may not be a properly formatted XML document, so this rendering process may or may not be successful.

3. EXPERIMENTAL RESULTS

In this section we present sample incipits generated by using all five approaches described in Section 2. We focus on qualitative analysis of the generated images in this section, and in Section 4 we perform several quantitative analyses on the two most promising approaches.

Figure 3. Sample images from generating pixel columns with AWD-LSTM (left) and GPT-2 (right).

All systems described in Section 2 were trained on the PrIMuS dataset [20]. It contains 87,678 real-music incipits, which are sequences of notes (often the first ones) used to identify a melody or musical work. Each incipit in the dataset is available in five different formats: (1) Plaine and Easie code, (2) a rendered image, (3) an MEI representation, (4) a sequence of semantic tokens (as described in Section 2.4), and (5) a sequence of agnostic tokens, which encodes the graphical symbols in the music score with their position in the staff but without any musical meaning. This dataset is ideal for our study because the incipits are short, there are a large number of incipits, and there are multiple representations of the data. We use the rendered image for the first three approaches (pixel columns, image patches, visual word tokens), the semantic tokens for the fourth approach (semantic tokens), and the MEI representation for the fifth approach (XML code).

During language model training, we use a 90-10 train-validation split for AWD-LSTM and a 95-5 train-validation split for GPT-2. Once the language model training has converged, we use the model to generate sample incipits as described in Section 2. Below, we present sample images generated from each of the five approaches and comment on the problems with each approach.

Figure 3 shows sample images from generating pixel columns. The left half of the figure shows images generated from the AWD-LSTM model, and the right half of the figure shows images generated from the GPT-2 model. We can immediately see several issues with the generated images: there are visual artifacts that appear as vertical lines (particularly with the AWD-LSTM model), the measures do not have a consistent number of beats, there are invalid key signatures (top left incipit), and the AWD-LSTM model seems to reset the clef and key/time signatures frequently. On the positive side, this approach is able to model symbols like bar lines, grace notes, clefs, key signatures, time signatures, and multiple bar rests in a single unified framework.

Figure 4 shows sample images from generating image patches. The left half of the figure shows images generated from the AWD-LSTM model, and the right half of the figure shows images generated from the GPT-2 model. We see some visual artifacts that come from incoherently generated symbols (e.g. the time signature in the fourth example on the right, the sixteenth note beams in the last example on the right), the measures do not have a consistent number of beats, and occasionally the model seems to

Figure 4. Sample images from generating image patches with AWD-LSTM (left) and GPT-2 (right).

Figure 5. Sample images from generating visual word tokens with AWD-LSTM (left) and GPT-2 (right).

be confused about where each image patch is located relative to the global image (e.g. the incorrectly placed bar lines in the fifth example on the left). Again, the AWD-LSTM model seems to have a problem with resetting the clef and key signature too frequently (e.g. the second and third examples on the left). Compared to the pixel column approach, this approach seems to have somewhat less variety in terms of rhythms and durations (e.g. sixteenth notes, rests).

Figure 5 shows sample images from generating visual word tokens. The left half of the figure shows images generated from the AWD-LSTM model, and the right half of the figure shows images generated from the GPT-2 model. We don't see any visual artifacts in reconstructing symbols since each token is itself an entire symbol (or collection of symbols), but we see a lot of semantically incoherent patterns. For example, there are accidentals that appear without a corresponding note (fifth example on left), ties to notes that don't appear (second example on left), and bar lines sometimes appear too frequently (third example on right) and at other times too infrequently (last three examples on left). Measures still do not have a consistent number of beats, but we do notice that the model is often metrically coherent and correct immediately after a time signature symbol is generated. There are stylistic issues as well: some measures are technically coherent but do not follow typical conventions of sheet music, such as generating three consecutive quarter note rests in a measure rather than a whole measure rest (top example on right).

Figure 6 shows sample images from generating semantic tokens. The left half of the figure shows images generated from the AWD-LSTM model, and the right half of

Figure 6. Sample images from generating semantic tokens with AWD-LSTM (left) and GPT-2 (right).

Figure 7. Sample images from generating XML code with AWD-LSTM (left) and GPT-2 (right).

the figure shows images generated from the GPT-2 model. There is a noticeable improvement in semantic coherence compared to the previous three approaches. For example, most generated measures have the correct number of beats, even across different time signatures (e.g. 3/4 in the first example on left, 6/4 in the second example on left, 2/4 in the third example on left, 4/4 in last example on left). However, we still occasionally see measures with an incorrect number of beats (e.g. fifth example on left), and the model particularly seems to struggle with unusual time signatures (e.g. 5/4 in the fourth example on left). The models seem to display a good amount of diversity in rhythms and durations, both with notes and rests. Note that, because the incipit is translated from semantic tokens to Plaine and Easie code and then to a rendered image, accidentals are guaranteed to be rendered correctly with a given key signature (e.g. first and third examples on left).

Figure 7 shows sample images from generating MEI code. The left half of the figure shows images generated from the AWD-LSTM model, and the right half of the figure shows images generated from the GPT-2 model. Note that some generated MEI code was ill-formed and could not be rendered as an image, so the examples below are self-selected from the examples that were valid MEI files. We can see that most measures have the correct number of beats, and this holds true across a range of time signatures (e.g. 4/4, 3/4, 2/4, 2/2 in the examples in Figure 7). Because the MEI representation explicitly encodes symbols like note beams and ties, the generated incipits also seem to obey most stylistic conventions. The AWD-LSTM model has noticeably less diversity than the GPT-2 model, but the latter demonstrates a reasonably good diversity of rhythms and durations in notes and rests.

Summary. The three image-based approaches (pixel columns, image patches, visual word tokens) are not recommended because the generated incipits are not semantically coherent, even when they do not have any obvious visual artifacts. The primary issue with generating semantic tokens and MEI code is metrical coherence – ensuring that the number of beats in a measure is consistent with the time signature. Generating MEI code also has the issue of malformed XML code that cannot be rendered properly. [1]

Our experiments lead us to two main conclusions. First, the two approaches that we believe are most promising to explore in future work are generating sequences of semantic tokens and generating XML code. Second, the main technical issue that must be resolved to generate meaningful sheet music is metrical coherence – exploring ways to utilize powerful and flexible language models while also conforming to the strict metrical rules of music. This emerges as a main challenge for future work.

4. ANALYSIS

In this section we perform additional quantitative analyses on the two recommended approaches: generating semantic tokens and generating MEI code.

We can quantify how metrically coherent the generated semantic token sequences are in the following manner. First, we generate 16,000 incipits in the form of semantic token sequences. When generating these sequences, we specify the clef, key signature, and time signature as part of the seed sequence, and we divide the 16,000 incipits evenly across eight different time signatures. Second, we segment each incipit into distinct measures by detecting bar lines in the generated sequence. If the generated sequence contains a change of time signature, we only consider the portion of the incipit before the time signature change and ignore the rest. This policy allows us to measure and compare metrical coherence across different time signatures. Third, we calculate the fraction of measures that are metrically coherent, which we define as a measure that contains the correct number of beats specified by the time signature. We can determine this based on the time signature and the time duration of each semantic token. Note that some semantic tokens like slurs, bar lines, grace notes, and clef symbols have no duration, while all notes and rests have a non-zero duration.

Table 1 shows the results of this analysis on the generated semantic token sequences. The leftmost column shows the different time signatures that we used as starting seeds. The next two columns show the total number of measures generated by the AWD-LSTM model and the percentage of those generated measures that are metrically coherent. Note that each incipit will have a variable number of measures, so we can only indirectly control the total number of generated measures. The last two columns show the same information for the GPT-2 model. The bottom row shows a total across all time signatures.

[1] One caveat is that our recommendations assume that the amount of training data is the same across different encodings.

Time	AWD-LSTM		GPT-2	
Signature	# meas	% coh	# meas	% coh
2/4	5820	75.2	8794	80.9
3/4	6229	79.5	8191	79.4
4/4	4109	77.6	5936	77.9
5/4	3762	0.3	5276	35.1
6/4	3640	70.4	5553	77.0
7/4	3781	0.05	5947	0.4
3/8	7091	77.9	10069	77.0
6/8	4334	75.8	7303	75.7
Total	45982	61.7	57069	66.0

Table 1. Measuring metrical coherence of generated semantic token sequences. Columns indicate the number of generated measures and the percentage of measures that have the correct number of beats.

Time	LSTM		GPT-2	
Signature	# meas	% coh	# meas	% coh
2/4	4754	35.2	6650	85.4
3/4	4998	69.4	6098	86.9
4/4	4418	74.1	4810	77.8
5/4	5400	3.2	4391	9.0
6/4	4298	13.4	3519	59.5
7/4	5586	2.4	3667	8.3
3/8	4120	22.5	7060	91.5
6/8	4354	81.1	5048	83.0
Total	37928	36.3	41243	68.3

Table 2. Measuring metrical coherence of generated MEI code.

There are two things to notice about Table 1. First, both models have very low metrical coherence for uncommon time signatures like 5/4 and 7/4. For example, less than 1% of measures in 7/4 were metrically coherent in both models, which is likely a reflection of the fact that this time signature has little or no representation in the PrIMuS dataset. Clearly, these language models are not learning a notion of metrical structure and are unable to generalize to unseen or uncommon time signatures. Second, the metrical coherence measures for GPT-2 and AWD-LSTM are very similar for common time signatures like 3/4, 4/4, 3/8, and 6/8, with numbers falling somewhere between 75-80%. For less common time signatures, however, GPT-2 often significantly outperforms AWD-LSTM, suggesting that it is able to generalize slightly better.

We measure the quality of the generated MEI code in two different ways. The first measurement is simply the percentage of generated incipits that are valid XML documents. Note that every MEI document begins with a <music> tag and ends with a corresponding </music> tag. Therefore, when generating MEI code, we autoregressively generate tokens until a closing </music> tag is encountered. The resulting MEI document is then rendered with Verovio into an SVG file. If the rendering process generates an error or warning, we consider the MEI code to be malformed. We generated 16,000 incipits with each model (2,000 incipits for each of the 8 time signatures shown in Table 1) and found that 93.1% of the AWD-LSTM incipits and 95.9% of the GPT-2 incipits were valid.

The second way to measure the quality of generated MEI code is to quantify metrical coherence. This is done in a similar manner as described above: we generate 2,000 incipits for each of the same eight time signatures, segment each incipit into measures by detecting bar lines, and then calculate the percentage of measures that are metrically coherent. Note that some of the incipits will not be valid XML documents, so in our analysis we only consider measures from generated documents that are valid.

Table 2 shows the results of this analysis on the generated MEI incipits. There are two things to notice. First, we see that GPT-2 outperforms AWD-LSTM on metrical coherence for every time signature, sometimes by very large margins. For instance, on incipits with a 3/8 time signature, 91.5% of the measures generated by GPT-2 are metrically coherent, compared to only 22.5% for AWD-LSTM. Second, comparing metrical coherence between semantic tokens (Table 1) and MEI (Table 2), we see that AWD-LSTM performs substantially worse with MEI representations across all time signatures (61.7% vs 36.3% total). GPT-2 seems to perform better with MEI on common time signatures, but has extremely variable performance with uncommon time signatures.

Our quantitative analyses have a clear takeaway: metrical coherence is the primary issue with both approaches. The percentage of metrically coherent measures is sufficiently low as to be prohibitive, particularly with less common time signatures. It is clear that simply having more data will not solve this problem, since having more data will still have an extreme imbalance across different time signatures. Some possible solutions include using rejection sampling or incorporating timing and position information either into the Transformer model as additional embeddings or into the data itself (e.g. REMI [11]). We identify this as a main challenge for future work.

5. CONCLUSION

We explore the feasibility of generating monophonic sheet music images using sequence-based models. We consider five different approaches: generating sequences of pixel columns, image patches, visual word tokens, semantic tokens, and XML-like tags. We train language models for all five approaches on the PrIMuS dataset and generate sample incipits to better understand the pros and cons of each approach. Our main findings are that: (a) the image-based approaches can yield realistic looking sheet music but are often semantically incoherent and are therefore not recommended, (b) generating semantic tokens and MEI code yield the most semantically coherent sheet music, and (c) metrical coherence is the biggest issue that needs to be addressed in future work.

ABSTRACT

While neural network models are making significant progress in piano transcription, they are becoming more resource-consuming due to requiring larger model size and more computing power. In this paper, we attempt to apply more prior about piano to reduce model size and improve the transcription performance. The sound of a piano note contains various overtones, and the pitch of a key does not change over time. To make full use of such latent information, we propose HPPNet that using the Harmonic Dilated Convolution to capture the harmonic structures and the Frequency Grouped Recurrent Neural Network to model the pitch-invariance over time. Experimental results on the MAESTRO dataset show that our piano transcription system achieves state-of-the-art performance both in frame and note scores (frame F1 93.15%, note F1 97.18%). Moreover, the model size is much smaller than the previous state-of-the-art deep learning models.

1. INTRODUCTION

Automatic music transcription (AMT) is a crucial task in Music Information Retrieval (MIR). This task converts the music in audio format to musical notation formats such as MIDI and sheet music. Transcribing from wave format is a process of message compression that reduces the message from universe form (wave) to abstract form (sheet music) that will help with music understanding.

Piano transcription is a popular subtask of AMT. Predicting a set of concurrent pitches present in the same frame is a challenging problem. Over the past decades, plenty of methods have been applied to the piano transcription task, e.g., using Factorization-based models (Smaragdis et al. [1]), using sparsity coding and unsupervised analysis (Abdallah et al. [2]), adaptive estimation of harmonic spectra (Vincent et al. [3]), and using SVM-HMM structure (Nam et al. [4]). Some methods are motivated by the piano's acoustics features, such as the attack/decay [5] model.

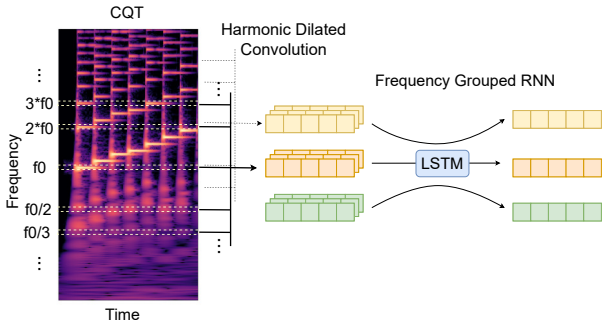

Figure 1. Harmonic Dilated Convolution and Freqency Grouped RNN. The former captures possible harmonic series information for all frequency groups by dilated convolution. The latter feeds each single frequency group to the same LSTM layer to detect whether there is a harmonic series in the frequency group.

In recent years, with the development of deep learning and the existence of large scale labeled datasets, neural networks have become a popular method, such as using RNNs [6] and using methods based on CNNs [7]. With the release of the MAESTRO [8] dataset in the field of piano transcription, the Onsets & Frames transcription system [9] made significant progress. Hawthorne et al. focus on onsets and offsets together to predict frame labels. Transformer is a revolutionary architecture in other fields, and Hawthorne et al. [10] explore Transformers potential on piano transcription. Generative Adversarial Networks [11] also show its potential in improving performance. Kong et al. [12] proposed a high-resolution AMT system trained by regressing precise onset and offset times of piano notes, which achieved state-of-the-art performance in note prediction.

However, previous SOTA models are becoming more and more resource-consuming. The spectrograms of the solo piano are highly structured. Each tone has a harmonic series, and the pitch of a key does not change over time. In view of this prior, we attempt to model such harmonic structure and pitch-invariance over time to improve model interpretability and algorithm efficiency.

Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

We propose the Harmonic Dilated Convolution (HD-Conv) to capture harmonic series information and the Frequency Grouped Long Short-Term Memory (FG-LSTM) to detect if there is an active pitch accounting for high energy in a specific frequency band. We apply HD-Conv and FG-LSTM to model the harmonic structure and pitch-invariance prior over time in a model called HPPNet. The model achieves state-of-the-art piano transcription performance. Remarkably, it is an approach that uses much fewer parameters of only 1.2 million while other models like the Transformer [10] use 54 million ones. The reduction of parameters is attributed to the use of FG-LSTM, which applies LSTM in a single frequency group, and the shared acoustic model. The primary contribution of this work is an tiny model that achieves state-of-the-art performance using much fewer parameters.

The rest of this paper is organised as follows: Section 2 describes the proposed model component's details: harmonic dilated convolution and the frequency grouped recurrent neural networks. Section 3 illustrates the experimental setup, with results analysed in Section 4. Conclusions are discussed in Section 5.

2. ARCHITECTURE

The two critical components of our model are the harmonic dilated convolution and the frequency grouped recurrent neural networks. The former is used to model harmonics structure, and the latter is designed based on the invariance of piano pitches over time as demonstrated in Figure 1.

2.1 CQT input

We use the Constant-Q Transform (CQT) [13] as our input feature. Unlike the log-mel spectrogram which is partially log-scaled, all the frequency bins of the CQT are geometrically spaced. As shown in Eq. (1), the spacing between fundamental frequency and overtones does not vary with the change of the fundamental frequency. Such property makes it suitable for dilated convolution, as described in [14].

$$\begin{aligned} d_k &= log_{2^{1/Q}}(k \cdot f_0) - log_{2^{1/Q}}(f_0) \\ &= Q \cdot log_2(k), \end{aligned} \tag{1}$$

where k is the serial number of the harmonic series, d_k denotes the distance between fundamental frequency and the k-th overtone on a log frequency scale, Q indicates the number of frequency bins per octave, and f_0 is the fundamental frequency.

2.2 Harmonic Dilated Convolution

In recent years, some methods are proposed to modeling harmonic structure in neural networks. The Harmonic constant-Q transform (HCQT) [15] captures the harmonic relationships by a 3-dimensional CQT array for pitch tracking in polyphonic music. Harmonic convolution is applied in [16] to denoise speech audios. Dilated convolution [17] and sparse convolution [18] are used in Wang's works but they are still not perfect ways to capture harmonic structure. Our model captures harmonic information in a simple but effective way. As shown in our acoustic model (Figure 2), we feed the CQT into multiple dilated convolution [19] layers with different dilation rates and sum the outputs for the following layers. The dilation rates are the distance between fundamental frequency and overtones on a log frequency scale as in Eq. (1). We call such dilated convolutions applied on the log-frequency dimension and with dilation rates of spaces between harmonic series the Harmonic Dilated Convolution (HD-Conv).

Model	Onsets & Frames		HPPNet	
	Acoustic	LSTM	Acoustic	FG-LSTM
inputs	T×229	T×768	T×352	T×128
outputs	T×768	T×88	T×88×128	T×1
units	-	256	-	128
parameters	4.3M	3.5M	421K	99K

Table 1. The parameters of different layers in Onsets & Frames and HPPNet. Acoustic denotes the acoustic models, T denotes the number of frames in a training sample.

2.3 Frequency Grouped LSTM

In the feature map output by the harmonic acoustic model, each frequency unit with multiple channels contains corresponding possible harmonic information to detect if there is an active pitch accounting for high energy in a specific frequency band. However, detecting multiple pitches in polyphonic music is challenging since harmonic series interfere with each other. Time-domain correlation is required to obtain smooth pitch contours. Previous works [9] [12] applied bidirectional Recurrent Neural Network (biRNN) [20] to model the temporal relationship of frames. They flatten the channel dimension and frequency dimension of the feature map output by the acoustic model to a long hidden dimension as the input of RNN. There are some problems with such processing. One is that the long hidden dimension led to an unnecessarily large amount of model parameters. This leads to large amount of parameters both in acoustic model and Long Short-Term Memory (LSTM) [21], as described in Table 1.

The sub-band and multi-band techniques are widely applied in speech and music processing [22–24]. The common practice is splitting the full-band spectral representation into multiple sub-bands and processing them separately, then concatenating the outputs of each sub-band for subsequent processing. Specifically, some methods based on splitting sub-bands (frequency-LSTM [25]) or generating sub-bands (multi-band MelGAN [26]) show impressive performance with lightweight models. The splitting of sub-bands reduces the size of network input, and different sub-bands sharing the same sub-network further reduces the model size.

Similar to the multi-bands techniques, we segment the output of harmonic dilated convolution to 88 frequency

groups. Since the piano is a fixed-pitch keyboard instrument, the fundamental frequency of each key does not vary as time changes. This enables the model process each frequency group independently. Based on this assumption, we feed each frequency group to the same LSTM layer individually to model the temporal relationship. We term this the Frequency Grouped LSTM (FG-LSTM) illustrated in Figure 1. Feeding a single frequency group to the LSTM makes inputs and units size of FG-LSTM smaller. This method significantly reduces the amount of parameters in our model.

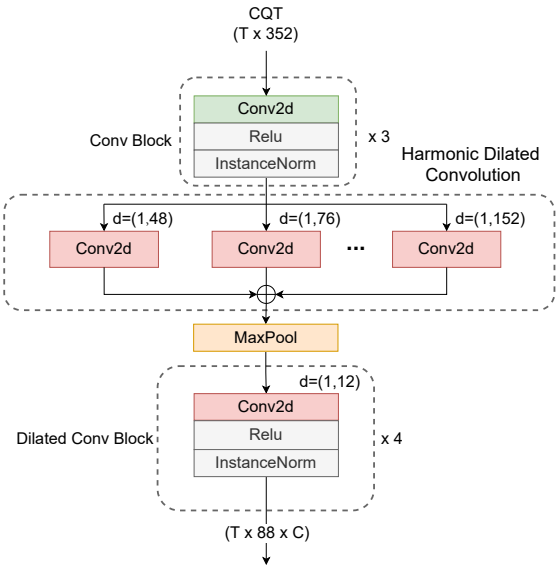

Figure 2. Acoustic model of HPPNet. It is composed of three identical regular convolution layers, a harmonic dilated convolution layer, a max pooling layer, and four identical dilated Conv blocks. Different dilated convolution layers have different dilation rates denote by d. The output is a feature map with size $T \times 88 \times C$, where T is the frame numbers, 88 denotes the numbers of piano keys, C is the channel size.

2.4 Model Details

Raw audios are clipped to 20-second pieces and resampled to 16 kHz. Then, the CQT is computed by nnAudio [27] with hop length 320 (20 millisecond), an FFT window of 2048, bins per octave of 48, fmin of 27.5 Hz, frequency bins number of 352, and log amplitude. The model takes the CQT feature with size $T \times 352$ as input, where T is the frame number of each audio clip. The time resolution and frequency resolution of inputs are limited by the computational resource, higher input resolution may have better performance.

The model is composed of a convolutional acoustic model and multiple FG-LSTM heads. The former structure captures the harmonic representations of a tone, and the latter establishes connections over temporal series. In the acoustic model shown in Figure 2, the first three convolution layers extract local information with kernel size 7×7, a ReLu activation, and instance normalization.

Then followed by eight dilated convolution layers parallel with different dilations of 48, 76, 96, 111, 124, 135, 144, and 152 in the frequency dimension. These dilation rates are calculated by Eq. (1) with $Q = 48$ and rounded to integers. All the outputs of these layers integrate the harmonic information for each frequency unit.

The max-pooling layer downsamples the frequency bins from 352 to 88 with pooling size of 4, four bins per semitone to one bin per semitone. Then four identical dilated convolution blocks make the network deeper to achieve higher learning capacity. Each block contains one convolution layer with kernel size of 5×3, and dilation of 1×12.

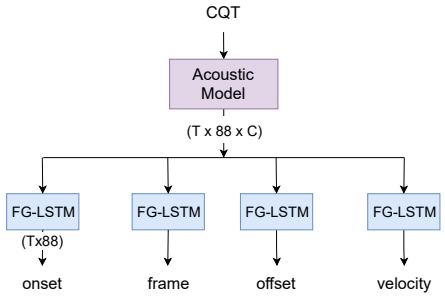

Figure 3. HPPNet-base. Onset, frame, offset, and velocity tasks share the same acoustic model.

Finally, four FG-LSTM heads are used to predict frames, onsets, offsets, and velocities separately as shown in Figure 3. These outputs are then decoding to note events with the same way as the Onsets & Frames [8] model. Note that the offset head is just used for training and not directly used during decoding. Each head uses a linear layer with a sigmoid activation function to output the prediction. All the outputs are matrices of size $T \times 88$, where T denotes frame number and 88 represents the 88 piano keys. The LSTM is bidirectional, and both forward and backward directions have 64 units. The hyperparameters of the network are summarized in Table 2. We denote this model the HPPNet-base.

Layer	repeat	kernel	filters	dilation
Conv	3	7×7	16	-
HD-Conv	1	1×3	128	48, 76, ..., 152
Dilated Conv	4	5×3	128	1×12

Table 2. Hyperparameters of convolution layers.

All the FG-LSTM heads in HPPNet-base share the same acoustic model, making it simple and efficient. But in our experiments, we try multiple acoustic models and find that if a stand-alone acoustic model is used to predict the onset, the model will perform better in onset detection. Since the onset F-measure is the metric that correlates best with human judgment [28], we use an individual acoustic model for onset. Frame, offset, and velocity share another acoustic model. The HPPNet-sp is shown in Figure 4. The output representations of the onset acoustic model are concatenated with outputs of the other acoustic model to pre-

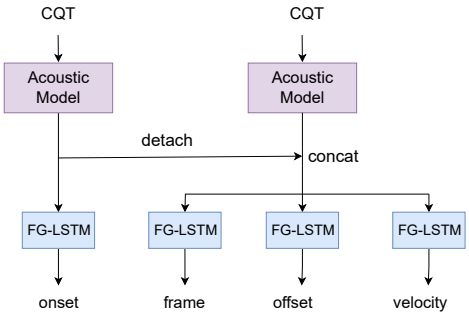

Figure 4. HPPNet-sp. Onset and other tasks use separate acoustic models.

dict frame, offset, and velocity (detach to avoid backward propagation).

3. EXPERIMENTS

In this section we first introduce the datasets we used. And then, we describe the details of the experiment and the training loss for our model.

3.1 Datasets

MAESTRO [8] (MIDI and Audio Edited for Synchronous Tracks and Organization): It includes about 200 hours of paired audio and MIDI recordings from ten years of International Piano-e-Competition. Audio and MIDI files are aligned with 3 ms accuracy and sliced to individual musical pieces annotated with composer, title, and year of performance. The MIDI have been collected by Yamaha Disklaviers which have a high-precision MIDI capture system.

MAPS [29] (MIDI Aligned Piano Sounds): It includes about 31 GB of CD-quality recordings and corresponding annotations of isolated notes, chords, and complete piano pieces. The records contain both synthesized audio and real audio by Virtual Piano software and a Yamaha Disklavier respectively.

3.2 Experimental setup

We use PyTorch [1] to implement our model. The training is performed by Adam [30] optimizer with mini-batch size 4, and a learning rate of 0.0006 for 200k to 500k steps with early stopping. The training time on an NVIDIA GeForce 3060 GPU with 12 GB VRAM is about 48 hours. The note and frame scores are calculated by the mir_eval library [31]. The evaluation uses a 50 ms tolerance for note onset and an offset ratio of 0.2 as the default configuration in mir_eval. The onset and frame thresholds are both set to 0.4 on the sigmoid output in our model. All the hyperparameters are selected by the performance on the validation split of MAESTRO.

The losses we use for training are similar to the Onsets & Frames model. The losses of onset, frame, and offset are binary cross-entropy losses. The weighted frame loss is not used in our training. The loss of velocity is the mean squared error loss. All losses are summed together as the final loss. All the losses are as follows:

$$l_{bce}\left(y\ ,\ \hat{y}\right) = -wy\log(\hat{y}) - (1-y)\log(1-\hat{y}), \quad (2)$$

$$L_{onset} = \sum_{p=1}^{88}\sum_{t=1}^{T} l_{bce}\left(n_{p,t}\ ,\ \hat{n}_{p,t}\right), \quad (3)$$

$$L_{frame} = \sum_{p=1}^{88}\sum_{t=1}^{T} l_{bce}\left(f_{p,t}\ ,\ \hat{f}_{p,t}\right), \quad (4)$$

$$L_{offset} = \sum_{p=1}^{88}\sum_{t=1}^{T} l_{bce}\left(o_{p,t}\ ,\ \hat{o}_{p,t}\right), \quad (5)$$

$$L_{velocity} = \sum_{p=1}^{88}\sum_{t=1}^{T} n_{p,t}\left(v_{p,t} - \hat{v}_{p,t}\right)^2, \quad (6)$$

$$L = L_{onset} + L_{frame} + L_{offset} + L_{velocity}. \quad (7)$$

where l_{bce} denotes the binary cross entropy loss, p is the piano note index range from 1 to 88, T is the frame number in a sample, w denotes the positive weight ($w = 2$ for onset, $w = 1$ for frame and offset), y denotes ground true and $\hat{y}$ denotes predicted values range from 0 to 1, $n_{p,t}$, $f_{p,t}$, $o_{p,t}$, and $v_{p,t}$ are the ground true of onset, frame, offset, and velocity seperately.

3.3 Baselines

Our model is compared with five typical models, including High-Resolution piano transcription [12], Onsets & Frames [9], Adversarial onsets & frames [11], Semi-CRFs [32] and the sequence-to-sequence Transformer [10]. The results are shown in Table 3. High-Resolution and Onsets & Frames are convolution-based models composed of convolution layers and LSMT layers. Especially, the High-Resolution is the best model in note F1 score which is 96.72%. Adversarial onsets & frames is an adversarial training scheme that operates on the Mel-spectrogram. Semi-CRFs is a Semi-Markov Conditional Random Fields (semi-CRF) based model, which treats note intervals as holistic events. Sequence-to-sequence Transformer uses a generic Transformer architecture with standard decoding methods.

4. RESULTS

We compare our model with some existing state-of-the-art methods using the MAESTRO dataset and the MAPS dataset. Then, ablation studies are done to demonstrate the affects of FG-LSTM, and HD-Conv. We also examine the model performance on small datasets.

4.1 Comparison with baselines

Along with the HPPNet-base and HPPNet-sp, we also evaluate the HPPNet-tiny, which has a similar structure as HPPNet-base but reduces the maximum convolution channel size and units in LSTM from 128 to 48.

Evaluation on the MAESTRO dataset is shown in Table 3. The HPPNet-sp achieves state-of-the-art in both frame F1 score and note F1 score, which improved 3.24 percentage points and 0.49 percentage points, reaching 92.86% and 97.21% in MAESTRO v2 respectively. In the last two columns, under the condition of note with offset, it still outperforms other models except the event-based Semi-CRFs method. Even slight structure of HPPNet-base still achieves 92.51% and 96.25% on frame F1 score and note F1 score, respectively.

Moreover, another significant advantage is that our model has much fewer parameters, around 820 thousand HPPNet-base and 1.2 million HPPNet-sp. The lightweight structure HPPNet-tiny with 151 thousand parameters still outperforms the baseline Onsets & Frames, that the frame F1 score and the note F1 score reaching 92.06% and 95.82%. This proves the effectiveness of HPPNet in both improving performance and reducing model size.

Empirical results in Table 3 show that among all compared frame-level models, our model performs best in all scores. It is interesting to note that HPPNet achieves improved recall while not or only slightly loosing precision. But the event-based Semi-CRFs has better prediction on offsets, for it predicts note intervals directly rather than individual frames. Maybe future works that combining the frame-level and event-level can take advantage of the both sides.

To further explore the generalization of the HPPNet in different datasets, we train the model on the MAESTRO dataset and evaluate it on the MAPS dataset. The result is shown in Table 4. we can find that the HPPNet-sp's note F1 still reaches 87.56%. This result is better than Onsets & Frames of 83.04%, even outperforming Onsets & Frames with audio augmentation of 86.44%. The result confirms that the HPPNet has better generalization ability on piano transcription task.

4.2 Ablation study

We further analyze the role of the HD-Conv layer and FG-LSTM in the HPPNet. In addition to the HPPNet, we evaluate three types of models, the F1 in frame-wise

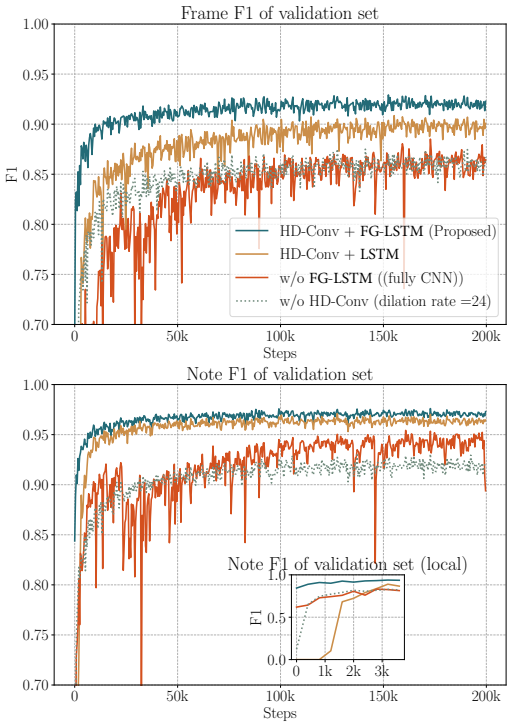

Figure 5. F1 in frame-wise and note-wise of MAESTRO v3 validation set.

and note-wise during training per epoch shown in Figure 5:

- To verify the effect of FG-LSTM: change FG-LSTM to normal LSTM with frequency flattening.
- To verify the effect of LSTM: remove time-series layers, which change them to linear layers.
- To verify the effect of harmonic dilated convolution: replace the harmonic dilated convolution with fixed dilated convolution (dilation rate of 24).

These results suggest that the the HPPNet outperforms the other three ablated models. The F1 of normal LSTM decreases about three percentage points and one percentage point on frame-wise and note-wise, respectively. Usual LSTM starts later than the HPPNet in note-wise F1 at the beginning of training, and it starts to increase after about 1k steps. The HD-Conv + vanilla LSTM is better than changing time-series layers to linear layers. Model without RNN converges slowly and fluctuates drastically. A large receptive field helps model get global information. Using the fixed dilation rate has a similar receptive field to HD-Conv. But the result shows it does not capture useful information for the detection of frames and onsets, leading to poor performance.

4.3 Performance on small datasets

The HPPNet trained on big dataset such as compete MAESTRO shows promising results, and it also shows better generalization when inference on MAPS. To evaluate the performance of the HPPNet on smaller dataset, we also train the model with 30% and 10% of MAESTRO training split. All the samples are randomly selected and without data augmentations. The results are displayed in Table 5. When the training set size decreases to 10%, the HPPNet-sp drops less than Onsets & Frames on frame F1 and note F1 scores with 88.31% and 93.52% respectively, while the Onsets & Frames approach only yields 80.36% and 90.62%. This demonstrates that the HPPNet relies less on data thanks to the small amount of parameters and priors contained in HD-Conv and FG-LSTM.

Model	Data	FRAME			NOTE		
		P (%)	R (%)	F1(%)	P (%)	R (%)	F1(%)
Onsets& Frames	100%	94.43	85.50	89.68	98.67	92.08	95.22
	30%	91.14	80.00	85.08	98.13	89.57	93.60
	10%	90.66	72.70	80.36	96.64	85.46	90.62

	30%	90.72	92.11	91.35	96.46	94.46	95.43
	10%	92.10	84.96	88.31	96.59	90.94	93.52

Table 5. The transcription evaluation result on MAESTRO v3 test split, which training was done on the 100%, 30%, and 10% of MAESTRO v3 training split respectively. Considering the annotation accuracy, we use subsets of MAESTRO rather than the MAPS for evaluation.

5. CONCLUSION

In this paper, we design a model that carries piano inductive biases to capture piano priors. The HPPNet is proposed to model the harmonic structure and the pitch-invariance over time in piano transcription. Experimental results show that the model achieves state-of-the-art performance on the MAESTRO dataset, with frame F1 of 93.15% and note F1 of 97.18%. The success stems from two aspects: (i) the harmonic dilated convolution exploited to capture harmonics structure; and (ii) the frequency grouped LSTM designed based on the pitch-invariance of piano key over time. Furthermore, the model parameters are much fewer than the previous state-of-the-art models.

The results of the model on piano transcription are encouraging. And it may also be suitable for other instruments with similar pitch characteristics. But some challenges remain, such as improving performance in offset detection and modifying the model to other polyphonic transcriptions involving vocals and instruments with a less stable pitch. The harmonic dilated convolution implemented by multiple parallel dilated convolutions is computational consuming and needs to be optimized in the future.

6. ACKNOLEDGEMENT

This work was supported by National Key R&D Program of China(2019YFC1711800), NSFC(62171138). Wei Li and Yi Yu are corresponding authors of this paper.

ABSTRACT

The field of Automatic Music Generation has seen significant progress thanks to the advent of Deep Learning. However, most of these results have been produced by unconditional models, which lack the ability to interact with their users, not allowing them to guide the generative process in meaningful and practical ways. Moreover, synthesizing music that remains coherent across longer timescales while still capturing the local aspects that make it sound "realistic" or "human-like" is still challenging. This is due to the large computational requirements needed to work with long sequences of data, and also to limitations imposed by the training schemes that are often employed. In this paper, we propose a generative model of symbolic music conditioned by data retrieved from human sentiment. The model is a Transformer-GAN trained with labels that correspond to different configurations of the valence and arousal dimensions that quantitatively represent human affective states. We try to tackle both of the problems above by employing an efficient linear version of Attention and using a Discriminator both as a tool to improve the overall quality of the generated music and its ability to follow the conditioning signals.

1. INTRODUCTION

One of the driving factors behind the human experience of music is the emotional content that it conveys. Several works in the area of Musical Information Retrieval (MIR) have focused on Music emotion recognition, that is, automatic recognition of the perceived emotion of music based solely on the musical information itself [1]. In this context, emotion is often represented according to the valence and arousal dimensions originated from to the Russell circumplex model [2]. While valence expresses how pleasurable or displeasurable an emotion is, arousal represents the level of alertness associated with that emotion, going from relaxed to excited. However, within the realm of *Deep Learning* comparatively little research has focused on reverting this process, that is, instead of predicting the affective content of a musical passage, being able to generate musical pieces that project a desired emotional state.

Deep Neural Networks are now capable of generating songs that display coherent chord progressions, melodies and even lyrics [3], despite the fact that these characteristics often do not persist across longer time scales. While there are several reasons behind this fact, two of them stand out. Firstly, there are the inherent computational and memory costs involved in modeling longer sequences of data. Secondly, the most common technique used to train these models, teacher forcing or Maximum Likelihood Estimation (MLE) [4], makes them work with data distributions that are different during training and inference time (real vs synthetic). This is known as exposure bias [5]. One of the ways to alleviate this problem is by delegating the task of judging which samples are good and which are not to a different neural network that is trained in conjunction with the generative model. This is the motivation behind the use of Generative Adversarial Networks (GANs) [6] within the realm of sequence generation [7].

In this work, we present a generative model of music capable of synthesizing songs conditioned by values of valence and arousal that correspond to perceived sentiment [2]. The ability of automatically generating music that follows a specific pattern of emotions can be interesting in various contexts, e.g. producing soundtracks to accompany story-driven forms of media such as Video-Games and Movies, which often use music as a means of guiding the audience towards a specific emotional state that suits the narrative. The goal here is to provide users who may not have the musical background necessary for composition a way of translating their perception into songs that can suit their artistic aspirations.

In an effort to mitigate the shortcomings of teacher forcing-style training, we complement it with an additional adversarial signal provided by a Discriminator network. This addition has a positive effect on the generated samples, and we demonstrate, through evaluations of our model both via automatic metrics and human feedback, that the proposed Transformer GAN obtains a performance that competes with a current state-of-the-art model, even while having a smaller set of parameters and using a simpler representation of music. To summarise, our contributions are as following:

- We present a neural network that, up to our knowledge, is the first generative model based on GANs to produce symbolic music conditioned by sentiment.

Neves, Jose Fornari, and João Batista Florindo, "Generating music with sentiment using Transformer-GANs", in *Proc. of the 23rd Int. Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

- We show, both through automatic and human evaluation, that our model obtains a competitive performance with that of a current state-of-the-art model on the task of music generation conditioned by sentiment.
- We show that promising results come from using Generative Adversarial Networks within the context of music generation conditioned by sentiment, as our model obtains a good performance despite having less parameters, using a simpler symbolic representation, and, being, up to our knowledge, the first on this task to be trained via an adversarial scheme.

2. RELATED WORKS

2.1 Generative Adversarial Networks

Generative Adversarial Networks, or simply GANs, consist of a theoretical framework in which two Neural Networks, the Generator and the Discriminator, through competition, optimize a model that implicitly approximates a data distribution by generating samples that try to mimic the features that it observes on a given set of samples originating from that distribution. Each of the networks is trained to optimize an objective function. The objective of the Discriminator D is to separate the real samples from those that are created by the Generator G, whose job is to produce samples that are so similar to those of the real distribution that the Discriminator is unable to determine which of them are real and which are fake. This whole process is equivalent to a min-max game that can be formalized by Equation 1.

$$\min_G \max_D V(D,G) = \mathbb{E}_{\boldsymbol{x}\sim p_{data}(\boldsymbol{x})}[\log D(\boldsymbol{x})] + \mathbb{E}_{\boldsymbol{z}\sim p_z(\boldsymbol{z})}[\log(1 - D(G(\boldsymbol{z})))]. \quad (1)$$

In the equation above, $p_{\text{data}}(\boldsymbol{x})$ is the real data distribution, and $p_z(\boldsymbol{z})$ is a prior on input noise variables that come from a normal distribution, and which are then mapped to data space by G, so that the synthetic distribution, p_g, can be learned.

Due to the inherent instability of the adversarial process, several works have focused on improving the convergence and the quality of the samples generated by GANs via new objective functions, regularization and normalization techniques, and model architectures. Of particular interest to this work is RSGAN [8], which substitutes the standard GAN loss for the non-saturating Relativistic Standard Loss. Here, as the authors put it, the Discriminator estimates the probability that the given real data is more realistic than a randomly sampled fake data. Equations 2 and 3 correspond to the objectives for the Discriminator and the Generator, respectively.

$$\mathcal{L}_{RSGAN,D} = - \mathbb{E}_{(x_r,x_f)\sim(\mathbb{P},\mathbb{Q})}[\log(\text{sigmoid}(D(x_r) - D(x_f)))] \quad (2)$$

$$\mathcal{L}_{RSGAN,G} = - \mathbb{E}_{(x_r,x_f)\sim(\mathbb{P},\mathbb{Q})}[\log(\text{sigmoid}(D(x_f) - D(x_r)))], \quad (3)$$

in which $\mathbb{P}$ and $\mathbb{Q}$ are, in this order, the real and fake disributions.

In order to provide more stability to the training process, WGAN-GP [9] introduces a Gradient Penalty in the form of an additional loss that enforces a Lipschitz constraint on the Discriminator. This loss is expressed in Equation 4:

$$\mathcal{L}_{GP} = \mathbb{E}_{\hat{x}\sim\mathbb{P}_{\hat{x}}}[(\|\nabla_{\hat{x}} D_\phi(\hat{x})\|_2 - 1)^2] \quad (4)$$

where $\hat{x}$ is sampled along straight lines between pairs of points taken from the real and fake data distributions, and ϕ are the Discriminator parameters.

One possible strategy that can be used to combat the effect known as exposure bias [5], characterized by the disparity between the data available to the network during training and inference time when the model is trained via standard Maximum Likelihood Estimation (MLE), is the insertion of a Discriminator into the training process as a tool to guide the Generator. Nevertheless, generating discrete sequences with GANs is notoriously hard. This is mostly due to the fact that the outputs of some sequence models are discretized in a way that prohibits the gradient of the Discriminator loss to propagate through the Generator. Several strategies have been proposed to circumvent this issue [10–12]. Here, we employ the Gumbel-Softmax technique presented in [11] and applied to adversarial training in [12]. Mathematically, if we have a categorical distribution with class probabilities $\pi_i, i \in i, ..., d$, we can draw samples y from this distribution using:

$$y = \text{one\_hot}\left(\arg\max_i [g_i + \log \pi_i]\right) \quad (5)$$

where each $g_i, i \in i, ..., d$ is taken from a Gumbel Distribution with location 0 and scale 1. From this expression, one can obtain a continuously differentiable approximation of the categorical distribution parameterized in terms of the softmax function:

$$y = \text{softmax}((1/\tau)(\pi + g)), \quad (6)$$

where τ is a temperature parameter that regulates how close to the categorical (lower τ) *versus* to the uniform distribution (higher τ) is y. This parameter is annealed from large values to close to zero during training. Here, we use the same schedule as in [13], that is, $1/\tau = (1/\tau_{\min})^{n/N}$, where n is the index of the current global optimization, N is the total number of steps and $\tau_{\min}$ is a hyperparameter which we chose to be 10^{-2}.

2.2 Transformers

Shortly after its presentation in 2017, the Transformer [14] became the most popular architecture in the field of Natural Language Processing (NLP), and it has also been successfully applied to other areas, such as image recognition [15] and audio [16]. The main reason behind its success is the

Self-Attention mechanism, which allows it to model relationships between all elements of a sequence. The mechanism takes in matrices Q, K, and V, corresponding, respectively, to Queries, Keys and Values, and calculates a weighted sum of the values where the coefficients are given by a similarity function between the queries and the keys.

One of the models developed with the intent of decreasing the computational costs associated with the calculation of Attention matrices [17–20] is the Linear Transformer [18], which, as the name suggests, employs a version of the attention mechanism with computational and memory requirements that grow linearly with respect to sequence length (standard Attention has quadratic requirements), and is also faster than regular attention. This is achieved via the substitution of the standard softmax similarity score by one that allows the matrix multiplications necessary for the calculation of the attention matrix to be factorized in a more efficient way. If that kernel has a feature representation $\phi(x)$, one can write the Attention matrix as:

$$A(Q,K,V)_i = \frac{\sum_{j=1}^{N} \phi(Q_i)^T \phi(K_j) V_j}{\sum_{j=1}^{N} \phi(Q_i)^T \phi(K_j)}. \qquad (7)$$

With this expression, it is possible to calculate the factor inside the sum only once, and to reuse it to find all the queries. Specifically, the authors use the kernel with a feature map that results in a positive similarity function: $\phi(x) = \text{elu}(x)+1$, where elu is the exponential linear function [21]. In this same work, the authors also discover an analogy between the Transformer and the RNN. We refer to [18] for further details on the Linear Transformer.

2.3 Generative Models of Music

As of the writing of this paper, most of the state-of-the art generative models of symbolic music are Transformers or Transformer-based. Music Transformer [22] uses relative self-attention [23] to process longer sequences of data and generate music that exhibits long-term structure. MuseNet [24] is able to produce multi-track compositions spanning several musical genres and artists by employing time, note and structural embeddings that give the model more context.

Midinet [25] and MuseGAN [26] are GAN-based generative models of music that use Convolutional Neural Networks (CNNs) as both the Generator and Discriminator. In those works, music is represented in the form of piano-rolls that work analogously to images. Most similar to our work are [27], where the Discriminator is trained to judge the content both locally and globally, and [13], which uses a Transformers-XL [28] as Generator and a pre-trained BERT [29] as Discriminator, and also employs the Gumbel-Softmax trick discussed above.

Several works have also explored conditioning musical generation with emotional content. In [30], human emotions are captured from images of human faces and then categorized into 7 categories. Then, the researchers try to generate music based on these emotions. In [31], Biaxial LSTM networks are used to produce polyphonic music, and the generation can be conditioned by emotion via 4 parameters originating from the valence and arousal dimensions. In [32], the authors translate between the visual and musical domains via emotions. Specifically, they use neural networks to extract emotional content from images and music, and subsequently feed the content originated from both pieces of data into a network to condition music generation. Music Fadernets [33] constitute a framework that can infer high-level feature representations by first modelling their equivalent low-level attributes, which are easier to quantify. These low-level features are then used for style transfer across arousal states. In [34], a model dubbed Bardo Composer is presented as a system to generate backgorund music for tabletop role-playing games. This is done through Stochastic Bi-Objective Beam Search (SBBS), a search algorithm that samples from a distribution of sequences and selects for one that maximizes for realism and emotion. Furthermore, [35] uses a genetic algorithm to influence specific LSTM units that learn to encode sentiment in a pre-training language modeling stage, allowing it to steer the passages that it generates towards a desired affective state. In [36], the authors use pre-defined mood-tags associated with each chord in a progression to guide the generative process step-by-step. The EMOPIA dataset [37] contains musical passages separated into four quadrants that each corresponds to a combination of positive or negative arousal and valence. The excerpts on the dataset are from piano transcriptions of pop songs that were labeled by its authors. In this same work, the authors also use a Transformer model that employs the Compound Word representation [38] to generate songs conditioned by affective states.

One of the factors that influence the final quality of the samples generated by models of symbolic music is the representation used to train them. For contemporary styles, like Pop or Hip-Hop, where a rigid metrical grid is often followed, it is desirable to incorporate data about the rhythmic structure of the songs into the representation. REMI [39], which stands for revamped MIDI-derived events, is a beat-based approach to modeling music that encodes this information through tokens that signal the beginning of a bar and the passage of each beat, while still maintaining some flexibility by allowing local tempo changes. More specifically, there NOTE_ON, NOTE_DURATION, VELOCITY, TEMPO, BAR and BEAT. A NOTE_ON event indicates the start of a note, NOTE_DURATION corresponds to the duration of that note, and VELOCITY is a parameter that indicates the intensity with which the keys on a piano are played, and correlates to the volume of the note produced. Finally, TEMPO dictates the tempo of the musical excerpt from the moment the token is produced forward, and BAR events indicate the start of a new bar. The Compound-Word Transformer [38] uses a separate embedding for each type of musical element (pitch, chord, tempo value, etc.).

3. METHODS

3.1 Architecture and Loss functions

Both the Generator and Discriminator are Transformers with linear versions of the Attention Mechanism [18]. Each of the models is composed by 6 Attention blocks.

The Generator has two roles. In the first place, it has to predict each item of each sequence from the real dataset based on the previous elements, that is, it has to complete pieces of already existing sequences. In standard Transformer fashion, a lower triangular or look-ahead mask is applied to the original sequence in order to prevent the model from seeing its future elements. The second objective of the network is to generate sequences that are similar to those of the real set from scratch, that is, without context from the real dataset, such that these sequences can fool the Discriminator. These sequences are generated step-by-step in an autoregressive manner, which is done via the Transformer-RNN analogy made in [18]. ¨

The Generator is conditioned via special scale and bias parameters that influence the Layer Normalization [40] layers existing within the Attention mechanism. There is one of these couples for each class on the dataset and one for the unlabeled sequences. Formally, if i, k and c stand, respectively, for position in the sequence, feature channel and class label, we have:

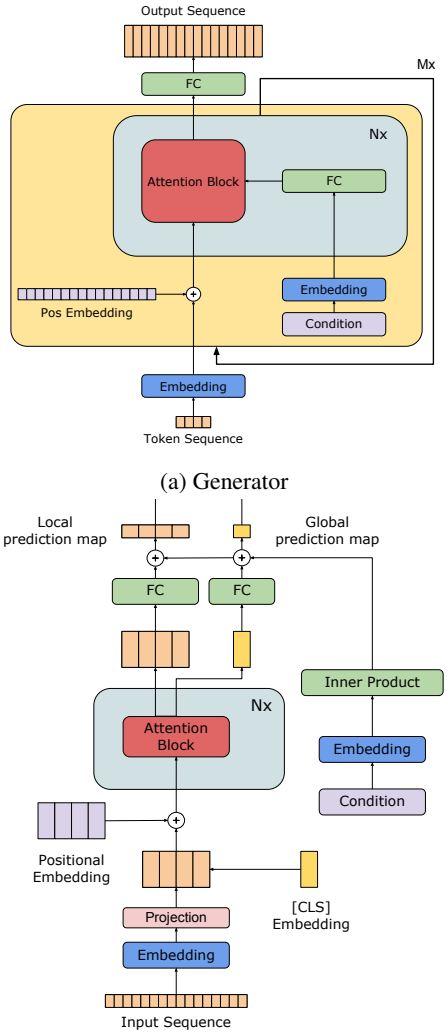
$$s'_{i,k} = \gamma^c_k \cdot s_{i,k} + \beta^c_k \tag{8}$$

where s and s' are input and output sequences, and γ and β are scale and bias.

The Discriminator takes each sequence as a whole and tries to determine if it is real or fake. To design this network, we took inspiration from the Visual Transformer [15], separating the sequences into patches of a certain length and transforming each patch into a single feature vector.

Our Discriminator has two outputs. First, there is a single feature unit that indicates if the passage originates from the real or fake datasets and if it exhibits the desired characteristics provided by the conditional signal. To produce this output, a [CLS] token is concatenated to the input sequence, similarly to BERT [29]. Then, the conditional information is incorporated via an inner product between an embedding of this information and the [CLS] representation. This essentially means that the model works as a Projection Discriminator [41]. The second output is a prediction map where each unit corresponds to a single patch in the sequence, that is, for every collection of musical symbols with length equal to the patch size, there is a value predicting whether that patch is real or fake. This technique, often used in image generating-GANs [42], ensures that the model prioritizes local structure.

Each of these two outputs serves the purpose of incorporating priors about musical structure into our model. A common way to frame the task of musical generation is as a language modelling one: each individual symbol is treated as a word, and these words compose phrases, periods, and so on. Using this analogy, the goal behind the proposed local loss is to inform if each particular sentence in a text is realistic or not, or, translating that to music, if every short musical idea in the form of a phrase or part of a phrase is realistic or not. The global prediction unit, on the other hand, acts as a signal that encapsulates the overall quality of the sequence and its ability to convey the desired emotional state, complementing the local prediction map. The networks are illustrated in Figure 1.



(a) Generator

(b) Discriminator

Figure 1: Generator and Discriminator. FC stands for Fully-Connected Layer. N is the number of self-attention blocks from which the models are made. M represents the number of autoregressive steps the Generator executes, that is, the sequence length.

3.2 Datasets

We used two datasets to train our models, mainly as a means to allow the networks to use a larger training corpus. Both consist only of songs performed on piano. The AILABS17k dataset [38] contains over 108 hours of piano covers of pop songs automatically transcribed by a state-of the art piano transcription model [43] and converted into MIDI files. The EMOPIA dataset [37] was constructed in

a similar fashion to the one above, but its songs were afterwards labeled by the authors of the dataset according to perceived sentiment [2]. The clips on this dataset amount to approximately 11 hours. We used AILABS 17K to allow the networks to learn a general representation of music in a larger corpus, while also being trained on a smaller collection of songs that contains annotated data.

3.3 Training

We use the data representation proposed in [39], which consists of the NOTE_ON, NOTE_DURATION, VELOCITY, TEMPO, BAR and BEAT events described previously. Before the introduction of the Discriminator, the Generator was trained until convergence through the teacher forcing method (26000 steps). This pre-training stage guaranteed the stability of the adversarial stage that was to follow [13, 27, 44]. In this stage, the Generator was trained simultaneously on both datasets, and taking into consideration the difference in size between these datasets, to balance the training process, we alternated between optimization steps on randomly sampled batches from each set. The network worked with sequences of length 2048, corresponding, on average, to 1 minute of content.

For the adversarial stage, we used sequences of size 128. In order to reduce the effects of gradient variance that are inherent to the sampling process, sequences with length 16 originated from the real set were given to the Generator such that it could have a starting point to perform generation [27]. The Discriminator worked with subsequences of length 16, and the training was done exclusively on the EMOPIA dataset [37].

The networks were trained via a combination of the teacher forcing objective plus the RSGAN objective [8] with gradient penalty [9]. We performed 1 optimization step of the Discriminator per Generator step, using a learning rate of $1 \cdot 10^{-4}$. In total, 26000 global optimization steps were performed. The overall objective for the generator in this training stage is:

$$\mathcal{L}_G = \mathcal{L}_{\text{MLE}} + \alpha\mathcal{L}_{\text{RSGAN}_G\text{-global}} + \beta\mathcal{L}_{\text{RSGAN}_G\text{-local}}, \quad (9)$$

$$\text{where } \mathcal{L}_{mle} = -\mathbb{E}_{x\sim P}[\log G_\theta(x)] \quad (10)$$

where the factors $\mathcal{L}_{\text{RSGAN}_G\text{-global}}$ and $\mathcal{L}_{\text{RSGAN}_G\text{-local}}$ are respectively the global and local GAN losses detailed above, α and β, which we empirically chose to be equal to 1, are hyperparameters controlling the relative intensity of each loss factor, and $\mathcal{L}_{\text{MLE}}$ is the Maximum Likelihood. The Discriminator was simply trained with the local and global RSGAN objectives given previously in Equation 2 plus the global and local gradient penalties based on Equation 4 and regulated by a hyperparameter λ (which as per [9], we chose to be 10) . This loss is expressed as Equation 11. An algorithm outlining the training scheme is available in the supplementary material.

$$\mathcal{L}_D = \mathcal{L}_{\text{RSGAN}_D\text{-global}} + \beta\mathcal{L}_{\text{RSGAN}_D\text{-local}} + \lambda(\mathcal{L}_{\text{GP-global}} + \mathcal{L}_{\text{GP-local}}). \quad (11)$$

4. EXPERIMENTS

We evaluated our models both with respect to the overall quality of the samples they produce and their ability to generate songs that convey the conditioning emotional signals. To achieve this purpose, we used both the automatic evaluation metrics proposed in [26, 45] and a set of human evaluation metrics to compare our GAN with the system that, as far as we know, corresponds to a state-of-the-art generative model of symbolic music conditioned by sentiment currently available in the literature. Specifically, our model was compared with the Compound-Word Transformer [38] variation used by the authors of the EMOPIA article [37] to generate music conditioned by emotional class. We also compared our adversarially trained model with a Vanilla Transformer model that was not trained with the adversarial scheme. This model corresponds to the version of the generator network obtained after the pretraining was completed. Code for this work, along with audio samples, are available at [1] .

For the automatic metrics, we chose Pitch Range (distance between highest and lowest pitch), Number of Pitch Classes, and Polyphony (the average number of simultaneous notes). These metrics were calculated using the Muspy library [46]. For each model, we generated 400 samples (100 for each class) and evaluated these samples with respect to the characteristics above, then averaged the results to produce the overall model score. The results are presented in Table 1.

	PR	NPC	POLY
Real Data (EMOPIA) [37]	50.94	8.50	5.60
Baseline [37]	49.76	**8.52**	4.36
Transformer	48.79	8.65	4.37
Transformer GAN	**50.73**	9.45	**4.43**

Table 1: Comparison between the samples generated by ours and a state-of-art model. PR stands for Pitch Range, NPC is Number of Pitch Classes and POLY is Polyphony. The best results are highlighted in bold.

As it can be seen, our model obtains a superior performance than that of the baseline and the pre-trained model on two of the three metrics. Furthermore, it should be mentioned that the Generator is significantly smaller than the baseline, having only 6 Attention layers, while the latter has 12. To be more precise, the baseline has $\sim 40M$ parameters, while our generator has $\sim 25M$ and our Discriminator has $\sim 27M$. Also relevant is the fact that the representation used to train the baseline, that is, the Compound-Word representation [38], is more complex than the REMI representation that we use [39], and has also been proved to be better than REMI. Since the focus of our work was to implement the GAN framework within the context of symbolic music generation conditioned by sentiment, and given the complexity of this framework, especially when it is applied to the discrete domain, we chose to use a simpler representation in order to maintain the focus of our work on the implementation of the GAN. But as

[1] http://github.com/pneves1051/transformers_sentiment

our results show, adapting it to work within the adversarial context, which we leave to future work, could bring about even better results.

Finally, we performed a survey in which participants were asked to judge the musical excerpts generated by the models both in terms of their overall quality and their ability to convey the desired sentiments. Specifically, participants rated the samples on a 5-point Likert scale that ranged from very low to very high with respect to the following characteristics: Human-likeness, Originality, Structure, Overall Quality, Valence, and Arousal. Details from each characteristic and the corresponding scale are given in the supplementary material. The participants were recruited from the researchers' online circles. Each of the participants had to listen to 12 musical excerpts in total, 4 from each model, and within those 4 item groups, one from each of the 4 emotional classes. Before the test, some text explaining the basic concepts behind the research was shown to the participants. In total, 18 individuals participated in the experiment.

We present the average participants' scores given to each model for Human-likeness, Originality, Structure and Overall Quality in Table 2. These results suggest that both the proposed Transformer, and the Transformer GAN, are competitive with a state-of-the-art model with respect to the four qualitative metrics.

On the next step of the evaluations, we took the participants' answers to the questions related to Valence and Arousal and compared them to the real emotional labels provided to the model during the generation process. Figure 2 illustrates the results of this experiment.

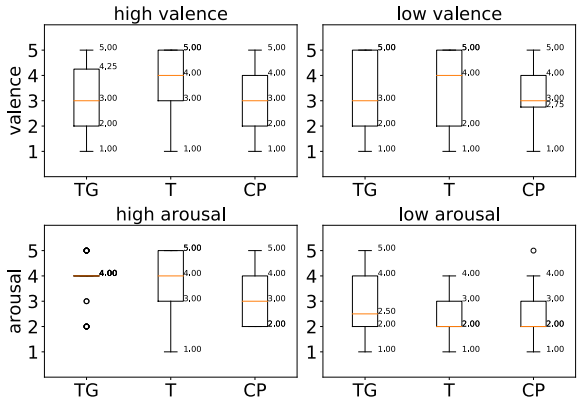


Figure 2: Results of the experiment where participants rated musical samples according to their perceptions about valence and arousal. The acronyms TG, T and CP correspond, respectively, to the Transformer GAN, Transformer and Compound-Word Transformer Baseline models.

Once again, we find that the models we developed obtain a performance that competes with that of the current state-of-the-art. By comparing the medians and quartiles of these boxplots, we can draw several conclusions. Firstly, all models seem to have more difficulty capturing valence than they do arousal. This may be an indication that musical aspects which have a great impact over arousal, such as velocity and tempo, are more easily understood by neural networks, while factors which have an impact over valence, such as modality or frequency of harmonic change [47], are more difficult to model for these systems.

Furthermore, we see that, in general, our models do not stand behind when compared to the baseline. Between the three, by observing the boxplots, it seems that while the Transformer and the Compound-Word baseline sometimes produce samples that situate themselves more strongly to the side to which they theoretically pertain (e.g., for the high valence and low arousal categories), the Transformer GAN surpasses the simple Transformer due to the fact that it never situates more than 50% of the excerpts on the incorrect side of the middle line, which in this case is represented by the number 3. While the excerpts generated by the Compound Word Transformer also show this same characteristic, we see that there is not a strong reason for us to believe that one stands out in comparison to the other.

Overall, given the superior ratings of the Transformer GAN respective to the automatic metrics and its competitiveness with a state-of-the art model with respect to the human evaluations, and given the considerations above about model size and representation, the Transformer GAN seems to be a promising model for music generation conditioned by sentiment.

4.1 Conclusion and future work

We introduced a model capable of generating musical excerpts conditioned by labels that represent perceived emotion. Through the use of MLE pre-training and adversarial training, we guided our model towards understanding some aspects of the relationship between musical structure and affect. Our experiments show that both in terms of quality and the ability to communicate emotion, the samples generated by the proposed model achieve competitive results. Furthermore, our work points to several possible avenues for future research, such as the use of other symbolic representations of music, the development of generative models conditioned by emotion that work directly on audio, and further exploration of the use of affective conditioning signals, e.g., using them to guide automatic composition second-by-second or to automatically generate royalty free music notation based on specific sentiments.

	H	O	S	OQ
Baseline [37]	3.32 ± 1.29	2.93 ± 1.13	3.18 ± 1.30	3.49 ± 1.04
Transformer	3.75 ± 1.24	3.22 ± 1.19	3.76 ± 1.14	3.89 ± 1.14
Transformer-GAN	3.56 ± 1.34	3.06 ± 1.21	3.38 ± 1.09	3.44 ± 1.15

Table 2: Results of the Survey where participants were asked to rate the samples generated by several models. The columns are, respectively, Human-Likeness, Originality, Structure and Overall Quality.

ABSTRACT

Choral music separation refers to the task of extracting tracks of voice parts (e.g., soprano, alto, tenor, and bass) from mixed audio. The lack of datasets has impeded research on this topic as previous work has only been able to train and evaluate models on a few minutes of choral music data due to copyright issues and dataset collection difficulties. In this paper, we investigate the use of synthesized training data for the source separation task on real choral music. We make three contributions: first, we provide an automated pipeline for synthesizing choral music data from sampled instrument plugins within controllable options for instrument expressiveness. This produces an 8.2-hour-long choral music dataset from the JSB Chorales Dataset and one can easily synthesize additional data. Second, we conduct an experiment to evaluate multiple separation models on available choral music separation datasets from previous work. To the best of our knowledge, this is the first experiment to comprehensively evaluate choral music separation. Third, experiments demonstrate that the synthesized choral data is of sufficient quality to improve the model's performance on real choral music datasets. This provides additional experimental statistics and data support for the choral music separation study.

1. INTRODUCTION

Choral music is a distinct artistic genre that includes several vocal parts (e.g. soprano, alto, tenor, and bass) arranged into intricate patterns from strict counterpoint to polyphonic echoes and flows of lyrics. One useful tool in the analysis and re-production of choral tracks is the ability to take mixed-down choral music and separate it back into audio tracks of isolated vocal parts: i.e. choral music separation, as a subtask of audio source separation.

Audio source separation is an audio signal processing task that involves separating one or more sound sources from a multi-source audio mixture. This task has a wide range of applications in a variety of domains, including speech separation, vocal-accompaniment separation and musical instrument separation. The latter two tasks are primary tasks in the field of music signal processing and have been adopted for practical use in the entertainment industry [1]. Many models, such as Open-Unmix [2], Demucs [3], and Spleeter [4], achieve great separation performance. Some models [5] further extend the source separation task to a zero-shot or query-based setting. However, choral music separation has received limited attention. Unlike general musical instrument separation, which seeks to separate non-homologous sources (e.g., piano, drums, and singing voice), choral music instrument separation seeks to separate homologous or close-homologous sources (e.g., soprano, alto, tenor, bass). Additionally, the scarcity of data on choral music separation impedes further progress. Choral music separation could be used in a wide variety of scenarios. Individuals could obtain solo tracks from choral recordings for practice, analysis, and re-production. Not only does it fill a void in a particular type of musical instrument separation, but it also provides convenience for music educators.

In this paper, we investigate the choral music separation task from the perspective of addressing the insufficiency of available datasets. We begin by introducing related works in the field of choral music separation. Second, we present the discovery of how to improve the performance of choral music separation using high-quality, synthesized music data. Then, we conduct comprehensive experiments with multiple models and datasets to evaluate the improvement of using synthesized data on choral music separation in real datasets. Finally, we discuss the extensibility of our pipeline to more choral-related separations, such as string quartet separation, as well as its future directions. The code and the dataset are publicly available [1] .

2. RELATED WORK

Research in choral music separation receives relatively less attention. Deep learning methods for audio source separation has already outperformed traditional methods (e.g. Non-negative Matrix Factorization [6]) for a long time. Separation models have been developed following two directions: frequency-domain models and time-domain separation models.

Table 1: Existing datasets for choral music separation.

2.1 Frequency-Domain and Time-Domain Models

The traditional method of audio separation is to mask the frequency-domain representation and then inversely transform it to the time-domain signal, referred as frequency-domain separation models. Spec-U-Net [7], based on the U-Net architecture, contains convolutional neural network (CNN) blocks for downsampling the input short-time Fourier transform (STFT) spectrogram and upsampling the bottom feature back into a separation mask. The mask is applied into the input to obtain the separate spectrogram as output. Res-U-Net [8] replaces the original CNN blocks with residual CNN blocks to accelerate convergence speed. On the other hand, time-domain models perform the separation directly on the audio waveform. Wave-U-Net [9] incorporates an end-to-end U-Net structure on the input and output of waveforms. Conv-TasNet [10] applies a CNN encoder-decoder structure to process waveforms into latent features and generates the mask. The masked latent features are decoded back to waveforms as separation results. Bypassing the spectrogram processing, time-domain models can save parameters and perform efficiently in low-latency systems for speech separation. Some hybrid models, such as Demucs v3 [3], can leverage both time-domain and frequency-domain features to achieve the best performance for musical instrument separation, while the size of the model is a little bit large.

2.2 Choral Music Separation

For choral music separation, [15] proposed a score-informed separation model based on Wave-U-Net and performed experiments on 347 (synthesized) Bach Chorale pieces from MIDI files with *MuseScore_General* SoundFont. This model performs well on this SoundFont-Synthesis dataset but poorly on real choral music datasets. [16] proposed a conditional Spec-U-Net to optimize the separation performance by conditioning on the fundamental frequency contour. However, as mentioned in their paper, due to the lack of choral music datasets, the evaluation was conducted on only three songs with a total duration of seven minutes. [14] proposed a harmonic overlap score to increase the model's sensitivity to different choral voices, thereby improving performance. It made use of a relatively large dataset containing 105 minutes of Bach and Barbershop Collections, but this dataset is *not* publicly available due to copyright concerns, which prevents it from being open source. And indeed, 100-minute is still not enough to help achieve an audio separation model with a high generalization ability, we expect to obtain a size more than that.

		Pitch range			
Name	Type	Soprano	Alto	Tenor	Bass
Standard MIDI		A0–C8	A0–C8	A0–C8	A0–C8
Noire [17]	Piano	A0–C8	A0–C8	A0–C8	A0–C8
Grandeur [18]	Piano	A0–C8	A0–C8	A0–C8	A0–C8
Voices Of Rapture [19]	Vocal	B3–D6	E3–G5	B2–C#5	A1–D4
Dominus Choir [20]	Vocal	G3–A5	G3–A5	E2–G4	E2–G4

Table 2: Sample instrument libraries we use for synthesizing choral music separation datasets.

In this paper, we first conduct four fundamental models: Spec-U-Net, Res-U-Net, Wave-U-Net and Conv-TasNet. Our objective is to demonstrate the efficacy of synthesized expressive data in improving separation performance on **real choral music datasets**. As a result, fundamental models enable us to consider the performance gains more directly associated with data changes and augmentations. Also, score-informed and conditional separation models introduce external information, such as musical notes of original songs or multi-pitch estimation results, to guide the separation's goal, while it also limits its applications. In practice, we frequently find ourselves in situations where the only available input is the audio. We continue to demand **unconditioned choral music separation**. As a result, we proceed directly to unconditioned choral music separation in this paper, without relying on any score conditions.

3. METHODOLOGY

3.1 Scarcity of Datasets

Existing datasets for choral music are listed in Table 1, collected from previous works and other public sources. We observe that most of these datasets have short total lengths; three of them are less than 20 minutes. The Choral Singing Dataset [11] and ESMUC Choir Dataset [13] have been used for choral music separation by [16], while the Dagstuhl ChoirSet [12] and Cantoria [13] Datasets were never used for separation tasks but instead for singing performance analysis. The Bach and Barbershop Collection [14] is relatively longer, but is not publicly available. As a result, when a model is trained and tested on such a small amount of data, its generalization and separation capabilities are severely limited. [15] directly synthesized 347 choral pieces of Bach's from MIDI files with *MuseScore_General* SoundFont and trained the model. However, this SoundFont-Synthesis dataset is dissimilar to true choral vocals. Moreover, it lacks lyrics and syllables. As a result, the trained model performs poorly on real datasets [15].

In the next section, we first introduce the pipeline of synthesizing audio datasets for choral music separation from sampled instrument libraries. Then, we train various models on our datasets and compare them to determine the best model. Finally, we transfer the best model weights to the real-world datasets shown in Table 1, fine-tune the model and determine whether it truly improves

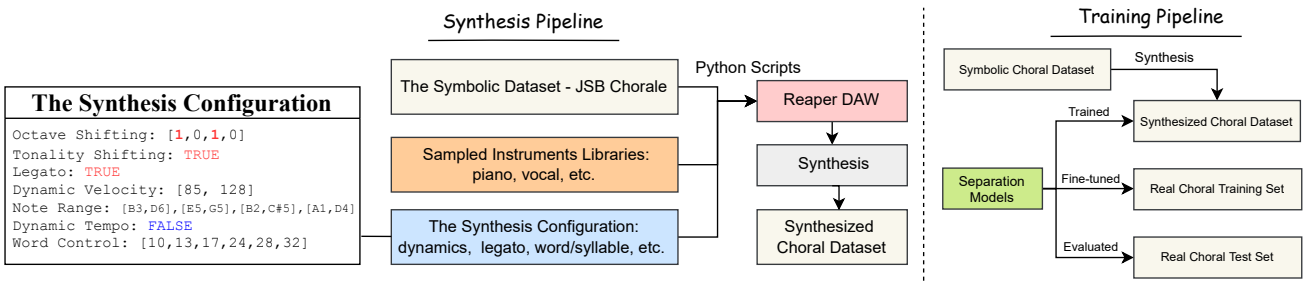

Figure 1: The synthesis pipeline of choral music data from sample instruments and the training pipeline to utilize it.

performance when compared to the previous settings.

3.2 Data Synthesis Pipeline

Figure 1 shows our pipeline of choral music dataset creation and training methods. Generally, we need three collection steps:

1. The symbolic choral music dataset (MIDI, MusicXML)
2. The sampled instrument libraries (standalone VST plugin, or Kontakt sample libraries)
3. The synthesis configuration (syllables or lyrics choices, legato, velocity, and tempo)

Then, our provided code can completely automate the data synthesis process. It is built on top of the python-support and free digital audio workstation (DAW) – Reaper [2] . With the above three steps, one could complete any choral music data synthesis process on supported system platforms.

3.3 Data and Instrument Collection

For Step 1, following [15], we use the JSB Chorales Dataset [21], which contains 347 pieces of choral music in MusicXML format. The total duration is 248 minutes at a tempo of 90 bpm (a.k.a. beat per minute). The data is first transformed into MIDI files, which serves as the symbolic dataset source for the creation of choral music audio. For Step 2, a sampled instrument [3] is a sound source plugin applied in a DAW. Unlike a SoundFont, it contains samples of real instruments recorded in a professional acoustic environment. The human singing voice is also considered as an instrument type. And many vocal sampled instruments support a variety of lyrical or syllabic sets (e.g., vowels, Latin words, etc.). We first choose two types of instruments for our purposes: piano and vocal (soprano, alto, tenor, and bass). Then, we choose two sampled instruments for each type, as shown in Table 2. The reason to choose the piano instrument is to evaluate the separation performance of piano as a common and same-source instrument. In this case, the model needs to consider most on the pitch difference between each voice part. When it comes to the vocal dataset, the model can distinguish the timbres slightly between soprano, alto, tenor, and bass voices, but it is more difficult to model the acoustic features of these four voices than piano. This allows us to determine whether the model can improve performance by exploiting the timbre difference between vocal datasets, or if it fails to model these timbres and perform a bad separation result.

Due to the fact that we have two sampled libraries for each type of instrument, each dataset contains $248 \times 2 = 496$ minutes (8.2 hours) of synthesized choral music data. All sampled instrument libraries that we use have a paid license.

3.4 Synthesis Configuration for Expressiveness

For Step 3, we adopt two methods to further improve the scalability and quality of synthesized data: the basic data augmentation, and expressiveness incorporation. The left of Figure 1 shows a specification.

We perform two operations to augment the data. First, we notice that the pitch ranges of sampled instrument libraries do not always correspond exactly to the pitch ranges of tracks in JSB Chorales Dataset. For instance, some bass melodies in JSB appear to be lower than the lowest note in sampled instrument libraries. Instead of directly discarding these tracks, we implement "octave shifting" by shifting out-of-range notes up or down some octaves until they fall within the range. While it produces non-realistic jumps between some melodies, it saves the whole track to preserve more realistic data. Second, we apply "tonality shifting" to each track. The tonality was shifted upward and downward by three semitones before synthesis. Therefore, the effective length of training data will be further augmented several times.

For expressiveness incorporation, we provide several options, which are supported by sampled instrument libraries, to synthesize audio:

- Legato: for vocal, this includes whether or not to change breath or sing continuously. In vocal instrument libraries, legato is controlled by detecting the presence of an overlap between adjacent notes. To support the legato configuration, we begin by segmenting the track into *musical phrases* using the breath break information in MusicXML (if provided) or the note intervals (if specified). Then, in each phrase, we add overlap to adjacent notes (to activate the legato) if their pitch distance is less than 7 semitones (i.e., a perfect fifth).

[2] https://www.reaper.fm/
[3] A detailed introduction can be found at https://tinyurl.com/2p8trn2u

- Velocity: for each phrase, we provide three types of volume/velocity change curves: *crescendo*, *diminuendo*, and *cresc.→dim.*. The configuration establishes the maximum and minimum velocity ranges.

- Word Control: for vocal, we support the word control of sampled instrument libraries by assigning random combinations of words or syllables to each phrase. Note that real-world performance may not contain random word changes, but for model training, this still increases the data richness on each training batch.

The configuration also supports the reverberation as a designed feature, but currently it is not applied in this work.

4. EXPERIMENTS

In this section, we conduct an experiment on evaluating different separation models on our synthesized datasets. The purpose of this experiment is to identify the best model on synthesized datasets and then transfer it to real choral music datasets.

4.1 Datasets, Models and Hyperparameters

As introduced above, we use two datasets (piano and vocal) to train four models (Spec-U-Net, Res-U-Net, Conv-TasNet, and Wave-U-Net). Each track is in 22,050 Hz sample rate. Each dataset contains 496 minutes data. We use 277 tracks for training, 35 tracks for validation and another 35 tracks for testing. Since we have training combinations among four models, two datasets, and four choral voices, to save training time, we first train models on the dataset *without* the expressiveness incorporation in section 3.4, named as **Standard-Piano** and **Standard-Vocal** datasets. After finding the best model, we will train it on the expressive datasets in section 4.3.

For model hyper-parameters, In Spec-U-Net [7], we use a window size of 2048, FFT size of 2048, and hop size of 441. We apply 7 CNN blocks to downsample the input spectrogram, and another 7 CNN blocks to upsample it into the separation mask. In Res-U-Net, we apply the implementation from [8], with 10 residual CNN blocks to downsample the input spectrogram, then another 6 residual CNN blocks to upsample. In Wave-U-Net, we follow the settings of [9] to adopt 6 downsampling CNN layers and 6 upsampling CNN layers for separation. The filter channels are set from 32 to 1024 in order for each layer. The kernel size is 15 for the first layer and 5 for remaining layers. In Conv-TasNet, we follow the setting of [10] to set hyper-parameters as $N = 512$, $L = 20$, $B = 128$, $H = 512$, $P = 3$, $R = 3$, $X = 8$. Spec-U-Net and Res-U-Net use their default mean absolute error (MAE) loss function; Conv-TasNet uses the default scale-invariant source-to-noise ratio (SI-SDR) loss; and Wave-U-Net with mean squared error (MSE) loss.

For training hyperparameters, the batch size is 8, the learning rate is 1e-3, and each training sample is a 2-sec audio segment randomly chosen from one music track in the training set. The number of steps for each epoch is 700. We apply the Adam optimizer [22] with $\beta_1 = 0.9$, $\beta_2 = 0.999$, $\epsilon = 1e-8$, and a learning rate scheduler where the learning rate is reduced with a multiplier $f = 0.65$ if the validation performance does not improve across 3 consecutive epochs. We implemented all methods in Pytorch using NVIDIA RTX 2080Ti GPUs. All models converged within 300 epochs with early stop using a 10-epoch patience.

Standard Dataset	Model	Median Source-Distortion Ratio (dB)				
		Soprano	Alto	Tenor	Bass	Avg.
Piano	Spec-U-Net [7]	**9.78**	**9.46**	**10.35**	10.60	**10.05**
Piano	Res-U-Net [8]	8.53	9.01	9.97	**12.23**	9.94
Piano	Wave-U-Net [9]	6.95	5.36	7.21	9.82	7.34
Piano	Conv-TasNet [10]	7.04	6.98	7.29	7.82	7.28
Vocal	Spec-U-Net [7]	**10.45**	10.19	**12.25**	9.53	**10.61**
Vocal	Res-U-Net [8]	9.35	**10.87**	10.20	**10.77**	10.30
Vocal	Wave-U-Net [9]	2.65	3.08	3.06	3.90	3.17
Vocal	Conv-TasNet [10]	6.60	6.12	6.41	6.58	6.43

Table 3: The separation performance of four models on the test sets of Standard-Piano and Standard-Vocal datasets.

For evaluation, source-to-distortion ratio (SDR) is one of the most widely used metrics for evaluating a source separation system's output, which measures a ratio between the original source track and the noise, interference, added artifacts in the separation track. It is considered to be an overall measure of how good a separation result sounds. We follow the music separation campaign SiSEC 2018 [23] to use the median SDR to evaluate separation performance. The median SDR is obtained by first computing segment-level SDR of each 2-sec segment in each track, then taking the median over them as track-level SDRs, finally taking the median over the track-level SDRs as the final SDR. The computing library is *mus_eval* [23].

4.2 Separation Performance

Table 3 shows all four parts median SDR performance on two standard datasets by four models. We can see that the frequency-domain models Spec-U-Net and Res-U-Net get similar results that are better than those of the time-domain models Conv-TasNet and Wave-U-Net. Spec-U-Net achieves the best average SDRs over four parts on two datasets as 10.05 and 10.61. The Res-U-Net achieves very close performance. When analyzing the results, frequency-domain models can take advantage of spectrograms in choral music to obtain better separation results. The performance on soprano, alto and tenor in vocal is better than that in the piano dataset, suggesting that the timbre difference can also help further discriminate different source tracks. Time-domain models can model the piano acoustic features well to achieve a good performance, but find it hard to model the vocal features solely on the waveform and face the drops in the vocal dataset.

4.3 Fine-Tuning Evaluation on Real Datasets

After comparing models in standard datasets, we chose the best model, Spec-U-Net, to conduct the next experiments. We trained Spec-U-Net on the **Expressive-Vocal** dataset, as we synthesized the data *with* the expressiveness incorporation. Then, as shown in the right of Figure 1, we saved

Fine-Tuning Evaluation Set	Pretraining Set	Avg. Median SDR (Fine-Tuning Ratio)		
		ratio=10%	ratio=40%	ratio=70%
Cantoria Dataset [13]	None	1.42	3.91	4.13
	SoundFont-Synthesis [15]	2.39	3.90	4.03
	Standard-Vocal (ours)	3.03	4.59	5.08
	Expressive-Vocal (ours)	3.73	5.48	5.71
Choral Singing Dataset (CSD) [11]	None	1.98	2.78	5.26
	SoundFont-Synthesis [15]	2.12	3.38	6.20
	Standard-Vocal (ours)	3.43	4.23	6.91
	Expressive-Vocal (ours)	4.19	4.78	7.50
Bach & Barbershop Collection (BBC) [14]	None	4.18	6.08	6.94
	SoundFont-Synthesis [15]	4.19	6.17	6.93
	Standard-Vocal (ours)	4.98	6.71	7.27
	Expressive-Vocal (ours)	5.58	7.17	7.64

Table 4: The fine-tuning performance of three real datasets by our best model – Spec-U-Net.

the best model checkpoints, and conducted a fine-tuning experiment to verify whether our data is useful for transfer learning on real choral music datasets. Table 4 and Figure 2 illustrate the median SDR performance of three real choral music datasets under different fine-tuning ratios with different pretrained models.

For datasets, we chose the Cantoria Dataset, Choral Singing Dataset (CSD), and Bach & Barbershop Collection [4] (BBC). The reason for these choices is that Cantoria contains the best recording quality, CSD is most frequently used in previous works, and BBC contains the longest length. The meta information of each dataset has been described in Table 1.

We considered three ratios for fine-tuning: (1) 10% for training, 90% for evaluation; (2) 40% for training, 60% for evaluation; and (3) 70% for training, 30% for evaluation. The fine-tuning experiments demonstrate if our synthesized datasets can improve the separation performance in real datasets under different settings (e.g., few-shot as 10% and fairly enough as 70%). The intermediate ratio 40% is conducted to further investigate the tendency of the improvement brought by our datasets.

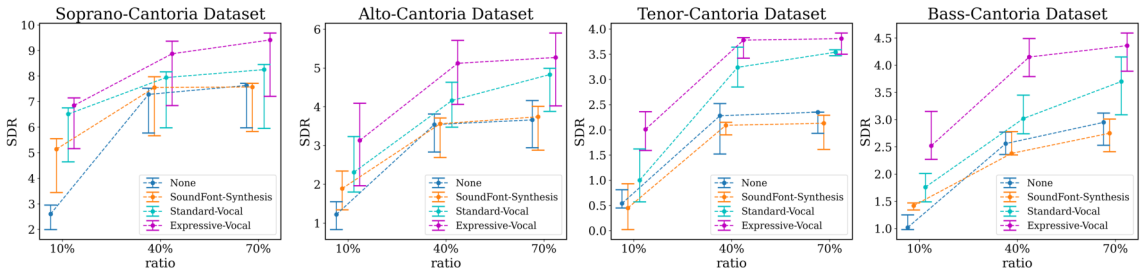
There are four dataset choices on which to pretrain the models: (1) None: without any pretraining; (2) SoundFont-Synthesis: the synthesis dataset in [15] by the *Musescore_General* SoundFont as a baseline; (3) the Standard-Vocal dataset; and (4) the Expressive-Vocal dataset. Since the SoundFont-Synthesis dataset only contains 248 minutes, instead of using two sampled libraries (496 minutes), we only provide the data synthesized from one library – Voices Of Rapture [19] in Standard-Vocal and Expressive-Vocal for the pretraining. Data augmentations of "octave shifting" and "tonality shifting" are applied in all three datasets, except (4) incorporates more expressiveness settings. The fine-tuning learning rate is 1e-4, with the scheduler in section 4.1.

Table 4 shows the average median SDR performance of Spec-U-Net over four voice parts under different fine-tuning ratios and different pretraining settings. We can see that under all three training-test ratios, the performance of the model pretrained on Standard-Vocal and Expressive-Vocal is better than that on SoundFont-Synthesis and none-dataset, where the performance of Expressive-Vocal achieves the best. When the training-test ratio is small as 10%, the performance of SoundFont-Synthesis and non-dataset has the largeest difference, showing that the model learns some priors from SoundFont-Synthesis and converges to a better optimum. However, when the ratio increases to 40% and 70%, their performance is close to each other and does not vary much, especially on Cantoria and BBC. Thus, pretraining on SoundFont-Synthesis dataset provides a very useful initialization – but gains diminish (or even no gain) as the initializer is dominated by larger and larger quantities of real training data.

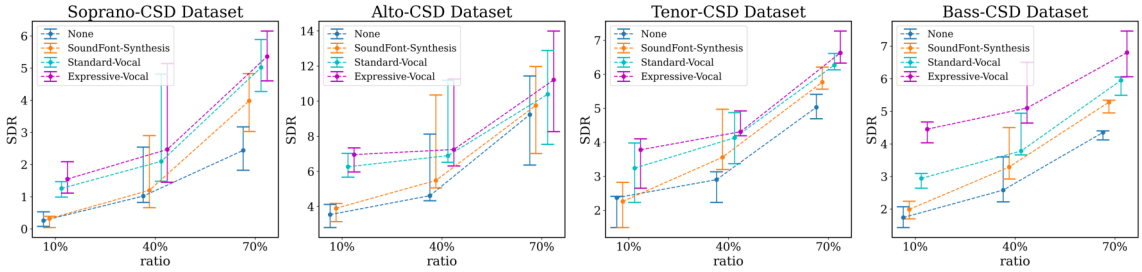
However, when the model is pretrained on Standard-Vocal, it has a strong generalization to real choral music datasets under all fine-tuning ratios, because acoustic features of synthesis tracks share large similarity to the real datasets. This performance is further boosted by Expressive-Vocal as we introduce expressiveness during synthesis, such as lyrics and velocity dynamics. Even under the 70% fine-tuning ratio, as the model has received many real data, Standard-Vocal and Expressive-Vocal pretrained model can still get improvements. In conclusion, our synthesized datasets provide not only additional data volume, but also high-quality and close-to-real choral music samples for boosting the separation performance.

To further verify our analysis, we visualized the trends of median SDRs (blue, orange, cyan, and magenta colors), with a 25th-75th percentile range, for each voice part of three real datasets in Figure 2. We can see the performance of our synthesized datasets (magenta & cyan lines) marks a clear performance increase and a large gap to that of SoundFont-Synthesis and non-dataset (orange & blue lines). However, the trends of SoundFont-Synthesis and non-dataset are close to each other, and even overlap in BBC. When analyzing the percentile range of each model, on Cantoria and CSD, our Standard-Vocal and Expressive-Vocal pretrained models reveal a clear difference of percentile ranges to the left two models, demonstrating that our models get a large improvement. However, the percentile ranges of the SoundFont-Synthesis and non-dataset pretrained models have a large overlap, demonstrating no

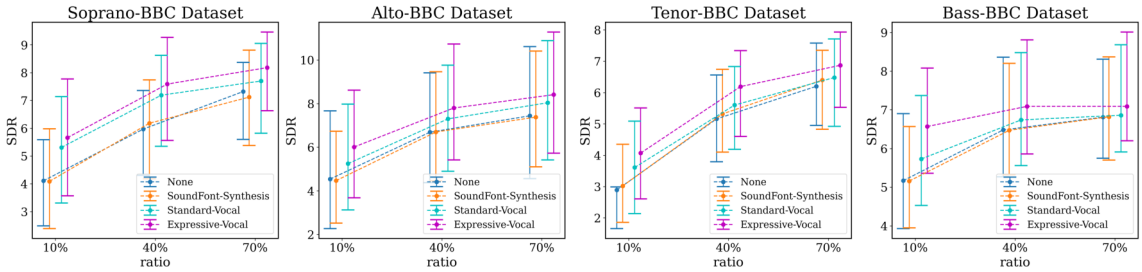
[4] We appreciate the help from authors in [14] to offer the dataset.



(a) The Median SDR performance on the Cantoria Dataset.



(b) The Median SDR performance on the Choral Singing Dataset (CSD).



(c) The Median SDR performance on the Bach & Barbershop Collection Dataset (BBC).

Figure 2: The Median SDR performance, with a 25th–75th percentile range, of soprano, alto, tenor and bass on three datasets by Spec-UNet with different pretrained models and different ratios of training-test sets.

difference even though their median SDRs differ a little. On the BBC dataset, our models yield improvements on both the 25th and 75th percentile values but are not as pronounced as those observed on Cantoria and CSD. The potential reason is because the BBC dataset contains a relatively large data size (105 minutes), which makes the model already achieve a good convergence and hard to get more significant improvements without model designs. These trends further demonstrates that our synthesized dataset plays a role in making up the data scarcity and improving generalization ability.

5. EXTENSIBILITY AND LIMITATIONS

Our provided synthesis pipeline from symbolic datasets to real audio datasets not only benefits choral music separation tasks, but also other choral-related separation tasks. For example, string quartet separation, to separate two violins, viola, and cello parts from a mixed audio, can also be trained with synthesized data of our pipeline. The details of the string quartet separation experiment can be accessed in the code repository. Similarly, our best pretrained model shows a 100%/30% performance increase to the SoundFont-Synthesis and non-dataset pretrained models. This further shows a potential application of our synthesis pipeline to improve other choral-related separation tasks.

There are also some limitations and future improvements to our work. First of all, our implementations of expressiveness are still based on random template modes. Deep learning methods can improve this expressiveness modeling [24]. Second, the design of the choral separation model is needed to learn more priors from weak synthesized data that can be transferred to real data, then it will complement our proposed pipeline better. These limitations are planned for exploration in our future work.

6. CONCLUSION

In this paper, we proposed an automated pipeline for synthesizing choral music data from sampled instrument plugins, and created an 8.2-hour choral music dataset to improve separation performance on real choral music datasets. We comprehensively evaluated multiple separation models to demonstrate that synthesized choral data is of sufficient quality to improve model's performance on real datasets. This provides additional experimental statistics and data support for choral music separation study. In the future, we will focus on the design of timbre-pitch disentanglement model [25] for achieving better separation performance. The application of choral music separation results into other music-related tasks, such as music recommendation [26], is also planned as the future work.

ABSTRACT

Singing Voice Synthesis (SVS) has recently garnered much attention as its quality has improved vastly with the use of artificial intelligence (AI), creating many opportunities for supporting music creators and listeners. Recently, there have been growing concerns about ethical issues related to AI development in general, and to AI-based SVS development specifically. Many questions remain unexplored about how to ethically develop and use such technology. In this paper, we investigate the perception of ethical issues related to SVS from the perspectives of two different groups: the general public and developers. We collected 3,075 user comments from YouTube videos showcasing various uses of SVS as part of a mainstream variety show. Additionally, we interviewed six researchers developing SVS technology. Through thematic analysis, we identify and discuss three different aspects related to ethical issues in SVS development, highlighting the similarities and differences between the perspectives of the general public and developers: (1) Use scenarios, (2) Attitudes towards development, and (3) Meaning of "Creativity", and (4) Concerns about human rights, intellectual property (IP) and legal issues.

1. INTRODUCTION AND BACKGROUND

Artificial intelligence (AI) is developing rapidly and becoming increasingly pervasive in our lives through various forms of technology, including robots and smart devices. The AI field has been thriving over the past decade due to the increasing availability of massive data, computational resources, and deep-learning-based architectures [1, 2]. Related to music, there are various AI technologies to support music organization, production, and enjoyment, including recommendation [3, 4], music generation [5, 6], instrument sound synthesis [7] and singing voice synthesis [8–10]. Singing Voice Synthesis (SVS) has existed since the late 1950s [11] and has been used and enjoyed by many users through applications like singing synthesizers and vocaloids [8]. The significant improvement in the quality of voices due to the use of recent techniques, specifically deep learning, has given rise to more opportunities for the use of SVS, but has also led to more questions regarding its ethical use and increased concern for potential misuse. While the SVS community has started discussing some of the ethical issues related to the development and use of SVS, the discussion is in the early, nascent stage [2]. Furthermore, there is limited research investigating how the general public, as potential users, perceive and feel about the use of SVS, especially since the synthesized singing voices are sounding increasingly realistic and almost indistinguishable from human voices.

The ethical issues encompass multiple areas, including intellectual property (IP) (e.g., the ownership of the media with AI voices) and human rights (e.g., who decides how the voices are used). In addition to understanding how the general public thinks about SVS, it is important to consider what influences their perceptions and whether developers are aware of them. If developers are aware, does that impact their goals and direction? Understanding how the general public perceives AI technology may offer useful insights to developers on how to address negative perception and ensure AI is well-received by users. It is not only important for envisioning the potential commercialization of such technologies, but also for discussing ethical issues and collaboratively thinking about how society should address such issues.

In this paper, we aim to improve our understanding of how people perceive the uses of SVS technology through a content analysis of user comments collected from online videos showcasing various applications of SVS. To examine how user perception on ethical issues related to SVS can influence the development of the technology and vice versa, we also interviewed SVS developers regarding viewpoints on potential ethical issues. We aim to answer the following research questions: (1) How does the general public react to AI-generated singing voices, and what are the implications to SVS developers? (2) What kinds of ethical issues do users and SVS developers consider?

2. LITERATURE REVIEW

2.1 Music-related AI Technologies and SVS

With the advancement of generative models in deep learning, creative applications of music AI technology have be-

© K. Lee, G. Hitt, E. Terada, and J. H. Lee. Licensed under a Creative Commons Attribution 4.0 International License (CC BY 4.0). **Attribution:** K. Lee, G. Hitt, E. Terada, and J. H. Lee, "Ethics of Singing Voice Synthesis: Perceptions of Users and Developers", in *Proc. of the 23rd Int. Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

come a popular research topic in music information retrieval (MIR). Music generation is one area, encompassing various tasks, such as melody generation [5], expressive performance generation [12], sound synthesis [7] and pop song generation [6]. Research in generative music not only varies in tasks, but also in their data formats, which can be at a symbolic-level (e.g., scores and MIDI tracks), at an audio-level (e.g., mp3 and wav files) or a mix of both. In the past years, music AI technologies have become increasingly available and accessible to the public. One example is the BachDoodle, a Bach-like harmonization system from Google Magenta [13], which received much attention when made publicly available as an interactive Google Doodle [1] . Another example is an audio-level pop music generation system, called Jukebox, which generates raw audio of pop songs, including singing voices [6]. This system is conditioned on lyrics and artists, therefore allowing control over such features to obtain desired outcomes. The quality of generated music has vastly improved, even motivating musicians, such as The Flaming Lips, to experiment with AI systems in their music creation process [2] .

SVS has been researched for more than two decades. The goal of SVS is to learn human-like singing voices given input conditions, like speech, lyrics and melodies. A thread of research focuses on creating non-existent voices as seen in popular applications like vocaloids [14]. Other areas handle existing voices: replicating existing singing voices [9,10] such as those of popular artists, correcting the singing expressions for performance improvement [15], and converting speech to singing voice [16]. We have observed significant improvements in the synthesis quality through the adaptation of advanced deep learning models, such as Tacotron [17] and DeepVoice [18]. In particular, the YouTube videos analyzed in this paper replicated voices of popular singers from music scores and lyrics [9], incorporating techniques from text-to-speech (TTS) with adversarial training to achieve state-of-the-art results.

2.2 Ethical Issues Related to Music AI

Concerns regarding intellectual property and AI are growing. Many are concerned about how to protect artists' value in the music industry when "automation" may drive music production costs to zero [19]. While we may still doubt the quality of AI musicality, SKYGGE's Hello World [3] and virtual musicians such as Vocaloid Hatsune Miku [4] are clear signs that the "trend to autonomous and human-like virtual musicians is extremely well established" [20]. As such, ethical concerns are also tied to concerns over excessive loss in human creativity [14]. There is also an aspect of insufficient public knowledge about these technologies, which in turn, informs the lack of legal regulations. Furthermore, such regulations would be heavily influenced by corporations which have "incentives to ignore public input and shift regulation to their benefit" [21]. According to Floridi, there are five digital ethics pitfalls that can be applied when examining case studies and potential consequences of SVS/AI technologies: 1) Ethics Shopping, 2) Ethics Bluewashing, 3) Ethics Lobbying, 4) Ethics dumping, 5) and Ethics Shirking [22].

Beyond the ethics of artist getting compensated for their voices or work, there are also additional questions with regards to human rights – should artists be allowed to "refuse" having their voices or work serve as data sets for generating new voices, and potentially a third party profiting from it [23, 24]?

Existing literature emphasizes the importance of drawing ethical considerations and conclusion within the context of AI's socio-technical systems, rather than on the specific features of AI itself as today's digital technology "ecosystem" necessitates the inclusion of more stakeholders and perspectives [25]. Research finds that Western perspectives often dominate the conversation surrounding AI [26–28] and increasingly emphasizes the importance of considering cultural differences when examining human-AI interactions and attitudes towards AI [29, 30]. There is a pressing need for specific applications of ethics and accountability measures rather than current abstract principles [26] with the argument that stakeholders in the music ecosystem must be the ones responsible for establishing an ethical response for the purpose of a sustainable music industry that includes humans and non-humans [31].

3. STUDY DESIGN AND METHODS

To understand users' and developers' perspectives on AI-based SVS technology, we employed a mixed method approach using thematic analysis of online user comments and interviews. Given that there is currently no widely distributed commercial application using this technology (other than vocaloid communities which are generally considered to be niche), it was challenging to identify a specific community to represent the perception of the general public. Inviting people to react in an experimental setting also has the potential for increased participant response bias [32]. Therefore we opted to find data sources which would allow us to capture user reactions in a more natural setting. We looked into public online videos showcasing state of the art technology and found promising examples from Korean TV shows called "AI versus Humans" [5] and "One More Time," [6] where several different use cases for this technology were presented, such as generating voices of artists (both currently active and deceased), manipulating the artists' voice, generating singing voices in languages different from the language of the original voice samples, and joint performance of artist and AI. A total of 3,075 comments were collected from eight videos from 2020 to 2021 where they presented various applications of AI-based SVS technology.

Most comments were in Korean and a few in English. Two authors who are fluent in Korean independently coded

[1] https://www.google.com/doodles/celebrating-johann-sebastian-bach
[2] https://magenta.tensorflow.org/fruitgenie
[3] https://www.skygge.fr/
[4] https://ec.crypton.co.jp/pages/prod/virtualsinger/cv01
[5] https://programs.sbs.co.kr/enter/aivshuman/about/67201
[6] https://program.genie.co.kr/onemoretime/main

these comments. Taking an inductive approach, the two authors reviewed partial data, used Mural board (a collaborative online tool) to organize the concepts, and came up with the initial codebook through a thematic analysis [33]. Afterwards, the authors coded sample comments together and iterated on the design of the codebook based on discussion. These discussions resulted in addition of a new code (Positive tech-Other) and redefinition of “Commercial” and “Personal" for a clearer distinction. The two coders then used the final codebook (https://osf.io/7em95/) to code all the comments following a consensus model [34], and discrepancy in code application was discussed with the goal of reaching a consensus.

For additional data on developers' perspectives, we reached out to authors of recent publications on this technology asking whether they would participate in an online interview. Each interview was recorded via Zoom and verbal consent was obtained at the start of recording, following the protocol approved by the UW Institutional Review Board. Using Zoom to host and record interviews also enabled us to generate interview transcripts which the authors cleaned and coded for analysis. Interview questions focused on the kinds of ethical issues developers consider, the broader implications to designers of music AI technology, how they perceive the general public's reaction to music AI technology, and what ethical and legal precautions they believe should be implemented.

We reached out to 12 authors, and were able to recruit six developers from three different countries. Five developers were faculty or students building and testing the AI-based SVS technology, and one was an artist who provided their voice samples to build the data set for this technology. Since there is a limited number of researchers who work on this particular technology, the overall pool of users is smaller compared to the number of general AI researchers. The small sample size makes this exploratory in nature.

All interviews were fully transcribed and coded using an inductive approach [35]. Two authors created the initial codebook through thematic analysis, following a similar process as above. The final codebook had 16 codes. Using a qualitative coding software ATLAS.ti, the four authors coded the interviews. We assigned two different coders to each interview, and followed the consensus model [34].

4. FINDINGS

4.1 Perception of the General Public

Eight categories and 27 associated codes emerged from our analysis of online user comments from YouTube videos. "Positive emotions" (e.g., awe) and "Negative emotions" (e.g., fear) categories include responses that reflect users' emotions evoked by seeing the application of SVS. We also created "Positive tech" and "Negative tech" categories that consist of comments about how good or limited they think the current SVS technology is. We dedicated a category, "Conflicted", for comments that showed users' mixed feelings on whether their current emotion is justifiable or not. "Considerations" category contains codes representing different aspects related to ethical issues (e.g., copyright, human right). "Challenges" contains codes that mention realistic problems related to SVS and AI (e.g., misuse). Lastly, "Opportunities" includes comments that suggest new possible use cases and applications of the current SVS technology (e.g,. commercial, personal). Reviewing 3,075 comments, excluding incomprehensible ones, resulted in 1,190 comments that were coded. The result of our analysis as a code distribution can be accessed at: https://osf.io/7em95/.

Overall, we observed positive and negative sentiments in a 65% to 35% ratio. The most observed comment, coded as "awe" (130/1,190), conveyed surprise and fascination towards the level of today's SVS technology. Along with "awe", "moving" (104) and "nostalgia" (84) were commonly appearing positive themes. Several users were touched by the revival of voices of the singers they grew up with (e.g., *"I am thankful for the opportunity to listen to [the artist's] voice again"*). The particular use of the technology did seem to influence audiences' emotion (e.g., nostalgia for deceased artists). The high frequency of the code "moving" implies the potential power and influence of AI on humans. Negative and cynical comments about SVS and AI were represented by codes "fear" (81), "guilt" (25) and "neg-emotions-other" (19). We encountered comments, such as *"this is giving me goosebumps"*, expressing shock and even discomfort towards the quality of reenactments of familiar voices. Feelings of "guilt" were also represented - *"isn't this humiliating the deceased?"*, *"I don't think it's appropriate to do this"* - showing irritation and criticizing lack of morality and respect towards the deceased artists. We observed some conflicted feelings - *"I don't know if I feel good or scared about the regeneration of artists' voice. I feel resistance, as well as curiosity at the same time. I don't know"*, *"It feels weird...I feel scared. Maybe I shouldn't have listened to this"* and *"I do want to see the artist, but not in this way."* Regarding the aspect of technical advancements, there were comments both praising and belittling the results. Some were impressed and rated AI as sounding exactly like the original artists-*"(AI) even replicated the way (the artist uniquely) pronounces 'r'"*- with a few users thinking the AI even sounded better than the original artists.

The "Opportunities" category included comments about audiences' desire to use the presented SVS technology for their personal interest. There were series of comments asking for the regeneration of the voices of other artists or their family members - *"Can they also replicate X?"* and *"I wish to hear my father's voice."* Several comments requested the commercialization of the SVS technology, expressing interest in purchasing the application if made available. There were also comments discussing other potential use cases, such as voice actors in films or saving their own voices to sing songs to their grandchildren posthumously.

From the prominence of the code "misuse," we witnessed growing concerns towards AI in today's society. Often referencing deepfakes, users were afraid of the rise of potential scams (e.g., voice phishing). Some even expressed anger at the irresponsible development of such "dangerous" technology, arguing that it will do more harm

than good. Along this line of negativity, dystopic comments expressed concerns about the potential of AI to replace humans-*"I am a vocal student...Help me, I think my job is disappearing"*,*"I wonder how many jobs will be lost to AI in the near future."* These comments led to sentiments of inevitability and reluctant acceptance- *"we need to make ourselves irreplaceable by AI."* Meanwhile, we observed only one comment discussing the ways to overcome the potential dangers of the technology ("counter").

As reflected in the code "guilt", some addressed issues regarding the legality of SVS usage in terms of human rights and copyright. Many considered it disrespectful and unethical to use voices without the actual owner's consent, invalidating families' and relatives' compliance. They were also critical of the notion that the show could be profiting from the exhibition of deceased artists' voices.

4.2 Perception of Developers

Six interviewees were highly involved in the development of SVS technology, with experience ranging from two to 20 years. Their initial motivation driving their research was curiosity about the technology. All participants envisioned their work potentially helping musicians increase their productivity and creativity. For example, they envisioned SVS being used to quickly generate demo tracks for vocalists, as it is inefficient to invite the vocalists each time to record demos (P1, P5). While participants unanimously predicted that the current SVS technology will reach the level of human voices within the next five to 10 years, they also listed limitations, including data constraint and the need for higher quality results for commercial applications. Developers' thoughts on the "meaning of creativity" were related to the limited data set. They questioned the possibility of AI becoming truly creative, as *"AI can only generate average of the data"* and *"AI is not able to generate something better than humans since it is only trained on the input data"* (P1, P4). P1 mentioned that artists incorporate context and history into the music they are making, which AI lacks. P6 pointed out that the well-known vocaloid Hatsune Miku's fandom is not just towards the virtual character itself, but also towards the human creators behind it.

On the discussion about ethical issues of SVS, a prevalent response was that developers are aware of such issues and their importance, but no one knows specific ways to handle them. Debates have arisen around the unclear standards and practices regarding ownership problems in the music industry. Regarding who is responsible for addressing ethical issues, some participants emphasized that developers should take more caution when it comes to data use and how they make their technology available to the public (P4), while others suggested that there should be a group of experts dealing specifically with ethical issues so the developers can focus solely on the advancement of the technology (P3). However, half of the developers noted that the SVS technology of today is not yet advanced enough to consider ethical issues seriously (P2, P3, P4).

Regarding how to address the ethical and legal implications of this technology, participants indicated that solutions to counteract the misuse of AI are necessary. For example, most participants (all but P5) mentioned the development of counter technologies which can detect AI generated voices as one of the solutions to the potential misuse, and were fairly confident in the power of counter technologies. In general, participants maintained positive views on the future of SVS and considered the general public's negative reactions towards AI to be no different than similar reactions towards other technologies in the past. P5, for instance, talked about the initial negative reactions towards the sound of electronic keyboards and how those attitudes changed as keyboards become more widely used in the music industry. They noted that, similarly, the advancement of AI is inevitable and the general public will slowly accept it. Upon closing the interviews, participants commented on the future of SVS technology, ranging from concerns - *"I'm not sure if it's okay to get comfortable with the mass production of voice through AI"* (P1)-to practical directions to take-*"Humans should try to figure out ways to co-exist with AI, not compete with or hinder its development, because AI will never be able to replace humans"* (P2)-to the need for developers, artists, and the public to maintain an open line of communication regarding differing motivations (P4,P6).

5. DISCUSSION AND IMPLICATIONS

5.1 Perspectives on Use Scenarios

All of the developers interviewed considered supporting creators including composers, performers, and producers, as one of the main goals of their research. When asked to share what kinds of use scenarios they envisioned for the application of their work, they discussed various situations in which AI supports and benefits the creators: *"a tool for the creator like autotune or mixing"* (P2), a tool for generating demo tracks for vocalists (P1), and a means of *"style transfer to correct and improve singing"* (P4). P6, in particular, emphasized that mimicking the human voice to make it sound "natural" is only one aspect of SVS and the true potential lies in generating a variety of voices. They explained how some users may want the voice to sound "artificial" and even prefer that, as exemplified by the popularity of Vocaloid's Hatsune Miku, and the frequent use of Autotune in mainstream music.

The developers also tended to lean towards a more controlled model where a select few have direct access to the use of technology or data set to prevent potential misuse. A question was raised about the commercialization of SVS and its implications. P2, in particular, explained using SVS to recreate the voices of existing or deceased artists will have limitations due to ethical issues beyond just using it as a proof-of-concept or for an event, but generating new voices might have more freedom to be used commercially.

However, the user comments demonstrate a range of desires and ideas for different kinds of commercial uses for SVS technology. Of the 62 comments mentioning potential commercial uses, many expressed that they would be interested in purchasing a song or album by a deceased artist using SVS. Some even envisioned specific apps peo-

ple could download and use like *"a paid app that lets us pick the singer's voice and the song we want to hear in that voice. Maybe in our own voice!"* or *"a business with streaming websites that lets people pay and save the songs.* Many users also imagined the use of the SVS technology beyond the context of music, such as using *"this technology to speak with dead people"*. A user wondered about their future with this technology in relation to human interactions across time (*"Even if I die early, I can sing a lullaby to my grandchildren?"*).

Users also had more diverse ideas about the potential misuse of the technology, including ethical and legal issues that could stem from its development. While this could potentially be attributed to the larger number of comments seen on YouTube compared to those gathered from the interviews, it does indicate that users are definitely considering the commercialization of this technology and are willing to pay for and use it for "personal" goals.

5.2 Attitudes Towards AI Technology Development

Developers tended to be interested in and focused on enhancing the current technology, often recognizing the potential misuse or abuse of technology while accepting the reality that the technology will continue to improve over time regardless of how they feel or act. Despite their initial interest in the research being motivated from the excitement about the technology itself (all but P5), they reported becoming more aware of potential ethical issues when they started seeing "how good" the current level of technology is (e.g., *"I didn't think we'd be able to reproduce it to this level. We'd need technologies to counter the misuse of this technology."* (P1)). P3 shared that while developers are starting to engage in discussion related to these issues, at least in their social circles, people are not yet seriously considering these issues, nor have a clear idea or direction on what to do. Developers also felt that not enough actions are currently being taken. There were different opinions as to who needs to take the lead when it comes to implementing ethical and legal measures to counteract misuse. P3, for instance, viewed that "big players," such as large corporations investing in AI development, should play a bigger role. P4, on the contrary, stated that it will be dangerous for one party to decide how to ethically limit and/or control AI development, be it the government or big corporations, and emphasized that the society as a whole needs to engage in discussion and arrive at social consensus.

User comments showed more mixed opinions. Many were awed and moved by hearing the realistic AI voices, but they also shared fear, guilt, and discomfort caused by "uncanny valley" [8]. Compared to the developers' point of view, users had more pessimistic views on the technology, and a few questioned whether we should be developing such technology in the first place:

"I became fearful as I was watching this [...] I feel lucky that I was born in an era when the AI isn't fully developed." "I think the technology is great, but I also wish we didn't overdo it. Do we really need to listen to songs created by machines? [...] there's no guarantee that the story in movies won't come true where people who wanted support from AI eventually become controlled by them."

These comments suggest that people's fears are influenced by how AI is portrayed in popular media. Several mentioned that the technology reminds them of science fiction TV shows or movies in which AI takes the role of the adversary. Compared to users, developers tended to be over-optimistic about the technology, trusting that counter technologies will exist and work well enough, with some passing the responsibilities to users to some extent (e.g., *"it is not the technology that is bad, but people who misuse it"* (P6), *"AI is just a tool"* (P3)). The discrepancy in how developers and users feel about the technology shows that it is important to encourage discussion on these issues between the two stakeholders, so the general public can be more informed about the actual state of the technology and the developers can understand how the technology is being received by the general public which will inevitably affect the future of such technology. P4 also emphasized the importance of communication with the general public about the technology as the developers' responsibility.

5.3 Meaning of "Creativity" in the Context of AI

A common question raised among developers and users concerns what it means to be "creative" and if AI generated voices can be considered as such. Defining what it means to be creative has ethical implications as determining who or what is responsible for the creative work affects the decision on who should "own" and benefit from the IP. Yet creativity has various definitions; one depends on the "ability to come up with ideas or artifacts that are new, surprising" [36] and another hinges on societal and cultural contexts and thus resists a concrete definition [37]. Some definitions disregard the notion of value and view it as irrelevant, instead emphasizing that creativity must look within the action of being creative itself [38].

As evident by the various perspectives, what is considered creative is widely contested, even more so once AI comes into frame. While it can certainly be agreed that creativity involves processes both cognitive and psychological, the question of whether AI can simulate these processes and the limitations to its approach via simulation remains [39]. P2 pointed out the lack of agency and intention from the AI, and questioned whether AI would be capable of creating something truly novel, stating: *"Even though AI can act perfectly like a human, we are just looking at the outcome. That doesn't mean the AI is really thinking about what it is expressing. It only learned from the data. So at the signal level, it might be similar but that is not an outcome from any kind of reasoning."* P4 also discussed how AI is good at interpolation from existing data sets, thus excelling in giving an "average" performance based on previous performances, but not something truly unique and novel. Some of the user comments also express similar sentiments, stating that the AI voice is "soulless", "lacks emotions", and sounds "too comfortable" or "too honest":

"There isn't something deep or substantial, there's no emotion so I'm not moved [...] It'd sound more natu-

ral if the machine does adlibs or intentionally has trouble singing or barely sings in certain parts."

"The voice is the same but it's missing a soul [...] it's just following exactly what's written in the sheet music."

Audry and Ippolito [40] propose a way of examining the relationship between AI and creativity by redirecting the focus from the artist, both human and artificial, towards the viewer. They draw on Foucault's designation of the "Meta-Artist" to postulate that regardless of whether or not AI can be creative/artists, they most certainly can give rise to an "artist function." As long as viewers continue to construct Meta-Artists, "artists will exist as social constructs" [40].

According to Gioti [39], while AI has generated impressive results in controlled environments, it has yet to break the barrier into autonomy. This leaves room for human artists and suggests the use of AI as an extended intelligence and thus another "actor contributing to a 'networked intelligence' that encompasses both humans and machines" [41]. From this, the concept of computational intelligence emerges where creative responsibility is shared among human and non-human actors where the latter is determined by the "extension of human intentionality through technological intentionality" [41]. The developers we interviewed also primarily considered the collaboration between humans and AI as a big area of opportunity, and none believed that the AI will truly replace the role of humans, partly because of the value ascribed to human skills [42]. Their perspective was focused on seeing AI's role as extending human abilities, similar to how Autotune is commonly used to manipulate singers' voices (P2). While this synergy between AI and humans is posed as ideal, it is limited in its exploration of ethical concerns and considerations of how such a teetering asymmetric relationship will affect both humans and machines.

5.4 Human Rights, IP, and Other Legal Issues

Questions of who should make decisions about the ethics, legitimacy, and legality of SVS remain challenging and unanswered [43]. Sturm et al. [2] asks if the "lack of copyright protection of AI-generated results [is] adequate from a policy point of view" and recommends further "legal and socio-economic analysis." As of 2019, only the "UK, South Africa, Hong Kong, India, Ireland, and New Zealand have envisaged protection for computer-generated works granted to the person by whom the arrangements necessary for the creation of the work have been undertaken" [2]. Users and developers alike question who should be given the rights to the final product in situations where SVS is used to generate new voices using an artist's voice. P5 shared how they wished *"there are some rules about where the profits go to. Currently there are no laws about that."*

Regarding neighboring rights, P4 questioned how the financial gain should be distributed between the AI developer and the artists. Another question was about generating a deceased artist's voice – who should decide how the voice is created and used? P3 shared that family or people close to the deceased artists currently have the rights. In contrast, P6 brought up that the family members are still not the artists themselves. Is it truly acceptable for the third party to make this decision? What if the voice sample is used with other samples to generate a new voice, so the voice data provider does not financially benefit from the result? Users commonly expressed concerns over the worth of human musicians in the event that AI becomes the norm rather than a collaborative tool. Both developers and users expressed conflicted feelings about SVS, with users expressing more negative sentiment such as fear or guilt, using phrases like 'superfluous man/잉여 인간'(i.e., humans with no roles or uses in the society). One proposed solution is to reintroduce scarcity via a Natural Talent certification, which identifies a composition or song as authentically made by human and differentiates it from music produced by AI [19]. However, the implementation is complicated given how human-computer collaboration on music already exists and is pervasive throughout the creation process.

In contrast to end users' concerns, developers are less worried about the "domination" of AI [44]. P2 stated that the individual performers should be able to maintain the performer's rights rather than the entertainment company they belong to, and that any speculated AI programs that will replace the artists will not succeed because of the backlash from the general public; and that coexisting is more likely to lead to success. Ultimately, P2 and P6 did not believe that any outcomes from AI can truly replace music created by humans because people will not want that to happen. As Sturm et al. state "humans still have an important involvement in creating music, even if assisted by an AI system" [2].

6. CONCLUSION AND FUTURE WORK

This study offers initial insights into the perceptions of users and developers regarding ethical issues to consider when developing and implementing SVS technologies. Our findings highlight the discrepancies between user and developer perspectives regarding their envisioned use scenarios and attitudes, but also show that both stakeholders are similarly questioning creativity in the age of AI and concerned about human rights and IP issues.

This is a qualitative exploratory study with limited user data with a goal of enriching our understanding of the topic, not claiming a generalization of the findings. Future research involving more and varied developers and artists should be conducted to gain a more holistic understanding of the different stakeholders' viewpoints. In addition, the 3,075 user comments were predominantly from one culture and one platform and other cultures or platform users will have different perspectives, warranting further investigation. As this study analyzes user perception of the application of AI technologies presented in TV programs, it could have been influenced by how the usage was showcased in the media. However this is also realistically how the user perception is formed on new technology as media plays a significant role in our society. In the future, we also plan to conduct a follow-up study focusing on the perception of ethical issues from the artists' point of view.

7. ACKNOWLEDGEMENTS

We thank the interviewees who shared their honest thoughts and opinions about SVS development.

EMOTION-DRIVEN HARMONISATION AND TEMPO ARRANGEMENT OF MELODIES USING TRANSFER LEARNING

Takuya Takahashi **Mathieu Barthet**
Centre for Digital Music, Queen Mary University of London
takahashi@uec.ac.jp, m.barthet@qmul.ac.uk

ABSTRACT

We propose and assess deep learning models for harmonic and tempo arrangement generation given melodies and emotional constraints. A dataset of 4000 symbolic scores and emotion labels was gathered by expanding the HTPD3 dataset with mood tags from last.fm and allmusic.com. We explore how bi-directional LSTM and Transformer encoder architectures can learn relationships between symbolic melodies, chord progressions, tempo, and expressed emotions, with and without a transfer learning strategy leveraging symbolic music data without emotion labels. Three emotion annotation summarisation methods based on the Arousal/Valence (AV) representation are compared: Emotion Average, Emotion Surface, and Emotion Category. 20 participants (average age: 30.2, 7 females and 13 males from Japan) rated how well generated accompaniments matched melodies (musical coherence) as well as perceived emotions for 75 arrangements corresponding to combinations of models and emotion summarisation methods. Musical coherence and match between target and perceived emotions were highest when melodies were encoded using a BLSTM model with transfer learning. The proposed method generates emotion-driven harmonic/tempo arrangements in a fast way, a keen advantage compared to state of the art. Applications of this work include AI-based composition assistant and live interactive music systems for entertainment such as video games.

1. INTRODUCTION

With the burgeoning of video games, user-generated video content, and tv/film productions released on streaming services, the demand of music for media seems to be growing. Although musicians have known for long how to produce music for such media, interactive music production systems can innovate the way producers create dynamic scores responding to contextual and user factors determined prior to or during the media experience. Deep generative models for music composition have made steady improvements but how to control them to support creative agency remains a challenge [1]. In this work, we investigate deep learning techniques to generate musical arrangements controlled by emotional features. Music composition and arrangement are art crafts which involve specialized knowledge and experience. Prior work used artificial intelligence to either fully automate the music composition [2] and arrangement process [3] or develop assistive tools helping producers to compose new material through human-machine interaction [4]. Our work falls into the second category and focuses on generating harmonisation and tempo arrangements for composed melodies given emotional constraints. Deep learning (DL) was recently used to learn relationships between musical attributes (e.g. notes, chords) and associated emotions [5]. As discussed in [6], music emotions can be considered as being communicated by music (perceived emotions), and as being induced or evoked in listeners (felt emotions) [7]. Depending on the nature of the emotional annotations used during training (e.g. Tan et al. [8]), DL models can be aimed at producing music matching perceived or felt emotions. Music emotion recognition (MER) is one of the most challenging music information retrieval challenge, and new developments aim towards personalized and context-sensitive applications [9]. The proposed system generates harmonic and tempo arrangements for input melodies encoded in the symbolic domain so as to express specific emotions controlling the generation. Harmony and tempo were chosen for the inference stage as they have been shown to affect emotional expression: changes in chord progressions influence the emotions expressed by music [10]; tempo can greatly affect music emotions (especially in terms of arousal) [11]. A challenge in stirring DL generative models using emotion controls is the difficulty in finding training datasets containing both a large number of music examples and emotion labels [12]. We produced the HTPD3 Emotion Dataset (HED) released with this paper by collecting crowd-sourced emotion labels for the 4,000 tracks from the HTPD3 dataset [3]. Given the fairly small size of the dataset, we test the effectiveness of transfer learning for emotion-driven music generation using a network pre-trained only considering musical attributes.

Applications include the design of assistant tools helping composers/producers to create different arrangements given input melodies and emotional intentions. This may be of help to musicians who do not have advanced musical knowledge and to find inspiration in musical ideas generated by the machine. Another use case is interactive

music systems which adapts to the user context, defined in [9] as the dynamic aspects from the listener that fluctuate frequently (e.g. physiological signals). If training was conducted using felt emotion labels, the method could be used for generative music produced on the fly driven by a user's felt emotions as predicted from e.g. biosignals. This could support affective gaming for example to produce responsive background music adapting itself to the emotional states of the game player, see e.g. [13].

2. RELATED WORK

A review of affective algorithmic composition dealing with automatic composition of music based on specific emotions can be found in Sulun et al. [5]. Guo et al. [14] proposed a variational autoencoder (VAE) for music generation controlled by tonal tension predicted from low-level symbolic music features. Tan et al. [8] introduced Music FaderNets enabling to stir music generation based on arousal - an emotional dimension related to excitation - using Gaussian Mixture VAEs (GM-VAEs). Makris et al. [12] proposed a method for assigning valence - an emotional dimension linked to pleasantness - to chords based on prior relationships between mood tags and chord qualities. This enabled the generation of lead sheet data (melody and chord) conditioned by valence, phrasing and time signature using a sequence-to-sequence model. Results from subjective evaluations with 42 participants showed consistency between targeted and perceived valence. However, a limitation is that only valence was considered but not arousal. Sulun et al. [5] recently proposed a promising approach for the generation of multi-instrument symbolic music driven by musical emotion using a Music Transformer architecture. The models can be conditioned by continuous-valued valence and arousal labels and yield results representative of current state of the art on a large scale dataset of 34791 songs. However, possible limitations towards generalisation come from the use of machine-predicted valence labels retrieved from Spotify and the modeling of arousal using MIDI note density.

3. DL ARCHITECTURE FOR AUTOMATIC ARRANGEMENT CONDITIONED BY EMOTIONS

The proposed DL architecture is divided into a melody context encoder and an arrangement decoder (Figure 1). The melody context encoder aims to capture information from the input melody taken as a sequence. Based on the encoded melodic context embedding and emotional information, the arrangement decoder predicts chords, harmonic functions, and tempo.

3.1 Melody Context Encoder

The melody context encoder is shown in the top part of Figure 1 and takes a representation of melodies as input and outputs a 128-dimensional embedding (similar to [15]) at every time unit. To reduce the dimensionality of the input, the melody is converted to a pitch class profile (PCP), as in [15]. A PCP is a 12-dimensional vector, in which each element of the vector contains the duration of each pitch class event. We compared the two following models for the melody context encoders (see Section 5):

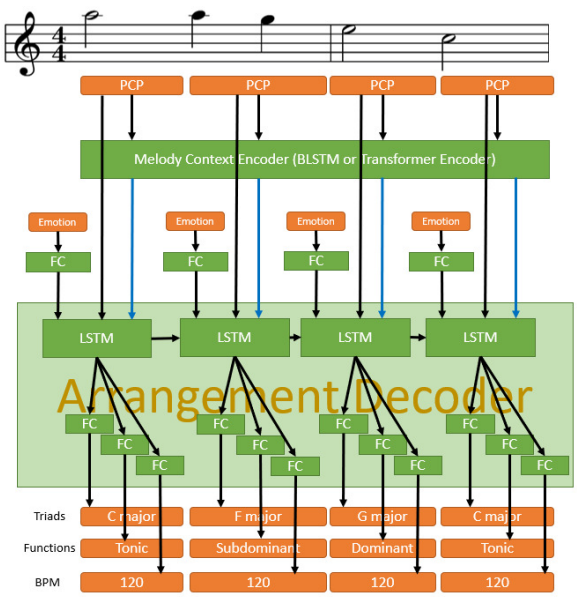

Figure 1. Architecture of the proposed model. The top represents the melodic context encoding, the bottom represents the arrangement generation (LSTM: long short-term memory network; FC: fully connected layers).

Bi-directional LSTM (BLSTM)
Inspired by the melody harmonizer proposed in [15], the same BLSTM model was used in this study with the aim of encoding the context of the melody.

Transformer encoder
The Transformer [16] is a network originally proposed for machine translation. Its self-attention mechanism supports more complex contexts and more efficient computations than BLSTM.

3.2 Arrangement Decoder

As shown at the bottom of Figure 1, the arrangement decoder is constructed using LSTM units only with forward propagation. This is to reduce the amount of computation required, and also to be able to make inferences based only on historical information for near real-time applications. The LSTM unit of each melodic time unit receives as input the hidden state of the past unit, the embedding of the melody context, PCP of the melody, and emotion conditions represented numerically. Finally, for every time units, the arrangement decoder outputs the chord labels and chord functions as a classification problem and the tempo as a regression problem. The output layer of each component consists of a fully connected layer. The loss function is expressed as:

$$L = \mathrm{CCE}(c, c^*) + 1.5\mathrm{CCE}(f, f^*) + 0.001\mathrm{MSE}(t, t^*) \quad (1)$$

where c, f and t are chord labels, chord functions, and tempo, respectively. c^*, f^* and t^* are the related groundtruth attributes. CCE represents the categorical cross-entropy and MSE represents the mean-squared error. The weight of each error was heuristically determined by observing the reduction in loss during training.

3.3 Training Strategies

When a sufficient amount of emotion-labelled musical data is available for training, the model can be commonly trained with a backpropagation algorithm. However, when the amount of emotion-labeled data is not sufficient, transfer learning strategy enabling to include data without emotion labels can be effective. In such case, encoders are pre-trained using music examples without emotion labels, then the pre-trained encoders (weights are fixed) and randomly initialized decoders are concatenated and retrained only for the subset of tracks with emotion labels. However, groundtruth data may not provide the best examples since there are several possible arrangements following music theory and perception considerations [3]. As in [3], training was stopped to a fixed number of epochs (500) without using validation, when the loss was significantly reduced (learning rate = 1e-3) and subjectively consistent arrangements were generated with the test data. Results on the effectiveness of the transfer learning strategy are reported in Section 5.4.

4. MUSIC EMOTION QUANTIFICATION

In order to input emotional conditions to the networks, perceived or felt emotions associated to music have to be represented numerically. We investigated three ways to map emotions into Russell's arousal-valence (AV) space [17].

4.1 Emotion Average Representation

In the Deezer Mood Detection Detaset [18], the emotional tags from last.fm [1] were mapped to arousal and valence values using [19]'s results. In [19], statistics on participant ratings for emotion words are reported for valence, arousal and dominance on a nine-point scale. In most cases, multiple emotion tags can be associated to music content. To address this, one of the methods used e.g. in [18, 20], consists in summarising multiple emotions tags using the geometrical mean of the tag projections in the emotion space (e.g. AV space). We used such method yielding two-dimensional emotional features from a set of mood tags for songs. These were normalized in the range 0-1 for network input. We refer to this emotional representation as emotion average representation (EAR) in the remainder.

4.2 Emotion Surface Representation

The EAR expresses emotions locally in the AV space. However, as investigated e.g. by [20], there is a possibility that a same song suggests/induces multiple emotions to a same listener, or different emotions to different listeners. Therefore, similar to [21], two-dimensional Gaussian mixture models (GMMs) can be used to represent perceived/felt emotions associated to multiple mood tags associated to songs in the AV space. The average and standard deviation corresponding to the mood tags associated to a song are obtained from the experimental results in [19]. Based on the average and standard deviation, random sampling is performed and 10000 samples are generated for each tag. Like for EAR, the emotional features were normalized in the range 0-1. Clustering is performed using two-dimensional GMMs based on the randomly sampled points. Two Gaussian components were assumed sufficient to represent the emotional feature surface in the AV plane as in [21]. Finally, the average and standard deviation of each Gaussian component were used as the network input representation. We refer to this emotional representation as the emotion surface representation (ESR) in the remainder.

4.3 Emotion Category Representation

EAR and ESR are both continuous. However, music emotions may not be best represented by a dimensional model [22]. Studies on music emotion recognition, such as [23], used discrete representations of emotions through categorical variables. We also tested emotional representations with discrete categories. We distinguish four quadrants in the AV space; Q1: high arousal & high valence [joyful], Q2: low arousal & high valence [relaxing], Q3: low arousal & low valence [sad], Q4: high arousal & low valence [angry]). The AV space quadrant with the highest AV annotations determines the emotional category of the music. We refer to this emotional representation as emotion category representation (ECR) in the remainder.

5. EXPERIMENTAL EVALUATION

In this section, the proposed emotion-driven automatic music arrangement systems are evaluated for differences in network architectures and the effect of transfer learning.

5.1 Dataset and training

Network training requires a dataset in which melody, chords, tempo and emotions (perceived or felt) are simultaneously available. As in [3], we rely on the HTPD3 dataset which provides symbolic melodies, chords, and tempo. Time units were set to two beats (half bars in the 4/4 time signature). The chord played for the longest time over two beats was selected as the chord in that time unit. Notes that spanned a segmentation were split. However, tracks in HTPD3 are not labelled with emotion features. We retrieved crowd-sourced mood tags from last.fm [1] and allmusic.com [2] for the song and artists contained in HTPD3. Tags from last.fm [1] and allmusic.com [2] have previously been used in music emotion studies, see e.g. [18]. As some of the last.fm tags are not related to emotions, we filtered these out using the criteria proposed in [24]. This

[1] https://www.last.fm/

[2] https://www.allmusic.com/

method allowed us to tag approximately 4000 tracks available in HTPD3. We refer to this expanded dataset as the HTPD3 Emotion Dataset (HED) available at the link below [3]. There is some uncertainty on whether crowdsourced mood tags relate to perceived or felt emotions. We assume here that these tags relate to perceived emotions, however this can limit the performance of the model in the experiments. Another caveat is that the mood tags relate to audio versions of songs, whereas our model deals with symbolic music. Hence, as in [5], they are considered as "weak labels" for symbolic music. The dataset was divided into 90% training data and 10% test data. As suggested in [25], the use of commercial songs to train AI models for research may be considered fair use.

5.2 Evaluation conditions and music stimuli

We conducted a listening experiment to assess the performance of the proposed model. The study received ethics approval from our institution. Four models (BLSTM without [BL] and with [BT] transfer learning, Transformer without [TR] and with [TT] transfer learning) and the groundtruth (G) were used to create five stimuli for each melody. As we do not investigate the role of key root in this study, the chosen input melodies were converted to either C major or C minor (both training and testing data). Since it is not possible to test all possible EAR and ESR in a continuous way, 15 emotion input presets were prepared for the evaluation. Four types of emotion are represented by EAR, another four by ECR, and seven emotion distributions using the ESR. These input emotions were determined heuristically in order to be able to express as various emotions as possible. The specific configurations are shown on the study website [4]. The chord progressions and tempo generated by the models were converted to MIDI along with the input melody. Audio was rendered from MIDI files using FluidSynth [26] using a SoundFont called SGM-V2.01. As the research [27] has suggested that humans can distinguish the timbre of brass instruments and guitars clearly, the melody part was played by a saxophone and the harmony part by a classical guitar.

5.3 Procedure and Participants

Participants were given instructions on how to complete the study on a dedicated website [5] which can be used to listen to examples of generated accompaniments. The website displayed participants melodies (sampled randomly from the test set) which were represented in the piano roll style. For each of the 15 cases (corresponding to emotional presets not explicitly revealed to participants), participants had to press the "Execute" button to obtain five (four models BT, TR, BT, TT, and groundtruth, G) musical arrangements to rate using three questions:

Q1 The melody and accompaniment were musically coherent. (Likert item: 0 [Disagree] - 6 [Agree]). Participants were instructed that musical coherence here represents a measure of how well the musical accompaniment matches the melody.

Q2 How exciting (arousal) do you perceive the music to be? (Continuous value from 0.0 to 1.0)

Q3 How negative or positive (valence) do you perceive the music to be? (Continuous value from 0.0 to 1.0)

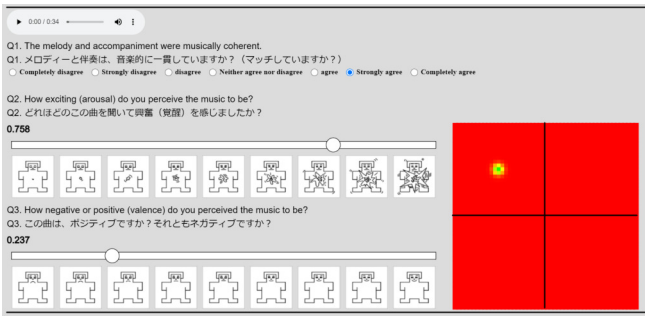

Figure 2. The evaluation interface (five panels had to be completed for each melody; four models plus groundtruth).

For Q2 and Q3, the self-assessment manikin [28] was used to support associations between numerical rating values and corresponding emotions, together with a representation of the rating in the AV space. Figure 2 provides a screenshot of the emotion rating interface. Participants rated 75 songs in total (15 emotion presets x 5 models) each lasting between approximately 15 to 30 seconds. As participants had to rate new arrangements, we assumed that familiarity with the melody, if any, did not affect the ratings (this would have to be assessed in future work). The whole experiment took about 45 minutes to complete.

Participants could not identify the models nor the groundtruth. Different melodies were randomly chosen from the test dataset and used for each emotional preset as, in a pilot testing phase, some participants expressed that listening to the same tune over and over made it difficult to evaluate after a while. For a given emotion preset, the five stimuli (BT, TR, BT, TT, and G) were generated for a same melody, to enable fair comparison between models.

The experiment was completed by 20 participants (7 females, 13 males). All participants were Japanese residents, 19 were Japanese and one was German. Their age ranged between 19 to 59 years (M=30.15, SD=14.05), where M and SD refer to mean and standard deviation, respectively. Six of them had at least one year of formal training in music theory. Eight had more than five years of formal training in their instrument (including voice).

5.4 Results

In statistical analyses, a Type I error of 0.05 was used except when mentioned otherwise.

5.4.1 Perceived musical coherence

Figure 3(a) illustrates the mean and standard error for each model, computed on the perceived musical coher-

[3] http://coconuts-palm-lab.com/EH/HED.zip
[4] http://coconuts-palm-lab.com/EmotionPresets/
[5] http://coconuts-palm-lab.com/EH/

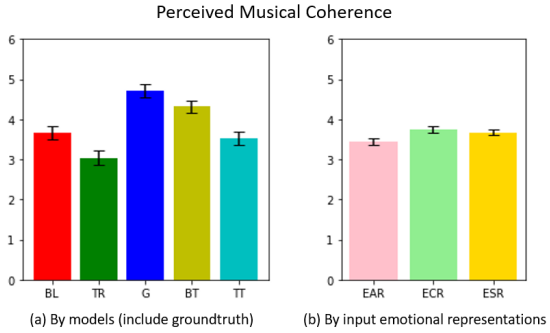

Figure 3. Results of a subjective evaluation experiment, with statistics on the musical coherence across comparisons. The means and standard errors are given.

ence considering all emotion presets. An analysis of variance (ANOVA) shows that the perceived music coherence yielded by the models presented significant differences (df=299, F = 66.750, p<.0001). Tukey's honestly significant difference (HSD) test shows that there is a significant difference between all pairs, except between the BLSTM melody context encoder without transfer learning and the Transformer melody context encoder with transfer learning. The BLSTM model with transfer learning achieves a significantly higher musical coherence compared to the other models. However, compared to the groundtruth, the arrangements generated by the machine learning models were found to be significantly less coherent.

Figure 3(b) displays the mean and standard error of the musical coherence for each emotional expression. ANOVA results showed a significant difference (df=319, F = 3.661, p = 0.025) and Tukey's HSD test showed that there was a significant difference only between EAR and ECR. This suggests that the type of emotional representation impacts perceived musical coherence. In particular, it is suggested that EAR may reduce the coherence of the generated music more than the other representations.

5.4.2 Errors between perceived and target emotions

By observing the error between target and rated emotions, it is possible to assess how well each model expresses the target emotions. The errors for the EAR were obtained using Euclidean distance. The ECR error was defined using the shortest distance between the emotion AV rating and the emotion category AV quadrant. The ESR error was defined by the negative log-likelihood that the rating belongs to the two Gaussians of the GMM component. It should be noted that each absolute emotion error is thus calculated on a different scale.

We also analyzed the relative emotion error, which indicates the degree of reflection of emotion, based on the ratio between the absolute error of the groundtruth and the absolute error of the arrangement generated by the model. If the absolute error for the music generated by the models is smaller than the absolute error for groundtruth, it suggests that the model may have been properly trained. Furthermore, the relative emotion error also makes it easier to compare different emotional representations. The relative error e_r is calculated as follows:

$$e_r = \frac{a_m}{a_g + \epsilon} \tag{2}$$

where a_m is the absolute emotion error for a model and a_g is the absolute emotion error for the groundtruth. ϵ is a small regularising term, avoiding cases where the denominator tends to zero.

The upper part of Figure 4 illustrates the mean and standard error of the absolute emotion error (a_m) for each model and emotional representation. The bottom part of Figure 4 shows relative emotion error (e_r) boxplots. The medians and quartiles are more appropriate to interpret the results than the averages (green triangles) which are strongly influenced by outliers. The blue dotted line is a threshold representing the absolute emotion error yielded by the groundtruth. If the relative emotion error is smaller than the threshold, it suggests that the model has been able to generate arrangements that are closer to the target emotion than the original groundtruth arrangement.

The hypothesis that all means are equal in the absolute error of the EAR is rejected based on the ANOVA (df=79, F=4.388, p=0.004). The results of Tukey's HSD test showed that there was a significant difference in absolute error between the BLSTM with transfer learning and the Transformer without transfer learning (p = 0.003). Moreover, based on the relative emotion errors of the EAR, it was found that the median and quartiles are smaller for BLSTM with transfer learning compared to without transfer learning. In particular, up to the third quartile, the errors were below the threshold, indicating that 75% of the arrangements generated by the model with the transfer-learned BLSTM are closer to the target emotion than the original one. The results show that the BLSTM with transfer learning can reduce the emotion error significantly more than the Transformer one.

ANOVA results suggest that the mean of the absolute error for ECR is not significantly different (df=79, F=1.757, p=0.155). Unlike for EAR, transfer learning does not seem to have had any particular impact for ECR.

According to ANOVA results, the mean of the absolute error for ESR is not significantly different (df=139, F=2.539, p=0.0557). The results of Tukey's HSD test also showed that there were only significant differences between the BLSTM with transfer learning and the Transformer without transfer learning (p = 0.042). When observing the relative error of the ESR, the smallest median, quartiles and mean were obtained with the BLSTM with transfer learning. Thus, when ESR was used, the emotional error was the smallest when BLSTM with transfer learning was used as for the EAR.

In addition, Figure 5 summarises the tempo of the generated arrangements for all the test data. The plotted points represent the actual tempo and the box plot shows the statistics. In all models, the tempo varied significantly when using ESR. This shows that ESR is the emotional representation that generates the most diverse tempi. The

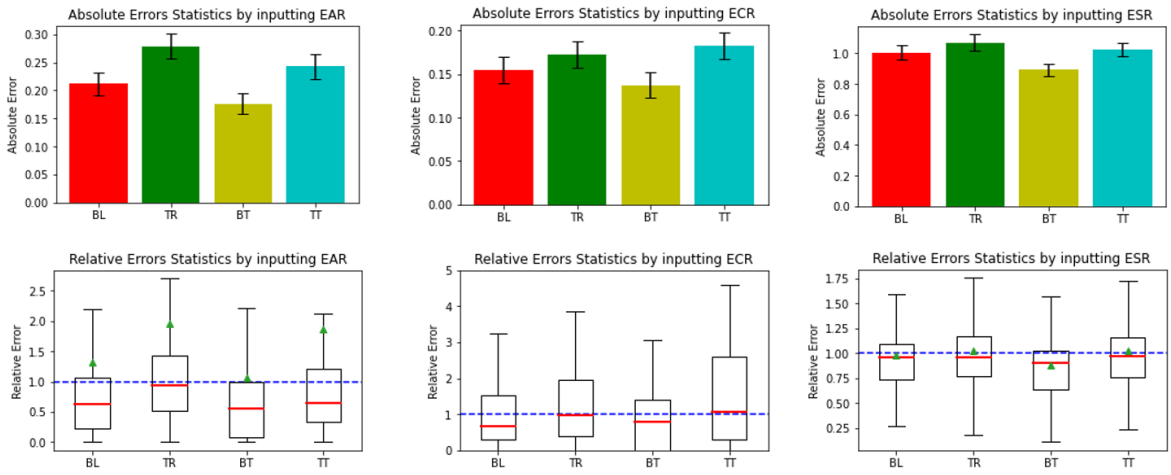

Figure 4. Results of the subjective evaluation experiment, with statistics on the absolute emotion error and relative emotion error across models.

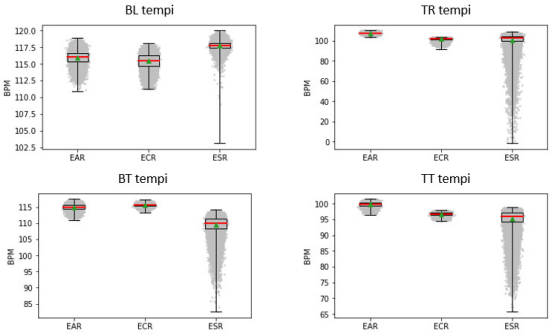

Figure 5. Statistics of the tempi generated for each model from the all melodies of the test data. Each point represents a generated tempo.

use of Gaussian variance, as in ESR, may support more complex emotional expressions.

5.5 Discussion

The highest perceived musical coherence and the lowest absolute and relative emotion errors were obtained when BLSTM with transfer learning was used for the melody context encoder. The results also show that transfer learning, a semi-supervised learning strategy, seems to be effective at generating emotional arrangements. A comparison of the relative errors of the BLSTM with transfer learning showed that the third quartile was not below the threshold only for the ECR, indicating that both EAR and ESR are superior representations for the emotion conditioning.

The generated arrangement could be computed quickly even with Intel(R) Core(TM) i7-9700K CPU (less than approximately 2.5 seconds per 16 bars of melody for any compared models). This could be useful for real-time music generation scenarios. Due to the simplicity of the model, the arrangement may be generated more quickly than state-of-the-art techniques such as that in [12] (approximately 50 seconds per 16 bars of melody for a lead sheet on the same CPU). However, the method in [12] generates the entire leadsheet, so the computation time cannot be directly compared to the ones reported here.

Several limitations should be highlighted. Observing the perceived musical coherence, there was no model in this experiment that could match the groundtruth. The reasons may be overfitting and a lack of data in the dataset. In most cases, the performance of the model was improved by transfer learning, so it is expected that more data and appropriate validation will help to build better models. Emotion errors remain relatively large and it is difficult to prove that the model consistently expresses the desired emotions. As it is unclear whether emotion labels in the training dataset represents perceived or felt emotions, this may contribute to inference errors. More knowledge about the listener's state and context would be needed to gauge more comprehensively emotion perception [9]. Results cannot be generalised since participants were from one provenance (Japan) and the sample size was small (20). More participants of different nationalities would be required to assess the generalisability of the proposed models.

6. CONCLUSION

We devised techniques for automatic harmonic and tempo arrangement of melodies controlled by emotional features, suitable for near real time applications. A network architecture to generate music expressing target emotions by predicting chord progressions and tempo for an input melody was proposed. In addition, three methods to quantify musical emotions were compared. To evaluate the results, we conducted an online listening experiment. For the melodic context encoder, the BLSTM model with transfer learning produced the most coherent arrangement and the one that best reflected the targeted emotions. The proposed method finds applications in assisting tools to create new music arrangements based on emotional directions and affective video games.

ABSTRACT

Audio synchronization aims at aligning multiple recordings of the same piece of music. Traditional synchronization approaches are often based on dynamic time warping using chroma features as an input representation. Previous work has shown how one can integrate onset cues into this pipeline for improving the alignment's temporal accuracy. Furthermore, recent work based on deep neural networks has led to significant improvements for learning onset, beat, and downbeat activation functions. However, for music with soft onsets and abrupt tempo changes, these functions may be unreliable, leading to unstable results. As the main contribution of this paper, we introduce a combined approach that integrates activation functions into the synchronization pipeline. We show that this approach improves the temporal accuracy thanks to the activation cues while inheriting the robustness of the traditional synchronization approach. Conducting experiments based on string quartet recordings, we evaluate our combined approach where we transfer measure annotations from a reference recording to a target recording.

1. INTRODUCTION

In music information retrieval (MIR), synchronization techniques are essential for several applications including score following [1], content-based retrieval [2], automatic accompaniment [3], or performance analysis [4, 5]. Beside these applications, music synchronization has a great potential to simplify data augmentation, data annotation, and model evaluation. For example, one can use music synchronization to obtain additional training data for deep learning methods semi-automatically by transferring annotations from one recording to another. Furthermore, using music synchronization, one can transfer measure positions between audio recordings for navigation purposes, structural segmentation, and cross-version analysis [6, 7].

Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

While traditional synchronization approaches typically rely on alignment algorithms such as dynamic time warping (DTW) and conventional chroma features used as the input representation [8, 9], the integration of additional onset-related information has proven to enhance the synchronization accuracy [10–12]. Inspired by the combined approach from [12], where *decaying locally adaptive chroma onset* (DLNCO) features are integrated into the synchronization pipeline, we incorporate in this paper onset, beat, and downbeat activation functions to obtain a better temporal accuracy while retaining the robustness of the original chroma-based synchronization approach (see Figure 1 for an illustration of the overall approach). The addition of activation functions results in a grid-like structure in the cost matrix, which guides the alignment through activation cues that point to note onsets or other musical events.

While the integration of DLNCO and spectral flux (SF) have led to substantial improvement of synchronization results [12,13], the detection of soft onsets constitutes a challenging problem due to their long attack phase with a slow rise in energy. To adapt the onset detection task to music recordings which comprise soft onsets and temporal–spectral modulations such as vibrato (e.g., string music), Böck and Widmer [14] introduced the superflux (SF*) feature. Furthermore, deep learning (DL) methods such as bidirectional long short-term memory (BLSTM) networks [15] and convolutional neural networks (CNN) [16] have led to significant improvements compared to conventional onset detectors.

As the main contribution of this paper, we show how one can integrate conventional and DL-based activation functions into the synchronization pipeline. Different from the approach in [12], we do not apply any hard peak picking but directly use onset-related activation cues. Furthermore, we go beyond onsets by integrating activation functions that indicate onset, beat, and downbeat positions. In particular for music with noisy and unreliable onset cues, we show that beat and downbeat cues are more reliable and better suited for improving the synchronization accuracy. For extracting beat and downbeat activation functions, we build on recent work by Böck et al. [17, 18], using recurrent neural network (RNN) models for extracting beat and downbeat activation functions.

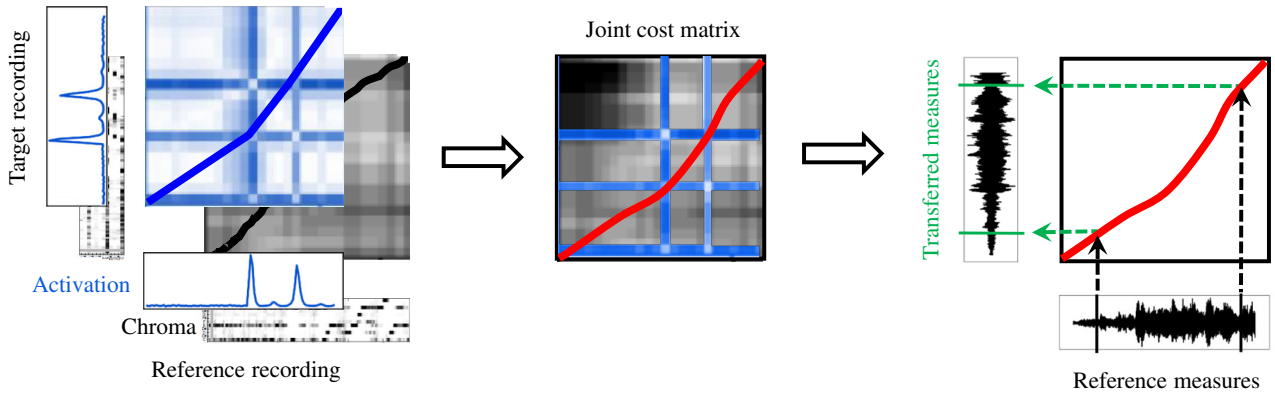

Figure 1: Overview of the combined approach integrating activation functions into a conventional chroma-based synchronization pipeline. The cost matrix computed with activation cues (blue) yields a grid-like structure to guide the alignment of musical events, whereas the chroma-based cost matrix (black) accounts for the robustness of the overall synchronization. The resulting warping path (red) is used for transferring measure positions.

To better understand our improved synchronization pipeline, we compare several synchronization approaches where we transfer measure annotations from a reference recording to a target recording, similar to [19]. In particular, we conduct systematic experiments based on three versions of the String Quartet No. 12 in F major, Op. 96, composed by Antonín Dvořák. As string music generally comprises vibrato, tremolo, rubato, and abrupt tempo changes, which increase the musical complexity, the synchronization of string quartets is a challenging scenario. We show that integrating DL-based activation functions significantly improves the temporal accuracy while retaining the robustness of chroma features.

The remainder of the paper is organized as follows. In Section 2, we introduce our combined synchronization approach, explore conventional and DL-based activation cues, and show how to integrate activation functions into the synchronization pipeline. In Section 3, we present our dataset, the measure transfer between string quartet recordings as our application scenario, and report on our systematic experiments and empirical results. Finally, we conclude in Section 4 with prospects on future work.

2. COMBINED SYNCHRONIZATION APPROACH

In this section, we show how activation functions can be integrated into the synchronization pipeline to enhance the temporal accuracy of traditional chroma-based synchronization approaches. Here, we regard the activation function as a function that yields a value between 0 and 1. Each entry in the function indicates the likelihood of a certain musical event, e.g., onsets, beats, or downbeats, for each frame (time position). In the ideal case, the value of the activation function is one when an event occurs and zero otherwise. Note that we do not apply any peak picking in our approach, but only use the activation functions as temporal cues. This is opposed to onset detection or beat tracking where one needs to apply a temporal decoding method to obtain an explicit representation of onset and beat positions from the activation functions.

In the following, we first explore conventional onset-based activation functions in Section 2.1. Then, in Section 2.2, we investigate DL-based onset, beat and downbeat detectors. Finally, in Section 2.3, we explain how we integrate activation functions into the synchronization pipeline.

2.1 Conventional Onset-Based Activation Functions

2.1.1 DLNCO

DLNCO features are 12-dimensional pitch-based onset features, which combine the robustness of the chroma features with the accuracy of one-dimensional onset features. To compute DLNCO features, we first apply a pitch-wise audio decomposition. Then, we derive pitch-wise onset cues by considering points of energy increase (see Figure 2c for an illustration). DLNCO features are particularly suited for the music with clear note attacks such as piano music. For further details about the computation of DLNCO features, we refer to [12].

2.1.2 SF

Spectral flux (SF) captures the changes in the spectral content of an audio signal, and is widely used for onset detection [9, 20]. For the computation of SF, we apply a first-order differentiator on the log-compressed magnitude spectrogram of a music recording. Half-wave rectification follows the differentiation to keep only the positive differences between subsequent frames. As a final step, we subtract a local average function to enhance the peak structure (see Figure 2d).

2.1.3 SF*

Superflux (SF*) is a modified version of SF for detecting soft onsets [14]. These features are suitable for music recordings with vibrato, such as strings quartets. Similar to

the SF algorithm, SF* also relies on the detection of positive changes in the energy over time. However, it includes a trajectory-tracking stage through maximum filtering, instead of simply calculating the difference between spectral bins over time. Trajectory tracking helps to suppress spurious spectral peaks, especially arising from vibrato. For further information, we refer to [14] (see also Figure 2e).

2.2 DL-Based Activation Functions

2.2.1 CNN Onset Detector

Schlüter and Böck [16] approach the onset detection task as a computer vision problem, where magnitude spectrograms of the audio recordings are used as the input to a CNN. Onsets are often characterized by rapid transient changes in the spectrum, resulting in sharp edges that are clearly visible in a spectrogram. Using convolutional kernels, one can easily detect these sharp edges of onsets. Similar to SF-based methods, the proposed CNN model computes spectro–temporal differences and captures percussive and pitched onsets. The resulting activation function is referred to as `DL-O` (see Figure 2f for an example).

2.2.2 RNN Beat Detector

In the case of unreliable and noisy onset cues, using beat activation functions constitutes a more feasible solution to improve the temporal alignment. To compute such activation functions, we use the BLSTM model by Böck and Schedl [17] for framewise beat detection. BLSTMs can effectively model the temporal context of the data and is therefore suitable for beat tracking. In the proposed approach, magnitude spectrograms computed with three different window lengths, and their first order differences are used as the input to the network. The network outputs encode the likelihoods of beat positions, as illustrated by Figure 2g. In our experiments, the resulting beat activation functions are denoted as `DL-B`.

2.2.3 RNN Downbeat Detector

Böck et. al [18] present an RNN model to jointly detect beat and downbeats. Like the previously mentioned onset and beat detectors, this model also operates on magnitude spectrograms. The downbeat detector uses an RNN similar to the proposed network in [17] to model beats and downbeats. In our experiments, we only use the probability of downbeats as the activation cues, which we denote as `DL-D` (see Figure 2h for an illustration).

2.3 Combined Synchronization with Activation Functions

To find the optimal alignment between two feature sequences $X := (x_1, \ldots, x_N)$ and $Y := (y_1, \ldots, y_M)$, where $n \in \{1, \ldots, N\}$ and $m \in \{1, \ldots, M\}$, we rely on DTW. By comparing each pair of elements in the feature sequences, we obtain a cost matrix $\mathbf{C}(n, m) := c(x_n, y_m)$ of size $N \times M$, where c defines a local cost measure. Then, an *optimal warping path* is determined via dynamic programming. We refer to [9] for a detailed account on DTW

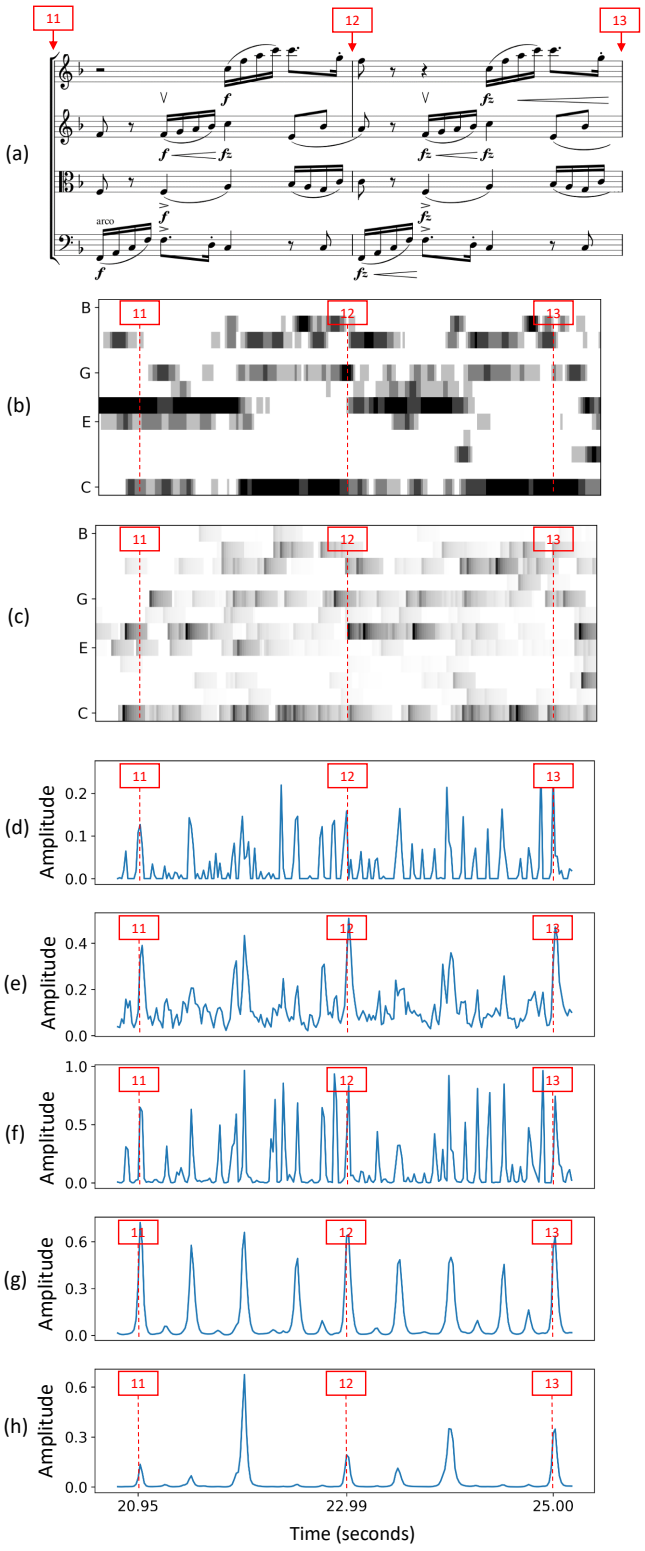

Figure 2: Chroma features and activation functions computed for an excerpt of the String Quartet No. 12 in F major, Op. 96 (first movement) composed by Antonín Dvořák, performed by the Borromeo Ensemble. Activation functions are shown in blue and ground-truth measure positions in red. **(a)** Sheet music representation of the measures 11–13. **(b)** Chroma **(c)** DLNCO **(d)** SF **(e)** SF* **(f)** Onsets (`DL-O`) **(g)** Beats (`DL-B`) **(h)** Downbeats (`DL-D`)

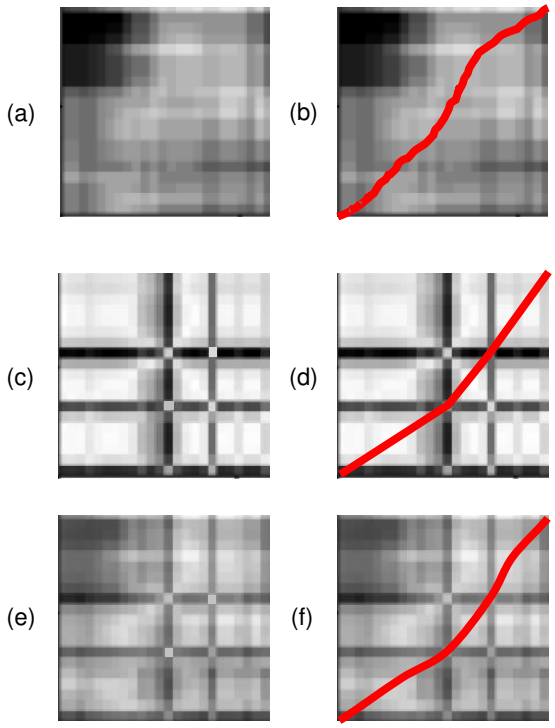

Figure 3: Excerpts from cost matrices and corresponding warping paths computed with DTW **(a) / (b)**: $\mathbf{C}_{\texttt{CHROMA}}$, **(c) / (d)**: $\mathbf{C}_{\texttt{ACT}}$, **(e) / (f)**: $\alpha\mathbf{C}_{\texttt{CHROMA}} + (1-\alpha)\mathbf{C}_{\texttt{ACT}}$, with $\alpha = 0.5$.

for music synchronization. For efficient implementations, we refer to [21, 22].

We now adapt the combined synchronization idea by Ewert et al. [12], integrating conventional onset-based and DL-based activation functions into the synchronization pipeline. Building upon this approach, we introduce three cost matrices. The first one $\mathbf{C}_{\texttt{CHROMA}}$ is a cost matrix based on the normalized chroma features and the cosine distance, see Figure 3a for an example. The second cost matrix $\mathbf{C}_{\texttt{ACT}}$ is computed using the Euclidean distance and conventional onset-based or DL-based activation functions as introduced in Section 2.1 and Section 2.2, respectively. Note that $\mathbf{C}_{\texttt{ACT}}$ exhibits grid-like structures. The visible horizontal and vertical grid lines of high cost (shown in black) correspond to high values in the first and second function, respectively. Only when a horizontal grid line intersects with a vertical grid line, the cost matrix has a small cost value at this intersection point (and also in a small neighborhood). This is where a high activation value of the first sequence meets another high activation value of the second sequence. In other words, these *intersection cells* encode a pair of time positions where two musical events (onsets, beats, downbeats) meet (see Figure 3c). Furthermore, the sections in the activation functions which have low values lead to homogeneous, zero-cost regions in the cost matrix $\mathbf{C}_{\texttt{ACT}}$. The third matrix is the sum of two cost matrices

$$\mathbf{C} = \alpha\mathbf{C}_{\texttt{CHROMA}} + (1-\alpha)\mathbf{C}_{\texttt{ACT}}, \qquad (1)$$

where $\alpha \in [0, 1]$ is a weighting parameter. The sum $\mathbf{C}$ accounts for both harmonic or melodic information of the representations via $\mathbf{C}_{\texttt{CHROMA}}$ and additional activation cues via $\mathbf{C}_{\texttt{ACT}}$. Figure 3e illustrates an example using $\alpha = 0.5$.

Comparing the resulting optimal warping paths using $\mathbf{C}_{\texttt{CHROMA}}$ in Figure 3b, $\mathbf{C}_{\texttt{ACT}}$ in Figure 3d, and $\mathbf{C}$ in Figure 3f, we can observe an enhancement of the temporal alignment. The inclusion of DL-based onset, beat, and downbeat cues leads to an improvement of the warping path guided by grid structure's intersection points. Note that $\mathbf{C}_{\texttt{ACT}}$ remains zero in the regions without any novel events, and the overall alignment of $\mathbf{C}$ is mainly guided by $\mathbf{C}_{\texttt{CHROMA}}$.

3. EXPERIMENTS

3.1 Dataset

The genre of string quartet is composed for a small conductor-less ensemble, which consists of two violins, a viola and a violoncello. In our experiments, we use three versions (performances) of the String Quartet No. 12 in F major, Op. 96, by Antonín Dvořák, which comprises four movements. To give an insight of the musical properties of the string quartet, Table 1 provides the number of measures, time signature, and global tempo for each movement based on the recordings in our dataset. Note that the global tempo does not reflect any local tempo deviations. Its purpose is to indicate at what pace (average of three performances) a given movement is performed. In each recording, the repetitions are played as notated in the sheet music, thus ensuring structural consistency.

Movement	#Measures	Time signature	Global Tempo
M1	239	4/4	100
M2	97	6/8	84
M3	244	3/4	185
M4	382	2/4	140

Table 1: Overview of four movements, including number of measures, time signature, and global tempo in BPM for each movement.

For each recording (in the following referred to as version), we manually annotated the measure positions. In Table 2, the name of the version, the identifier, the recording year for each version, and the duration of each movement are listed. Note that each of the three performances last around 26 minutes in total, whereas durations of the movements may vary across different versions.

			Duration (seconds)				
Version	ID	Year	M1	M2	M3	M4	Σ
Alban Berg	A	1991	599	410	238	323	1570
Borromeo	B	2012	540	465	228	338	1571
Prague	P	1973	584	424	250	322	1580
		Σ	1723	1299	716	983	4721

Table 2: Version, identifier, recording year, and duration of each movement.

	DL-B & DBN			DL-D & DBN		
	P	R	F	P	R	F
M1	0.194	0.806	0.312	0.648	0.586	0.612
M2	0.138	0.820	0.236	0.657	0.643	0.650
M3	0.327	0.539	0.407	0.524	0.224	0.314
M4	0.517	0.908	0.655	0.876	0.647	0.742
ϕ	0.294	0.768	0.403	0.676	0.525	0.580

Table 3: Precision (P), Recall (R), and F-measure (F) based on methods DL-B for beat, and DL-D for downbeat tracking with DBN post-processing, evaluated on reference measure annotations and tolerance $\tau = 70$ ms. ϕ denotes the average accuracy over four movements M1, M2, M3, and M4.

	$\tau = 30$ ms		$\tau = 70$ ms		$\tau = 100$ ms	
	CHROMA	DL-OBD	CHROMA	DL-OBD	CHROMA	DL-OBD
M1	0.408	0.576	0.723	0.813	0.817	0.877
M2	0.396	0.600	0.694	0.842	0.789	0.917
M3	0.528	0.655	0.827	0.912	0.910	0.956
M4	0.485	0.662	0.773	0.884	0.861	0.930
ϕ	0.454	0.624	0.754	0.863	0.844	0.920

Table 4: Accuracy values based on chroma and DL-OBD for different tolerances $\tau = 30,\ 70,\ 100$ ms. ϕ denotes the average accuracy over four movements M1, M2, M3, and M4.

3.2 Beat and Downbeat Tracking

As a baseline, we first introduce how DL-based beat [17] and downbeat trackers [18] perform in the detection of measure positions, where a dynamic Bayesian network (DBN) was used for post-processing (peak picking). Table 3 provides precision, recall, and F-measure values using a tolerance of $\tau = 70$ ms. Here, each entry indicates the mean value over different performances. Due to the higher density of beats, the beat tracker reveals a higher recall than the downbeat tracker for each movement, leading to a low precision and F-measure. Furthermore, each movement has a different time signature, which results in a different number of beats per measure and needs to be taken into consideration as prior information for the DBN.

3.3 Synchronization Results

In this section, we describe our experimental setting and evaluate audio alignments obtained using chroma features and different activation functions. In our experiments, we use the resulting warping path to transfer the measure positions annotated for the reference recording to the target recording. Given two versions of the same music piece with the time-continuous axes $[0, T_1]$ and $[0, T_2]$, the monotonous alignment can be modeled as a function

$$\mathcal{A} : [0, T_1] \to [0, T_2].$$

The pairwise alignment error ϵ_P for a given alignment of two recording is specified as the mean over the values

$$\epsilon_P(g_1) := |\mathcal{A}(g_1) - g_2|,$$

where $(g_1, g_2) \in [0, T_1] \times [0, T_2]$ denotes the ground-truth pairs of measure annotations. As an evaluation metric, we use *accuracy*, which is defined as the proportion of correctly transferred measure positions with a pairwise alignment error below a given tolerance τ [23].

In the following, we use eight different synchronization approaches based on conventional chroma features and the combination of chroma features with DLNCO features, SF, SF*, DL-based onsets (DL-O), DL-based beats (DL-B), DL-based downbeats (DL-D), and finally a 3-dimensional stacked activation function combining DL-based onsets, beats, and downbeats (DL-OBD) (see Section 2 for a detailed overview of activation functions). We use a feature rate of 50 Hz for the computation of chroma, and conventional onset features. To generate DL-based features, we use the *madmom* [24] library, for which we utilize the default setting 100 Hz as the feature rate, and downsample generated features to 50 Hz (after low-pass filtering).

3.3.1 Overall Result

To get a first impression of the alignment behavior of different approaches, Figure 4 illustrates an overview of average accuracy values (averaged over all movements and all pairs of different performances) and for different tolerances τ. Obviously, one can observe that the synchronization accuracy improves with increasing threshold. For example, using $\tau = 30$ ms, the average synchronization accuracy is 0.454 when using only chroma features, and the accuracy increases to 0.624 when integrating the DL-OBD activation cues. This is a substantial improvement.

Next, we focus on the comparison of different approaches for $\tau = 70$ ms, which is a common tolerance value for the evaluation of music synchronization and beat tracking procedures. The inclusion of DLNCO slightly worsens the alignment since DLNCO features are not suited for soft onsets as occuring in string music. However, the integration of SF and SF* into the synchronization pipeline results in a better accuracy. Among conventional onset features, SF* shows a better performance than SF and DLNCO, owing to the fact that SF* features account for the detection of soft onsets and are therefore more suitable for string music. Furthermore, using DL-based methods leads to a better synchronization result compared to the conventional methods. Note that the integration of DL-OBD, which combines DL-O, DL-B, DL-D, reveals the best accuracy among all the synchronization approaches. It is also interesting to observe that DL-B, which is based on beats, is the second-best among DL-based approaches and leads to better accuracy values than downbeat-based DL-D, whereas DL-O reveals the lowest accuracy among the DL-based approaches.

In general, similar trends can be observed when using other thresholds. Using $\tau = 500$ ms, all synchronization approaches yield nearly perfect results.

3.3.2 Dependency on Movement

In our next experiment, we analyze the synchronization accuracy across different movements. Table 4 provides a comparison of alignment results based on the conventional chroma-based approach and our proposed combined

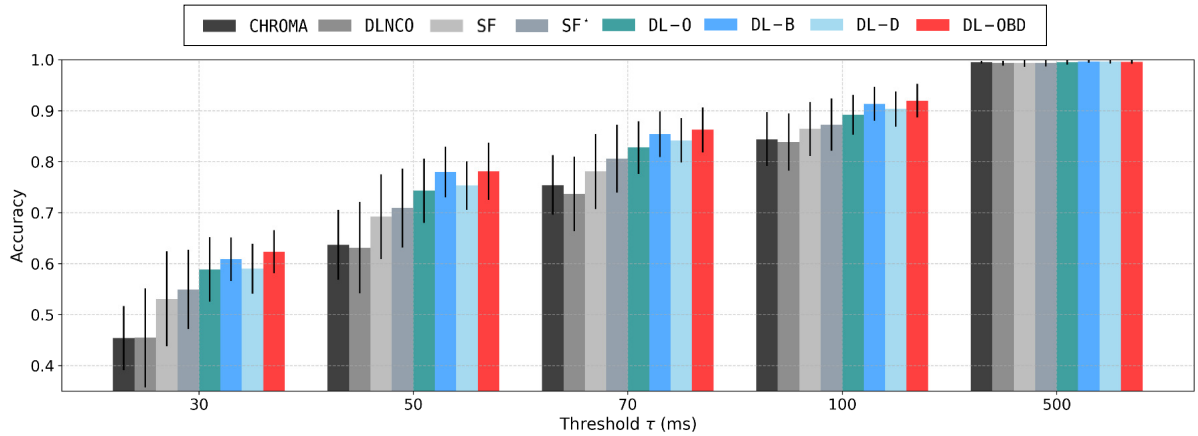

Figure 4: Comparison of the average accuracy values for different synchronization approaches and different threshold parameters τ. The accuracy denotes the proportion of correctly transferred measure positions having an error below a given tolerance τ.

	$\tau = 30$ ms		$\tau = 70$ ms		$\tau = 100$ ms	
	CHROMA	DL-OBD	CHROMA	DL-OBD	CHROMA	DL-OBD
AP	0.494	0.636	0.774	0.864	0.839	0.928
PA	0.500	0.632	0.778	0.864	0.847	0.928
AB	0.434	0.576	0.722	0.849	0.830	0.907
BA	0.451	0.580	0.743	0.863	0.857	0.920
BP	0.429	0.662	0.762	0.870	0.850	0.919
PB	0.417	0.657	0.746	0.866	0.843	0.915
ϕ	0.454	0.624	0.754	0.863	0.844	0.920

Table 5: Accuracy based on chroma and DL-OBD across different synchronization pairs, for different tolerances τ. The first column indicates the pair of versions (see Section 3.1).

method DL-OBD per movement for different tolerances τ. For example, considering the first movement and $\tau = 70$ ms, the accuracy of 0.723 for the chroma-based approach increases to 0.813 when using our combine approach DL-OBD. One can observe a similar trend across different movements for different tolerance parameters τ. The second movement tends to yield the lowest accuracy values when using only chroma features, while the integration of DL-OBD significantly improves the synchronization accuracy from 0.694 to 0.842 for the second movement. One reason may be that the beat and downbeat information leads to a significant improvement in synchronization accuracy of slower sections.

3.3.3 Dependency on Performance

As a final experiment, we provide a comparison of the accuracy values across different performances for different tolerance parameters τ in Table 5. In general, using a combination of chroma and activation functions significantly improves the accuracy for all the synchronization pairs and tolerances. For $\tau = 70$ ms, chroma reveals an average accuracy of 0.774 for AP and DL-OBD improves the accuracy to 0.864. Remarkably, across other synchronization pairs the synchronization accuracy values are similar. Nonetheless, deviations may occur due to soft onsets, slight inconsistencies in ground-truth annotations, and linear interpolation while measure transfer. Note that the synchronization accuracy rather depends on the musical complexity and structure, e.g., across different movements, but not on the performances.

4. CONCLUSION

In this article, we investigated the incorporation of conventional onset features, and activation cues obtained by recent DL-based onset, beat, and downbeat detectors to a conventional chroma-based synchronization pipeline. We showed that the integration of a combined version of onset, beat, and downbeat activation functions significantly improves the synchronization accuracy while maintaining the robustness of the original chroma-based synchronization approach. For the future, we will incorporate other features, which capture smoother note transitions for string quartets. We also aim at extending our string quartet dataset and evaluating the synchronization on beat-level annotations. Moreover, we will further investigate the role of the hyperparameter α (see Equation 1), which can be optimized as a time-dependent parameter.

A DEEP LEARNING METHOD FOR MELODY EXTRACTION FROM A POLYPHONIC SYMBOLIC MUSIC REPRESENTATION

ABSTRACT

The task of identifying melodic lines in polyphonic music is a known active research topic in the symbolic and audio domain. Its importance has attracted the interest of researchers focusing on Music Information Retrieval and musicological applications and achieving high results is a common goal in industrial applications. Distinguishing the melody from the rest of the material in a written score can be a challenging task, however improvements have been reported in recent years using deep learning methods. In this paper, we present a lightweight deep bidirectional LSTM model for identifying the most salient melodic line of a music piece using handcrafted features without requiring the input score to be separated into multiple parts. We evaluate our model to measure the effectiveness of several data augmentation techniques and to compare performance to other state-of-the-art models. We also identify the features' importance and evaluate their incremental contribution on the model performance using evaluation metrics. Results on the POP909 dataset show that our model approximates or outperforms current state of the art models trained on the same dataset, based on different implemented metrics and observations.

1. INTRODUCTION

The concept of the note-to-note organization of music naturally evolves to perceiving larger structures such as phrases and melodic contours. Identifying what a listener perceives to be the melody in a piece of music and, more generally, examining the musicological concept of a melodic line has emerged in recent years as an important topic in the Music Information Retrieval community [1].

A melodic line incorporates musical properties which are rich in contextual information such as structure and rhythm and it embeds expressive characteristics from the perspective of the composer when constructing a piece as well as the perspective of the performer interpreting it. From a musicological point of view, being able to extract a melodic line with high accuracy can reveal new research directions, from analysing a composition style to classifying a performer's tendencies. In industrial or other research applications, high accuracy in melody extraction can improve the results of music search or recommendation algorithms as well as music generation systems.

In both audio and symbolic domains, the task of retrieving the notes of the melody from a polyphonic piece is not trivial. For example, during the act of listening, one may find it hard to distinguish note intervals from one another. It may happen that an interval judged as a major third when heard by itself, is judged as fourth in a separate music context instead [2] (p. 217). During the act of reading a music score or rendering it using a single type of timbre, the note intervals within separate voices might be perceived as interchangeable. The aforementioned challenges have inspired the research on voice extraction, i.e. partitioning the polyphonic piece into a set of monophonic melodies (more details in [3] and [4]).

In this paper, we are focusing on the task of identifying the main melodic line in a symbolic score. Past work on this specific task can be divided into two broad categories. The first includes models predicting a melody part from a multiple-part score input, meaning that a series of notes have been separated to individual parts and the task is to predict which part, either globally or in segments, contains the main melodic line. Most common features used for this purpose are related to notes pitch, intensity, duration, as well as the total number of notes among a part. This type of melody identification is out of scope for this paper, however we refer to [5–7] for details.

Our approach belongs to the second category that is to identify the notes that constitute the main melody in the score without any prior knowledge of separated score parts. Hence, we process an unsegregated set of notes, as we believe that this approach give more flexibility on how it can be used in various applications.

Related work. There is a limited number of previous work on this matter. One of the first attempts is the skyline algorithm [8] which keeps the highest note starting at any time, from all simultaneous note events. The other existing algorithms can be separated in the way the music is represented as input. We can pinpoint two main strands. One handles the music as a piano-roll visualisation, which is a semantic segmentation where musical scores are treated as two-dimensional images. Melody extraction systems presented in [9] and [10] use this type of representation, with the aim to classify the notes represented as pixels. The

Chanquion, "A deep learning method for melody extraction from a polyphonic symbolic music representation", in *Proc. of the 23rd Int. Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

piano-roll representation is mainly used in deep learning methods using convolutional neural networks. The other strand, which our approach belongs to, treats the music sequentially, representing a series of tokens or low and mid-level features that best describe the input characteristics. Recurrent neural network based models employ the note-sequence representation. In the case of the system in [11], the input representation constitutes note-to-note affinity values coming directly from their contextual notes, constructing a weighted undirected graph, having as edge weights the corresponding affinity values. In order to obtain a single melody outcome, they employ spectral clustering to obtain one cluster over the learned graph.

The use of features is presented in [12], where each note is characterised by a set of note properties such as note dissonance, how close a note is to a note ranked with a high probability of being a melody note, or properties from the score metadata such as the musical instrument that a particular note has been assigned to. In our approach, we adapt a set of features which contain note information such as pitch and duration, as well as properties of a note in its polyphonic context.

A recent approach MIDIBERT [13] adopts the mask language model training strategy which is largely used in the field of natural language processing. The model accepts an input representation of sequence of tokens where each token represents a musical event. By training the model to reconstruct the masked input sequence, the transformer model can learn a latent representation of symbolic music. The experiment results show that with such pretraining, the model can be easily fine-tuned for other down stream tasks such as melody extraction.

Previous work reports high results in melody extraction accuracy, especially on recent systems that use deep learning methods. However, the resources used are either not publicly available or their use is copyright protected. Therefore, it is hard to compare and assess results due to unpublished datasets, different metrics reported and different test sets used. Datasets that clearly identify the primary melodic part from accompaniment are rare. For this publication, we have used the open-source POP909 dataset [14], where the salient melody notes have been distinguished. Pop music has been also used in [6, 9]. Folk music has been used in [10, 11] and classical in [9, 10]. The system in [13] adapts POP909 for the task of melody extraction.

Proposed method. The melody extraction model that we introduce in this paper is a supervised bidirectional Long-Short Term-Memory (biLSTM) model called LStoM, standing for Large Score to Melody. It receives a set of computed features as input derived from a MIDI score and classifies which notes constitute the main melodic line. We adapted the note events representation as a set of features in the form inspired by [4].

For our model input, we compute the following features for each note in our dataset, as described in Table 1. The first two features, `pitch` and `dur`, contain the basic pitch and duration information of a note, respectively, where pitch is expressed in a MIDI note number and the duration in a crotchet level. For `pitch_dist_below` and `pitch_dist_above`, we compute the distance to the pitch of the next (neighbouring) higher or lower note sounded simultaneously with the note in use. `pos_in_bar` records the score beat where the note onset is located within the score bar. `pitch_in_scale` records whether the note pitch is in the diatonic scale of the key signature. The features `pitch_dist_below` and `pitch_dist_above` are inspired by the work in [4]. The feature `pitch_in_scale` is inspired by the work in [12].

Feature name	Description
`pitch`	note pitch (MIDI number)
`dur`	note duration (crotchets)
`pitch_dist_below`	absolute pitch distance (semitones)
`pitch_dist_above`	absolute pitch distance (semitones)
`pos_in_bar`	note onset position in bar (crotchets)
`pitch_in_scale`	note pitch in key scale (boolean)

Table 1. The features that have been selected and computed, along with their description.

More on the data that we have processed and the model we have built in Sections 2 and 3 respectively. Section 4 includes a set of experiments and observations to assess the model's capabilities. Finally, in Section 5 we summarise our findings and suggest potential future directions.

2. DATA DETAILS

For our experiments, we have used the MIDI files from POP909 dataset [14]. This dataset includes piano arrangements of Chinese pop songs created by musicians playing on a MIDI keyboard, and the melody part has been identified by manually transcribing the lead vocal melody. The scores include the remaining parts "bridge" and "accompaniment" which we merge and consider as a single accompaniment part throughout our experiments.

The scores are rich in expressive characteristics, such as the note timing and duration. In our processing, we have used the dataset metadata information regarding the beats and the key. For our purpose, we have pre-processed the MIDI files, to rectify the following dysfunctions. Many scores include a time signature of '1/4', so we have updated the time signature by considering the meter information from the audio beat metadata. Time signatures of "2/4" and "2/2" have been mapped to "4/4". Also, many scores include a misalignment in the downbeat level, so we have fixed the start time of the piece to reduce this issue.

As mentioned before, the scores are performative and this means that they accommodate fine details or imprecision in timing. In order to setup our model, we have created a time-grid of the notes' onset and duration that is flexible enough to keep performative characteristics and strict enough to not explode the dimensions of possible values which would be hard to be trainable later on. The time-grid is setup to align onset times in triplets resolution. The note durations are adjusted to the minimum between the distance of current note onset and next note onset, and the current note duration in semiquaver resolution.

The key information is extracted from the dataset metadata. When a song has more than one key signatures reported, we consider a single key signature extracted from the music21 key detection algorithm [15]. At the inference level of our model, we apply the latter method on the test score input. We do not apply any type of post-processing on the extracted melody. Also, we automatically merge all notes into a single MIDI part per piece, keeping the information of a note being a melody one as ground truth.

To facilitate a fair comparison of the models in our experiments, we use the same dataset subset and train-validation-test set split as in [13], which results to 865 songs. The steps above give us the amount of 1,408,056 notes, from which 19.8% are melody notes.

3. MODEL DETAILS

In this section, we present the details of our model architecture (3.1), the details about our training setup (3.2), as well as the metrics we have established (3.3). We have released the code of the model as open-source [1] .

3.1 Architecture

We implement a deep bidirectional LSTM architecture (biLSTM) [16] for our model, which is a type of Recurrent Neural Network (RNN). In our implementation, the biLSTM model has been setup after implementing a grid-search on the model hyper-parameters, using hyperopt [17]. After this process, the model results in having 6 layers, with hidden size of 140, followed by a forward layer. The Adam optimizer is used with a start learning rate of 0.001. We identified the set of hyper-parameters that produce the highest melody F-measure score (metric described in the following Section 3.3).

One characteristic of our dataset is the imbalance of the data labels (i.e. the two classification classes), meaning that non-melody notes outnumber the melody ones. To overcome this issue in our classification task, we adopt the focal loss [18] as the loss function for the model, which is defined as:

$$FL(p_t) = -a_t(1-p_t)^{\gamma} log(p_t), \tag{1}$$

where p_t denotes the model's estimated probability for an input to be classified to class t and $a_t \in [0, 1]$ is a weighting factor for the imbalanced classes which balances the importance of positive and negative examples. The term $(1-p_t)^{\gamma}$ acts as a modulating factor with γ controlling the rate at which over-weighted examples are down-weighted. We set $a_t = 0.25$ and $\gamma = 2$.

3.2 Training setup

The train-validation-test sets that we used from [13] contain a data percentage of 80-10-10%, respectively. The features have been scaled, given the data points in the train and the validation sets.

[1] https://github.com/bytedance/midi_melody_extraction

3.3 Metrics

The metrics that we have computed for this task are the following: `accuracy` indicating the overall accuracy of the predicted notes in percentage, as well as the `mel_P`, `mel_R` and `mel_F` for melody notes precision, recall and F measure values, respectively:

$$\texttt{mel\_P} = \frac{|\text{Correctly predicted melody notes}|}{|\text{Notes predicted as melody}|} \tag{2}$$

$$\texttt{mel\_R} = \frac{|\text{Correctly predicted melody notes}|}{|\text{Melody notes}|} \tag{3}$$

$$\texttt{mel\_F} = 2 * (\frac{\texttt{mel\_P} * \texttt{mel\_R}}{\texttt{mel\_P} + \texttt{mel\_R}}) \tag{4}$$

Also, we include the metric `Voice False Alarm` (VFA) from mir_eval [19], which is defined as the number of notes predicted as melody notes, although they are not, divided by the number of non-melody notes.

4. EXPERIMENTS

To evaluate the performance of our system, we have prepared a list of separate model setups, given the same train, validation and test sets. Also, we were interested in whether two types of data augmentation techniques would improve the accuracy of LStoM when applied in isolation as well as together. The first type is to shift the score key by altering the note pitches, where each piece has been transposed by n semitones, for n in $\{-6, -5, ..., 4, 5\}$ (the model is tagged as "LStoM PSaugm" standing for pitch shifting augmentation). The second type is to shift the melody notes one octave lower than the original one (the model is tagged as "LStoM MOaugm" standing for melody octave augmentation). Both techniques are common in the literature for the task of symbolic melody extraction [10].

4.1 Comparison with the state of the art

We investigate how other models that report state of the art results in various datasets perform in the case of the specific train, validation and test sets. To this end, we were able to train two models. One is following the default settings of [11] tailored to the task of the melody identification, using the augmentation techniques that are provided from this work and the pitch proximity method as a segment merging mode among the created note clusters (the model is tagged as "Hsiao-Su"). The other is following the default settings of [10], again using the augmentation techniques that are provided from this work (the model is tagged as "Lu-Su").

The skyline algorithm [8], which is essentially picking the highest pitch at a given onset time, has been considered as our baseline. Also, we consider a skyline variation where we keep the duration of the note with the highest pitch, ignoring the lower-pitch notes that start after its onset and before its offset. Both original and variation skyline output are illustrated in Figure 1, using the input example as reported in [8].

Figure 1. Illustration of our baselines. a) Input example, b) Output of skyline algorithm, c) Output of skyline variation algorithm.

Model	acc (%)	mel_F	mel_P	mel_R	VFA
LStoM*	92.3	0.816	0.778	0.872	0.065
LStoM* PSaugm	91.6	0.788	0.791	0.799	0.054
LStoM* MOaugm	92.3	0.800	0.815	0.811	0.066
LStoM* MO+PSaugm	91.9	0.798	0.797	0.811	0.054
MIDIBERT* [13]	**97.1**	**0.930**	**0.912**	**0.952**	**0.024**
LStoM	90.7	**0.774**	0.751	0.814	0.070
MIDIBERT [13]	**91.9**	0.772	**0.841**	0.727	**0.035**
skyline	63.1	0.499	0.353	**0.881**	0.435
skyline-variation	78.7	0.569	0.485	0.697	0.192
Lu-Su [10]	66.6	0.614	0.600	0.638	0.299
Hsiao-Su [11]	82.5	0.650	0.544	0.821	0.176

Table 2. Basic comparison results among testing models. An '*' is added to indicate that the MIDI files in the test set have been pre-processed.

Both LStoM and MIDIBERT [2] include pre-processing steps for note quantisation and alignment in downbeat level when preparing the MIDI files for training. At the testing stage, we considered as a fair comparison to first replicate the results of [13] where the MIDI files of the test set have been pre-processed, therefore our pre-processing steps were applied to the test set as well for LStoM and its augmentations (metrics reported at the top part of Table 2). The augmentations do not appear to improve the overall performance of LStoM. In the bottom part of Table 2, we report the metrics of the remaining comparison, where the notes of the test set have not been quantised nor aligned to the downbeat. Interestingly, MIDIBERT outperforms in the first scenario, while the results are mixed in the second one.

Lastly, LStoM is significantly lighter than MIDIBERT; the number of parameters are 875,462 compared to 111,298,052, respectively.

In the next two subsections, we are exploring LStoM in terms of how important the selected features for the training process are (Section 4.2) and we are discussing some observations from the models' outcome, respectively (Section 4.3).

[2] Function `align_midi_beats` in `https://github.com/wazenmai/MIDI-BERT/blob/CP/data_creation/preprocess_pop909/preprocess.py`, accessed 31 August 2022

4.2 Importance of features

We were interested to know how relevant the selected features are for our task and whether any of them are more important in a sense that they contain an amount of information that is crucial for such systems. Algorithmically it is feasible to examine and improve the interpretability of a predictive model to a degree, and to identify a type of ranking of importance for the input features. However, most recent feature ranking algorithms assume feature independence (for more examples and details we refer to [20]), an assumption which is not safe in our case.

Ranking	Feature	Ranking	Feature
1	`pitch`	4	`dur`
2	`pitch_distance_above`	5	`pos_in_bar`
3	`pitch_distance_below`	6	`pitch_in_scale`

Table 3. The ranking of feature importance obtained by RELIEF algorithm.

One algorithm that is not based on this assumption is RELIEF [21] which elaborates on a simple comparison idea whereby feature value differences between nearest neighbour instance pairs are identified. If a feature value difference is observed in a neighbouring instance pair with the same class, the feature ranking score decreases. However, the score increases when a feature value difference is observed in a neighbouring instance pair with different class values. We applied RELIEF to our dataset and the resulting feature ranking is reported in Table 3.

Not by surprise, the pitch has been ranked as the most important feature, followed by the one that computes how much is the distance from the pitch above. The third feature in the ranking list is the similar one, computing the pitch distance from the pitch below. The note duration comes to the fourth place, followed by the metrical-related feature of computing the position of the note within the score bar, and finally whether the note pitch is in scale.

In order to evaluate the incremental contribution of each of the features studied, we have considered feature subsets by incrementally adding features to the training set one at a time, starting with the most important one, i.e. the note pitch, and continuing to add features according to their rank order. The results obtained are reported in Table 4.

Model	acc	mel_F	mel_P	mel_R	VFA
LStoM1	86.5%	0.672	0.652	0.708	0.094
LStoM1-2	88.4%	0.718	0.697	0.752	0.082
LStoM1-3	89.4%	0.738	0.723	0.768	0.073
LStoM1-4	90.3%	0.742	0.780	0.724	0.052
LStoM1-5	92.0%	0.797	0.803	0.806	0.051
LStoM1-6	92.3%	0.816	0.778	0.872	0.065

Table 4. Basic comparison results among the variations of LStoM model, where LStoM*x-x* indicates the range of ranked features used at the training process.

It is worth noticing that the highest ranked feature contains on its own substantial predictive power: the melody F-measure score for the model induced with only pitch information alone is 0.672, which is slighter higher than the

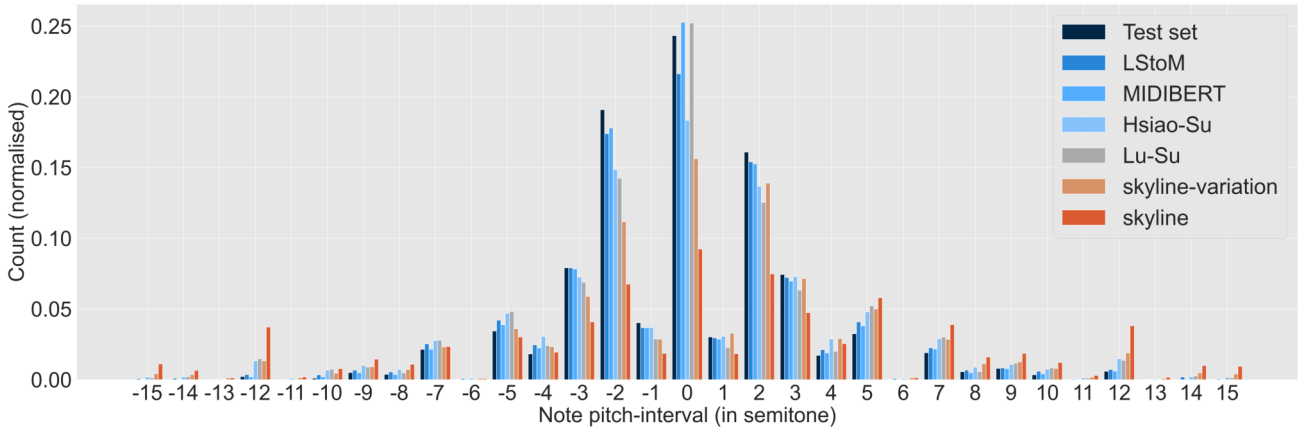

Figure 2. Pitch interval distribution among melodies predicted by LStoM, MIDIBERT, “Hsiao-Su", “Lu-Su", skyline and skyline-variation compared to the melodies from the test set.

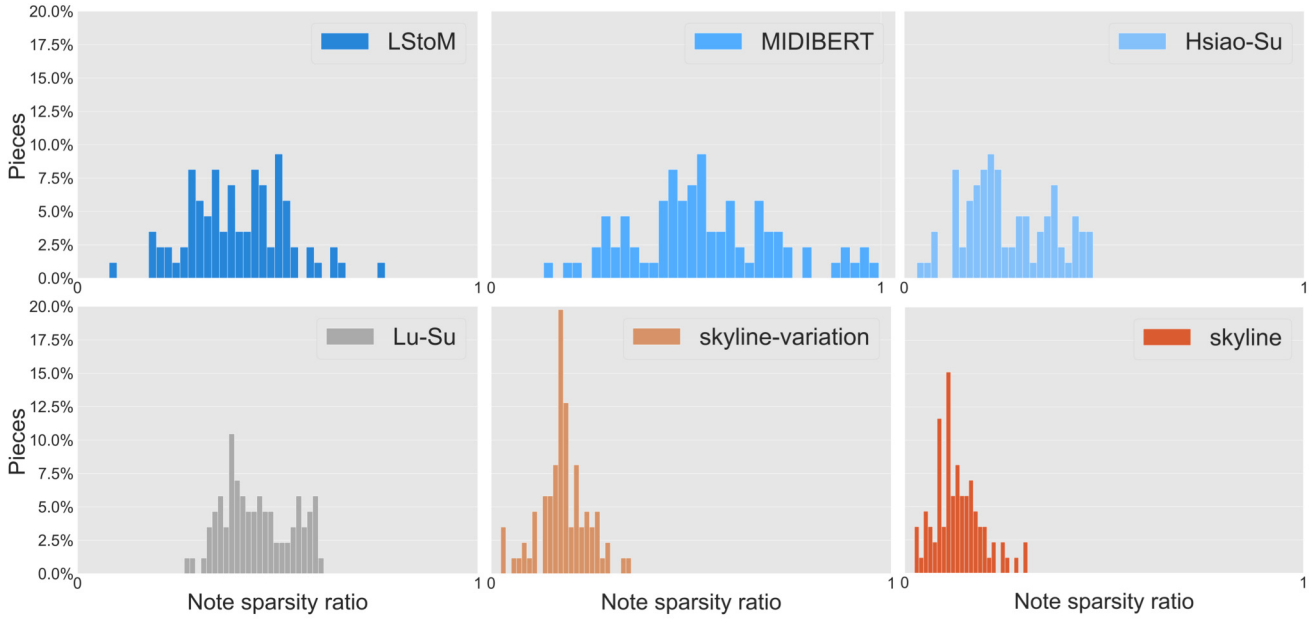

Figure 3a. Sparsity ratio among melodies predicted by LStoM, MIDIBERT, “Hsiao-Su", “Lu-Su", skyline and skyline-variation.

one obtained by our trainings on “Hsiao-Su" and “Lu-Su" systems. Interestingly, the precision is reduced by a very small margin and the voice alarm error value is slightly increased, when adding the feature `pitch_in_scale`, however the accuracy is increased at the same time.

4.3 Observations

Having a closer look to the predicted melodies by LStoM, MIDIBERT, “Hsiao-Su", “Lu-Su" and the baselines, we can highlight two separate statistics. One is the distribution of the note intervals among the consecutive melody note pairs (Figure 2 – the x axis has been limited to the range of around two and a half octaves for paper fitting purposes), where overall the melodies predicted by the models tended to reflect characteristics from the original melody contour. Another statistic is the percentage of predicted melodies with various degrees of sparsity in them. By sparsity, we mean the ratio of the total duration of the silent parts over the total duration of the notes in a score. Fig-

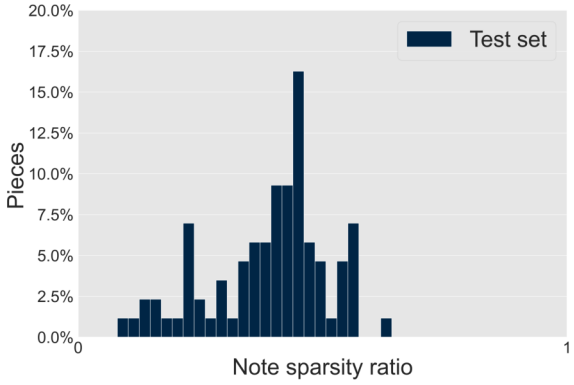

Figure 3b. Sparsity ratio among melodies in the test set.

ure 3a shows the sparsity distribution among the predicted melodies, while Figure 3b highlights the ground truth from the test set. A small amount of melodies from MIDIBERT tends to be more sparse than the scores from the test set.

The most challenging melody notes to classify are those that are not the highest note; i.e., those that the skyline method would certainly miss. We have used the same test set where around 28% of the melody notes are such challenging cases; of these, the LStoM system classifies correctly around 82%. What pattern in the feature data did the model use to achieve this high performance?

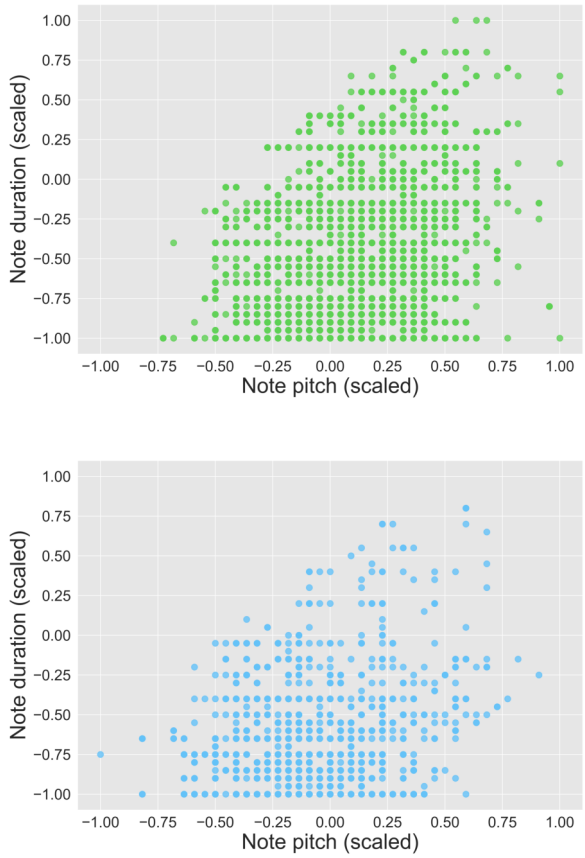

Figure 4. Scaled representation for the pitch-duration feature pair, for the melody notes that are not the highest note and have been either predicted correctly–top– or not (missed)–bottom.

It is not easy to examine the reason why sometimes such notes are not predicted as melody notes, but to investigate, we scaled the feature values of these true melody notes, and compared distributions of features between the correctly labelled (i.e., retrieved) and incorrectly labelled (i.e., missed) notes. One distribution that stood out is shown in Figure 4, a scatter plot of the pitch and duration of the melody notes. One may observe that although the distributions are similar, there are many more correctly labelled notes with high pitch and long duration. Such findings indicate that disentangling such points is not trivial, if at all feasible with our current feature set alone.

5. CONCLUSIONS AND PERSPECTIVES

In this paper we have presented a novel deep learning model of identifying the melody line from a polyphonic symbolic music. The key characteristics of the model is the input data representation as a set of features from the relevant task of multiple voice separation as well as the bidirectional nature of the architecture which provides information of future observations during the prediction process. The features have been examined regarding their ability to contain the information that the model needs to more accurately predict a melody note. Also, two data augmentation techniques are examined in isolation.

Results indicate that the proposed lightweight model which is trained and tested on a set of pop songs is capable of performing at the standard of existing benchmarks. Observations on the results reveal the ability of the model to reflect the concepts of score sparsity or the melodic pitch intervals from the test set. LStoM also performs well in situations where the melody note to be identified is not in the highest pitch of the score. One direction to explore is expanding the set of input features. Note velocity information or metrical representation extracted from the dataset could accommodate additional features for our model. Post-processing techniques have not been explored thoroughly, however they could help improving the results.

Setting research experiments for the task of melody extraction in the symbolic domain is challenging, in terms of data gathering and manipulating separate model architectures to fit the needs of a comparison task. Accumulating the available datasets and the existing systems to a common space for easy approach, such as in a dedicated MIREX page is a promising step forwards. To this end, examining how our model performs using different datasets in the training or inference process, is a step towards a more comprehensive review.

A direction that has been little explored is combining information from the symbolic domain to the prediction of melodies in the audio domain. Most of the existing literature for audio melody transcription relies only on information from the audio signal in isolation from other musical context explicitly. However, in [22], given a polyphonic music audio signal, the model is able to convert it to a piano arrangement; as part of this style transferring process, MIDI scores have been used as ground truth. Also, in [23], symbolic data representation has been used to pre-train a model which then operates to the audio domain. Tasks such as de-noising could be revisited following this perspective.

6. ACKNOWLEDGEMENTS

We thank Jordan B. L. Smith and Janne Spijkervet for their extensive paper review and support before submission.

ABSTRACT

Reproducibility of results is a central pillar of scientific work. In music information retrieval research, this is widely acknowledged and practiced by the community by re-implementing algorithms and re-validating machine learning experiments. In this paper, we argue for an increased need to also reproduce the results and findings of user studies, including qualitative work, especially since these often lay the foundations and serve as justification for choices taken in algorithmic design and optimization criteria. As an example, we attempt to reproduce the study by Kim et al. [1] presented in the RecSys (2020) paper "Do Channels Matter? Illuminating Interpersonal Influence on Music Recommendations". By repeating this study on how interpersonal relationships can affect a user's assessment of music recommendations on a new sample of $n = 142$ participants, we can largely confirm and support the validity of the original results. At the same time, we extend the analysis and also observe differences with regards to adoption rates between different channels as well as different factors that influences the adoption rate. From this specific reproducibility study, we conclude that potential cultural differences should be accounted for more explicitly in future studies and that systems development should be more explicitly connected to its intended target audience.

1. INTRODUCTION AND CONTEXT

Ensuring the demonstrable reproducibility of experiments is an essential part of the scientific method to acquire knowledge. Reproducibility in music information retrieval research traditionally has a strong focus on the repeatability of experiments that demonstrate the performance of a system. To this end, the formalization and complete documentation of MIR workflows and processes is a top priority (e.g., [2]). This includes proper documentation and provision of access to the data involved, to avoid contributing to the so-called reproducibility crisis found throughout virtually all scientific disciplines. In the MIR community the aspect of data access has been a topic of discussion since the beginning, as dataset sharing is a particularly challenging and sensitive matter, foremost due to copyright issues, cf. [3,4]. Also for evaluation, emphasis is given to applying transparent, open, and sustainable methods, to objectively quantify the performance of systems and consistently compare systems [5]. In short, many efforts of the community are devoted to sharing resources, re-implementing algorithms, and re-validating machine learning experiments to ensure reliable and valid scientific results.

In order to avoid potentially contributing to the reproducibility crisis on another front, we argue that there is urgent need in MIR research to also reproduce the results and findings of user-centric studies, including qualitative work. The system-centric view in MIR has been repeatedly subject to criticism and raised calls for more user-centric approaches (e.g., [6, 7]) as the objectives of the systems developed are ultimately rooted in users' needs. In practice this has led to user-centric work taking the essential roles of requirement engineering (e.g. [8–10]) and/or of a system evaluation vehicle, either by generating ground truth, rating the outcomes of systems, or reflecting on their use (e.g., [11–13]). As their outcomes have (or are supposed to have) a fundamental impact and serve as justification for choices taken in algorithmic design and deployed optimization criteria [14, 15], their validity is by no means of lesser importance than that of system-based experiments. Clearly, reproducibility of experiments involving human subjects is hard, as witnessed in the social sciences [16], and has led to the development of the current evaluation strategies as a workaround [17]. Nonetheless, when it comes to the justification of systems objectives, further attention should be paid to the scientific validity of findings by reproducing and corroborating the findings of studies.

As an example, in this paper, we attempt to reproduce the study by Kim et al. [1], presented in the ACM Rec-

Sys 2020 paper "Do Channels Matter? Illuminating Interpersonal Influence on Music Recommendations". We have chosen this particular user study for several reasons. First, the study subject is highly relevant for the development and understanding of music recommender systems, therefore clarifying the reproducibility of the experiments is important for future research. Second, the study is well documented with a clearly laid out methodology. Third, as the original data was collected via a web-based survey, to obtain a new set of responses of comparable quality, we can follow the same strategy, with the main difference that recruited participants have a different cultural, i.e. predominantly European, background.

In addition to repeating the original study to investigate the differences of music recommendations from music recommender systems (non-interpersonal) and friends and acquaintances (interpersonal), we carry out further analyses to gain insights regarding gender differences. We further make use of the PRIMAD framework for reproducibility of research in e-Science for positioning our work [18]. In the terminology of the PRIMAD framework, in our reproducibility study, we foremost prime the factor of data and consequently investigate the generalization capabilities of the analysis wrt. another sample of users. Through the additional analyses, we also extend the methodology used.

The remainder of this paper is structured as follows. Section 2 briefly motivates and summarizes the original study by Kim et al. [1]. In Section 3, we describe the methods used to reproduce the study. Section 4 reports on the results and findings of the reproduced study, which are further discussed in relation to the original study in Section 5. In Section 6, we use the PRIMAD model as a tool to systematically categorize the dimensions of reproducibility in this work and suggest its use for future reproducibility studies (not only) of user-centric studies in the MIR research community. Finally, in Section 7 we draw conclusions from this reproducibility study and point out aspects to be considered for future work.

2. ORIGINAL WORK TO BE REPRODUCED

We aim at reproducing the findings of Kim et al. [1], who have conducted a web survey to investigate the perceptions, evaluations, and differences of music recommendations received through two different channels: *interpersonal*, i.e., music recommendations received from friends or acquaintances, and *non-interpersonal*, i.e. music recommendations received from recommendation systems and through updates on artists followed. The rationale behind that study is to gain a deeper understanding of the characteristics of interpersonal music recommendations and how the interpersonal relationship affects the evaluation of the recommendation.

To this end they recruited 175 Korean-speaking participants (56% female; all above age 18, with 91% of participants between 18 and 32). [1] Furthermore, they collected information that 85% of the participants were active users of a music subscription service for more than one year and that 62% of participants were actively sharing music with others more than once per week (see Table 1).

Study	**Kim et al. [1]**	**Current study**
Number of participants (n)	175	142
Female participants	56%	45%
Age between 18 and 32	91%	86%
Use music subscription service	85%	69%
Sharing music with others	62%	16%

Table 1. Demographics and characteristics of survey participants in the original study and the reproducibility study. Values for the current study refer to percentages in recorded responses.

The study shows an interesting trend, namely that music recommendations obtained from a system are typically considered to be more relevant for a user's own taste (which is the primary objective of recommender systems), more convenient, and more frequently used and adopted than interpersonal recommendations. On the other hand, aspects of diversity, novelty, and serendipity were evaluated higher when recommendations were obtained through interpersonal channels. More detailed results of the study are also included in this paper for comparison in Section 4.

From these results, the authors conclude that indeed interpersonal and non-interpersonal channels have different characteristics that should be accounted for when designing music recommendation platforms, particular to take advantage of their individual strengths (e.g., relevance vs. diversity and novelty). They further highlight a limitation of their study and point to a possible next step: "Since the study was conducted in Korea, Korean cultural background was reflected in the results. Future studies with participants from other cultures (e.g., with different norms, technologies available, etc.) will enable us to explore how cultural differences can influence users' perceptions and behaviors towards music recommendations from different channels." In this paper, we aim at gaining such insights by conducting the same study again with a fresh set of participants, with a different background (i.e., predominantly European), as described next.

3. METHODS

Following the method of Kim et al. [1], we used a web-based survey to investigate interpersonal and non-interpersonal music channels in the context of music playlist creation and consumption. A similar survey was designed with a section regarding interpersonal channels (i.e., from friends or acquaintances) and a section regarding non-interpersonal channels (i.e., from recommendation systems) and sections with the respective questions were presented in a random order to the participants (see Table 2 for the survey questions). The survey was conducted in English with all participants. The questions for each

[1] Despite highlighting that all participants spoke Korean fluently, it is not explicitly stated whether the survey was conducted in Korean or English.

section consisted of the same questions, the only difference is whether they are related to interpersonal or non-interpersonal channels. Upon presenting a section to the participants, they were first asked if they had ever received recommendations through the respective channel. If they had not, they would skip the questions of that section and would move on to the next section.

The survey questions were divided into two parts: 1) evaluation criteria, and 2) usage behavior. Participants were asked to respond to the four evaluation criteria (i.e., relevance, diversity, novelty, and serendipity) using a 5-point Likert scale. Participants were then asked to respond to the usage behavioral questions of frequency and convenience in a similar 5-point Likert scale fashion. Additionally, participants were asked to estimate the adoption rate of the recommended music to their playlist (i.e., adding the music to their playlist) on a percentage level. As with the original survey, no actual recommendations were presented, as the survey solely focused on past experiences of received recommendations.

4. RESULTS

We recruited a total of 142 participants for this study in the context of three Master's course projects at TU Wien via open calls for participation advertised to other students in the course, as well as other peers and acquaintances in their extended networks, cf. [19–21]

Out of the disclosed and collected information of the total 142 participants, 45% identify as female, 55% as male, with 86% aged between 18 and 32. When it comes to the use of music subscription services, 69% of the participants indicated to use music subscription services for more than a year, and 16% shared music with others more than once a week (a side-by-side comparison with the original study can be found in Table 1). To investigate the reproducibility of Kim et al. [1], similar statistical tests were used. In terms of cultural background, 89% of reporting participants in our study state their origin to be in a European country. In contrast to the original study, where 100% of participants reported their background as Asian (specifically, Korean), in our study, only 7% report their origin to be in an Asian country (see Table 3).

4.1 Evaluation of music recommendation channels

Initial mean comparison show that diversity, novelty, and serendipity on average score higher for interpersonal music channels, while relevance, convenience, frequency, and adoption rate are higher for the non-interpersonal channels (see Table 4). When conducting significance testing on the four evaluation criteria, paired t-tests confirm that diversity ($p < .001$) and novelty ($p = .002$) are rated higher for interpersonal channels and relevance ($p < .001$) is rated higher for non-interpersonal channels (see Figure 1A).

An additional principal component analysis (PCA) was conducted to investigate the relationship between the four evaluation criteria. The correlation matrix show that some of the evaluation criteria appeared to be similar than others. The PCA show two components to be extracted from the data with a total accounted variance of 67%: component 1 accounts for 42% and component 2 accounts for 24%. PCA bi-plot (see Figure 2) show that relevance is mainly explained by component 1, and diversity, novelty, and serendipity by component 2. The bi-plot indicate that diversity, novelty, and serendipity are more closely aligned, while relevance is almost orthogonal to these three evaluation criteria.

4.2 Usage behavior of music recommendation channels

Non-interpersonal channels rated higher for convenience, frequency, and adoption rate (see Table 4). Significance testing by using paired t-tests show that frequency was significantly rated higher ($p < .001$) for non-interpersonal channels than for interpersonal channels (see Figure 1B). When it comes to the convenience of using a channel, non-interpersonal channels were rated higher ($p = .004$) as well (see Figure 1C). However, when it comes to the adoption rate, although the non-interpersonal channel scored slightly higher, there was no significant difference ($p = ns$) between non-interpersonal and interpersonal channels.

Additionally, a linear regression was conducted to investigate the effect of frequency on adoption rate. Frequency has a significant effect on adoption rate for interpersonal channels ($F(1, 110) = 4.416, p = .038$) as well as for non-interpersonal channels ($F(1, 90) = 4.971, p = .028$). Whereas convenience plays an additional role on adoption rate of non-interpersonal channels ($F(1, 90) = 4.312, p = .041$).

Furthermore, a univariate regression was conducted to investigate the four evaluation criteria on the adoption rate. For the interpersonal channels, diversity ($F(1.68) = 1.574, p = .003$), novelty ($F(1.68) = 2.220, p = .002$) show to have a significant effect on adoption rates, while for the non-interpersonal channels only novelty ($F(1.68) = 1.596, p = .06$) appeared to be significant.

4.3 Gender differences

We conducted an additional multivariate test to investigate the role of gender between interpersonal and non-interpersonal channels. Gender differences were found when it comes of frequency of the receiving recommendations through non-interpersonal channels ($F(1, 90) = 4.475, p = .035$), indicating that males receive more frequent recommendations through non-interpersonal channels than females. However, no significant gender differences ($p = ns$) were found within interpersonal channels.

Furthermore, a marginal significant effect was found of gender on novelty within interpersonal channels ($F(1, 68) = 3.138, p = .061$), indicating that males in particular receive more novel recommendations through interpersonal channels such as friends and acquaintances than females. No significant effects ($p = ns$) of gender were found within non-interpersonal channels.

Evaluation criteria	Relevance	Is the music recommend through the channel consistent with the context and theme of the playlist?
	Diversity	Does the music recommended through the channel diversify genre or mood of the playlist?
	Novelty	Is the music recommended through the channel new or novel?
	Serendipity	Is the music recommended through the channel unexpected but good in terms of the context and theme of the playlist?
Usage behavior	Frequency	How often do you receive music recommendations through the channel?
	Convenience	How convenient is the process of listening to the music recommended through the channel?
	Adoption rate	What percentage of the recommended music through the channel is added to the playlist?

Table 2. Survey questions. Same questions were used for both interpersonal and non-interpersonal channels. Adopted from Kim et al. [1].

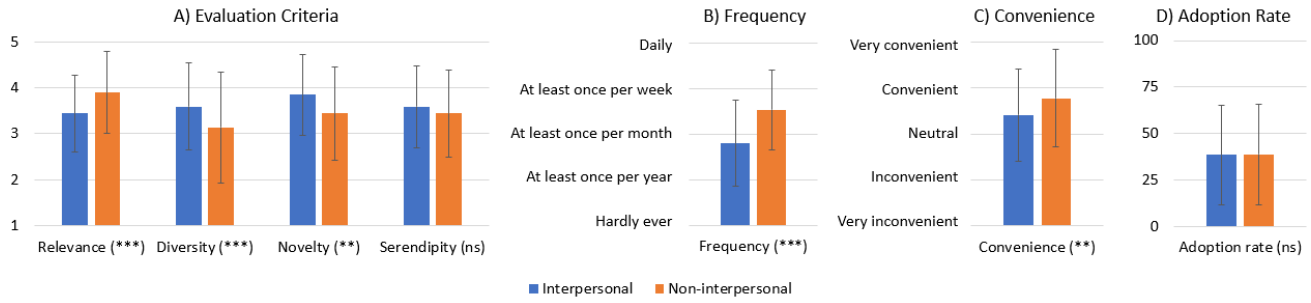

Figure 1. Mean scores with standard deviation error bars ($*\, p < 0.01$, $**\, p < 0.001$, $***\, p < 0.0001$).

Continent	Percentage
Europe	89%
Asia	7%
Africa/Middle East	3%
Oceania	1%

5. DISCUSSION

In this section, we discuss the results obtained with regards to reproducibility, deviations from the original study, and additional analyses carried out to gain further insights.

5.1 Reproducibility

For this reproducibility study we followed similar procedures and methods of the original work by Kim et al. [1]. Following the same procedures we recruited 142 participants to fill in questions on their music consumption behaviors through interpersonal and non-interpersonal music channels.

Looking at the mean values, the overall strength of the mean values suggest that similar trends are found (see Table 4) in the current study as in the original study of Kim et al. [1] between interpersonal channels and non-interpersonal channels. By additionally conducting paired t-tests, we tested whether there are significant differences between the interpersonal and non-interpersonal channels. Also here, we found in general similar results aside of that novelty returned significant, but serendipity and adoption rate became not significant. These results indicate that the sample in this reproducibility study showed less pronounced difference in the areas of serendipity and adoption rate between interpersonal and non-interpersonal channels, but more differences in novelty.

When looking at the relationship between the four evaluation criteria (i.e., relevance, diversity, novelty, and serendipity), we also found similar results as in the original study. The PCA results show the extraction of two components with a total of 67% of the variance accounted for: component 1 accounting for 43% of the variance and component 2 accounting for 24% of the variance. Our results show that the four evaluation criteria account for a

	Kim et al. [1]			Current study		
	Interpersonal ($n = 155$)	Non-Interpersonal ($n = 143$)	p	Interpersonal ($n = 118$)	Non-Interpersonal ($n = 100$)	p
Relevance	$3.47(0.86)$	**4.05**(0.70)	< 0.0001	$3.45(0.88)$	**3.90**(0.88)	< 0.0001
Diversity	**3.92**(0.77)	$3.59(0.90)$	< 0.001	**3.59**(0.95)	$3.14(1.2)$	< 0.001
Novelty	**4.09**(0.71)	$3.94(0.82)$	ns	**3.85**(0.88)	$3.44(1.0)$	< 0.01
Serendipity	**3.65**(0.96)	$3.23(0.98)$	< 0.001	**3.59**(0.85)	$3.44(0.94)$	ns
Convenience	$2.64(0.86)$	**3.05**(0.83)	< 0.0001	$3.41(1.0)$	**3.78**(1.0)	< 0.01
Frequency	$2.03(0.71)$	**2.65**(0.89)	< 0.01	$2.82(0.89)$	**3.54**(0.83)	< 0.001
Adoption rate	$38.34(22.47)$	**45.76**(22.51)	< 0.01	$38.57(26.80)$	**38.68**(27.24)	ns

Table 4. Mean values of each factor with standard deviations and significance levels. Boldfaced values indicate the higher mean values between interpersonal vs. non-interpersonal.

little less of the variance compared to the original study (75.2% with component 1 accounting for 49% and component 2 accounting for 26.2%). Although the accounted variance of the PCA is lower than of the original study, the extracted components still account for a large part of the variance.

Further linear regression show similar results as in the original study in which frequency plays a significant role in both interpersonal and non-interpersonal channels when it comes to adoption rates. Additional univariate testing show that adoption rates are influenced by diversity and novelty through interpersonal channels, while the novelty factor only plays a role on adoption rates in non-interpersonal channels. In this respect, our sample differs significantly compared to the Korean sample of the original study in which relevance and novelty factors play a role on adoption rates in interpersonal channels and relevance and diversity influenced adoption rates in non-interpersonal channels.

5.2 Deviations

Although in general similar results were found in line with the original study, there are obvious differences regarding the effect of certain evaluation criteria on the adoption rate. Where the original study found relevance and novelty to play a role in interpersonal channels and relevance and diversity in non-interpersonal channels on adoption rates, the current study found that it is especially diversity and novelty for interpersonal channels and novelty for non-interpersonal channels on adoption rates. This indicates that for the participants in the current study, they believe that non-system recommendations are able to provide them with more diverse music to listen to. Hence, music that gets recommended through friends or acquaintances consist of better ways to find new music to listen to in order to deepen or broaden people's music taste. This would suggest that people feel that music recommended through a system or service is more homogeneous (e.g., recommending music from the short tail). The need to include more diversified recommendations (or at least the perception of diversification) in those systems may play an important role on the satisfaction of users [22].

The found differences need to have further exploration to find the root-cause of occurring. A possible cause could be that cultural differences play a role [23]. The sample in the current study consisted of European participants whereas the original study only had Korean participants. Another difference in the demographics of the sample in the current study is the low amount of participants that is sharing music with others (merely 16% opposed to 62% in the original study), which could contribute to the differences in findings.

5.3 Additional findings

Aside of testing the reproducibility of the work of Kim et al. [1], we took this opportunity to further investigate other effects within interpersonal and non-interpersonal channels. Our findings show that the usability of non-interpersonal channels plays a significant role on the adoption rate of the music. In this case adding the recommended music to the user's playlist. Hence, even though improving algorithms is given a lot of attention, the usability still plays a vital role on whether recommendations of systems are being adopted by its users.

We furthermore found that gender plays a role in some aspects of interpersonal and non-interpersonal channels. In particular, males were found to receive more frequent music recommendations than females. This suggest that males in general might be using music recommendations systems more frequently than females. Additionally we found an effect of gender on receiving novel music recommendations through interpersonal channels. These results suggest that males believe that music recommendations received through friends or acquaintances are more often new or novel than females believe that they receive through interpersonal channels. Hence, it seems that the friends and acquaintances of males share and recommend more often music that is new or novel with each other.

6. ANALYSIS USING THE PRIMAD MODEL

In order to further analyze and systematically place the conducted reproducibility study, we apply the PRIMAD model [18]. The goal of PRIMAD is to systematically vary ("prime") the factors (P)latform, (R)esearch Objective, (I)mplementation, (M)ethod, (A)ctor, and (D)ata, and to categorize the various types of insights gained via the

resulting reproducibility characteristics by analyzing the variations made.

One of the core principles of the model is the underlying observation that a simple replication of experiments under completely identical conditions does not lead to any real knowledge gains, save from confirming a deterministic behavior of the process. A substantial knowledge gain, however, originates from specific priming and variation of factors. In the concrete case, we are *foremost interested in the effect of priming (D)ata*, with obvious deviations regarding (A)ctor, i.e. the persons executing the experiments, and (P)latform and (I)mplementation, which can be considered robust due to the well-established and replicable method, and are hence of lesser interest. By extending the analyses, we also vary the (M)ethod to gain further insights with regards to the unchanged overall (R)esearch Objective.

The repetition of user experiments using a different data sample with a different background provides insights on the generalization capabilities of the analysis. This offers insights on whether the original observations also hold in (slightly) different data settings. Simply using the same data but priming only the parameter settings, on the other hand, uncovers the parameter sensitivity of an analysis. While such a sensitivity evaluation should actually be performed by the initial investigation we frequently observe that studies report on the process of meta-search for the optimal parameter setting, yet sometimes failing to report on the performance variations observed. These, however, are crucial for understanding whether an insight holds as general observation and can thus be deployed, or whether a highly sensitive parameter that causes huge performance variations on minor changes to that parameter basically would limit application to predefined test settings.

More generally, the question of which factors to prime is difficult to answer. Priming of (D)ata (parameters, raw data) should be a given to derive conclusions that are not based on singular events and configurations. (M)ethod priming is essential for true confirmation of findings—and is finding additional support from the area of explainable AI, where (in principle) interpretable surrogate models are used to understand and explore the behavior of more powerful black-box models. Priming of the (P)latform, at the least, leads to information on the correctness of the (I)mplementation and completeness of the description. [2]

In the study investigated, the process was sufficiently documented and even could be reproduced without availability of the original code for the user study or for subsequent data analysis. In general, for user studies, the standards for description of study design, method description, and participants are high and expected to suffice for reproducing the study. Furthermore, as the number of settings and parameters to be documented and taken into account is much smaller than, e.g., in machine learning experiments, this should give further incentive to increasingly reproduce user studies and gather even further insights by systematically "priming" factors.

[2] Unfortunately, this aspect seems to see decreasing relevance through the trend of publicly sharing code as extensive testing of code before reuse appears to have lower priority. An investigation of the potentially harmful effects of code sharing on scientific practice are still pending, however.

7. CONCLUSION

In this work, we reproduced the study by Kim et al. [1] on differences of music recommendations obtained through non-interpersonal channels, i.e., recommender systems, and recommendations obtained through interpersonal channels, i.e. friends or acquaintances, with newly collected data (sample size $n = 142$). By re-implementing the analyses as carried out in the original study, we could largely confirm the original results and support their validity. Possibly caused by the differences in music sharing behavior and/or cultural differences (predominantly European vs. Korean study participants), we also found differences in our results mostly with regards to novelty in recommendations and their impact on adoption rate. From this we conclude that the aspect of cultural differences in music consumption should be accounted for more explicitly in future studies, i.e., by repeating and extending existing studies at larger, global scale, or specifically addressing cultures. As MIR systems ultimately are designed for users and user studies (if carried out) are the departing point for the design of these systems, findings of one existing study might not be reliable enough and generalize beyond the group it was conducted with.

For conducting the various types of reproducibility studies in MIR, using the PRIMAD model seems to be a meaningful framework and we suggest its use in future studies. We should stress, however, that in many reproducibility studies the priming does not happen due to according study design, but to compensate for lack of information available, be it a lack of parameter descriptions, the lack of sharing the data sets involved in training and evaluating systems, failure to make (thoroughly tested) code available or have sufficiently detailed information on architecture and design of, e.g., deep neural network models. Such incomplete information forces the actors in reproducibility studies to make documented assumptions on the according setting, leading most likely to slight variations in the according setting compared to the original study design.

ABSTRACT

Despite phenomenal progress in recent years, state-of-the-art music separation systems produce source estimates with significant perceptual shortcomings, such as adding extraneous noise or removing harmonics. We propose a post-processing model (the Make it Sound Good (MSG) post-processor) to enhance the output of music source separation systems. We apply our post-processing model to state-of-the-art waveform-based and spectrogram-based music source separators, including a separator unseen by MSG during training. Our analysis of the errors produced by source separators shows that waveform models tend to introduce more high-frequency noise, while spectrogram models tend to lose transients and high frequency content. We introduce objective measures to quantify both kinds of errors and show MSG improves the source reconstruction of both kinds of errors. Crowdsourced subjective evaluations demonstrate that human listeners prefer source estimates of bass and drums that have been post-processed by MSG.

1. INTRODUCTION

Audio source separation is the problem of isolating a sound producing source (e.g., a singer) or group of sources (e.g., a backing band) in an audio scene (e.g., a music recording). Source separation is a core problem in computer audition that can facilitate music remixing and other Music Information Retrieval (MIR) tasks such as music instrument labeling [1, 2] and transcription [3, 4].

Current state-of-the-art source separation systems often produce source estimates that contain perceptible artifacts, such as high-frequency noise, source leaking (e.g., drum hits heard in the bass source estimate), unnatural transients, or missing overtones. For many downstream tasks in MIR or music creation, it is preferable for source separators to minimize these errors. Given that we have observed these artifacts to be endemic to the separators themselves, we propose an additional post-processing step to clean up the initial outputs of these separators.

In this work, we introduce Make it Sound Good (MSG), a post-processing neural network for enhancing the quality of music source separation. MSG combines elements of off-the-shelf architectures from generative modeling tasks in speech vocoding and denoising to enhance the output of pre-trained source separation models in both the waveform and spectrogram domains.

The main contributions of this work are:

- A source separation post-processor (MSG) that performs imputation and denoising to enhance the output of both waveform and spectrogram models for music audio source separation.
- A subjective listener study that confirms MSG improves the perceptual quality of bass and drum source estimates on a set of five separation models, including one on which it was not trained.
- An in-depth exploration of the kinds of errors produced by different classes of source separators and how MSG affects these errors.

Audio examples and code can be found at `https://interactiveaudiolab.github.io/project/msg.html`.

2. RELATED WORK

Deep learning is the dominant approach for music source separation. For example, all entries to the 2021 Sony Music Demixing Challenge [5] were deep learning based separators. Most separators fall into one of two classes. *Waveform models* [6–9] take audio waveform input and produce an audio waveform for each separated source. *Spectrogram models* [10–18] take a mixture spectrogram as input and output a mask to apply to the spectrogram for each source being separated. Despite the recent successes of these deep learning methods, state of the art systems continue to exhibit perceptible artifacts in their outputs. We show in Section 5 that waveform models tend to introduce more high-frequency noise, while spectrogram models tend to lose transients and high frequency content.

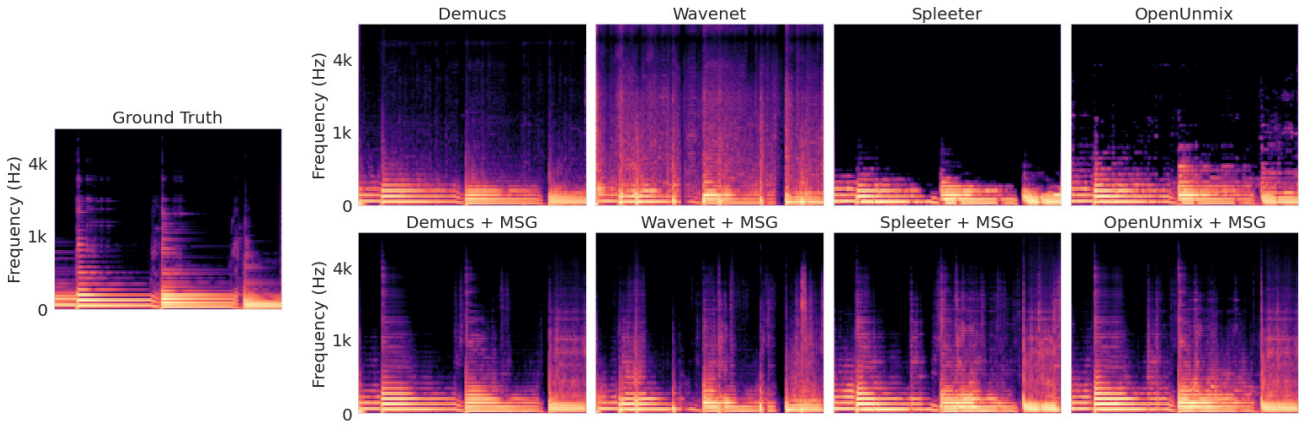

Figure 1: Spectrograms of ground-truth (left), source estimates (top), and MSG output (bottom) for the bass source. MSG is able to simultaneously infer missing frequencies and remove noise from the output of common source separation systems.

Recent works in adversarial audio synthesis [19–25] and end-to-end speech enhancement [26–32] show that the adversarial loss of Generative Adversarial Networks (GANs) [33] is effective in generating high-fidelity audio. Although such systems have been effective in audio synthesis and denoising, no previous work has explored using these systems for enhancing source separation output. Recent work has also shown that adversarial loss is effective for training source separation systems [34, 35], however this work does not look at using adversarial loss to enhance existing separation output.

While many recent works for speech enhancement have been proposed, music enhancement (e.g., denoising and artifact removal) is less common. There are only a few recent works in music denoising [36–38] and bandwidth expansion [39, 40]. Some work has also looked at potential causes of [41] and remedies for [42] audio artifacts in untrained source separation networks. Our work is most similar to Kandpal et. al [43], who proposed a generative model that can enhance the audio quality of a low-quality music recording taken on a consumer device. We are unaware of a prior system for enhancing the output of trained music separation systems.

3. "MAKE IT SOUND GOOD" POST-PROCESSOR

Here we describe our "Make it Sound Good" (MSG) post-processor, which perceptually improves a source estimate by removing artifacts that the separator introduced and imputing elements the separator omitted. We use the adversarial loss of Generative Adversarial Networks (GANs) [33] due to its success denoising many types of audio.

The generator of MSG is a waveform-to-waveform U-Net with 1D convolutions. This is very similar to the Demucs v2 [7] architecture with the exception that Demucs has two BLSTM layers at the bottleneck, which we omit.

We train the generator using three loss functions. The first is the LSGAN [44] generator loss,

$$L_G = \frac{1}{K}\sum_{k=1}^{K}\mathbb{E}\left[\left(D_k(G(\hat{s}))-1\right)^2\right], \qquad (1)$$

where $\hat{s}$ is the raw source estimate from the separator, D_k is the k-th discriminator, K is the total number of discriminators, and G is the generator.

Next is deep feature matching loss [45], which is the L_1 distance between the intermediate activations of the discriminators on corresponding real and generated data. The last loss function we use is a multi-scale Mel-spectrogram reconstruction loss [46, 47], which is the average Mel reconstruction loss over three different Short-time Fourier transforms (STFTs), each of which uses different parameters for the number of STFT bins, window lengths, and hop sizes.

We use two types of discriminators: the multi-period discriminators from HiFi-GAN [24] and the multi-resolution spectrogram discriminators from UnivNet [25]. The multi-period discriminators operate on the waveform, and reshapes the waveform to a 2D tensor with a prime-valued stride before processing the reshaped waveform with 2D convolutional layers. The multi-resolution spectrogram discriminators process a spectrogram with different STFT window sizes (see Section 4.3). We use five multi-period discriminators with strides $[2, 3, 5, 7, 11]$, respectively. We also use three multi-resolution discriminators with FFT windows $[512, 1024, 2048]$, for a total of eight discriminators. Each discriminator uses the LSGAN [44] loss,

$$L_D = \mathbb{E}\left[\left(D(s)-1\right)^2 + \left(D(G(\tilde{s}))\right)^2\right], \qquad (2)$$

where $\tilde{s}$ is the cleaned up source estimate from the MSG generator and s is the ground-truth source audio. Further details on the discriminator architectures are provided in the original papers [24, 25].

We use an adversarial loss typical of Generative Adversarial Networks, but do not condition on a random input vector. This produces a deterministic model that is not

technically generative. However, prior work has shown that the unique mode-selecting behaviors of these adversarial loss models are highly effective for densely-conditioned generative modeling tasks such as vocoding [20,24,25] and speech denoising and enhancement [26–32]. Our goal is not an exact reconstruction of ground truth, but an output that is perceptually improved. This means a distribution of viable outputs exists and the task can be framed as one of generative modeling.

4. EXPERIMENTAL VALIDATION

We conducted experiments to understand whether MSG perceptually enhances the raw output of a set of music source separation models. The remainder of this section is devoted to outlining the details of our experiments.

4.1 Models

We trained MSG post-processors using the output of four existing source separation models as the input to MSG. We train on two waveform-based separators: Demucs v2 [7] and Wavenet [8]; and two spectrogram-based separators: Spleeter [17] and OpenUnmix [16]. To investigate whether MSG can learn to correct the artifacts of different separators, we created one enhancement model that is trained and evaluated on all four separators instead of creating separator-specific models. We evaluated the MSG post-processor using the output of each of the four separators on a held out test set (see Section 4.2). Furthermore, to understand whether MSG can also reduce the artifacts produced by an unseen separator, we evaluate our post-processor on the output of a fifth separator that it was never trained on: Hybrid Demucs (v3) [48], which operates in both waveform and spectral domains. For all separation models we used the trained, frozen weights released by the authors, with no alterations. We refer readers to the papers on each separator for architectural and training details.

4.2 Data

All experiments were run with the MUSDB18 dataset [49]. MUSDB18 contains 150 songs: 100 in the training set and 50 in the test set. Each song in MUSDB18 has a full mixture and isolated source audio stems for vocals, bass, drums and a fourth catch-all category called "other". We omitted this catch-all category because we find that attempting to enhance many instruments at once with the same model greatly increases the difficulty of the task. We performed source separation on every song in MUSDB18 using all five of our source separators, producing source estimates of bass, drums and vocals.

The input audio was peak normalized before passing it through the network. Since Wavenet operates at 16 kHz we use this sample rate. We downsampled all systems to 16 kHz so that there was a uniform sample rate across all separation models. Here, we focus solely on enhancement and leave the task of bandwidth extension for future work. Thus, the output of MSG on all systems was at a sample rate of 16 kHz.

4.3 Training

We trained one MSG model on the MUSDB18 training set for each source class (bass, drums, or vocals). Each model was trained using source estimates from four separators (Demucs v2, Wavenet, Spleeter, and OpenUnmix) as input and the ground-truth sources as training targets. We segmented the audio into 1-second clips and rejected silent clips where the ground-truth source has an RMS below -60dB FS, resulting in over 100,000 training examples per model. On each training iteration, we randomly swapped the input data with ground-truth with a 10% probability. This encourages the model to leave high-quality audio unaltered.

We computed the three resolutions of STFTs passed to our multi-resolution spectrogram discriminators (Section 3) using window sizes of 512, 1024, and 2048 samples and hop sizes of 128, 256, and 512 samples, respectively. We used one Adam optimizer [50] for the generator and another for the discriminator. We used a learning rate of 2e-4 and beta values of $(.5, .9)$. To find suitable loss weights for all 3 types of losses on the generator (LSGAN loss, deep matching loss, and multi-scale spectral loss; see Section 3), we solved a least squares equation to weigh all loss terms equally for the first 1k training iterations. After that, we froze those weights applied to the losses for the remainder of training.

4.4 Subjective evaluation

The goal of our research is to improve the perceptual quality of source separation output. Therefore, we evaluate our MSG post-processor using a crowdsourced subjective evaluation (Section 4.4) rather than reporting an objective metric like Signal-to-Distortion Ratio (SDR) [51,52], since widely-used objective metrics for source separation are imperfect proxies for human perception [34, 52–57].

For evaluation data, we used one seven-second segment from each of the 50 songs from the MUSDB18 test set. We performed source separation on each seven-second segment using each of the five source separation systems (Section 4.1) to create source estimates of bass, drums, and vocals. Each output was then processed with MSG, resulting in 50 matched pairs for each combination of separator and source class: the raw output, and the output processed by MSG.

There are 15 unique combinations of the five separators and three sources (bass, drums, and vocals). For each combination, we performed a two-way forced-choice listening test between the raw output and the output processed by MSG. We initially recruited 20 participants for each test and omitted responses from participants that failed a prescreening listening test. This resulted in a minimum number of 15 participants in any test. Each participant evaluated 25 randomly-selected pairs from the 50 examples for that combination of source and separator.

A two-tailed binomial test was performed where the null hypothesis was that there was no difference between MSG-enhanced and raw separator output. If the results of a particular test showed no difference (i.e., $p < 0.05$) we

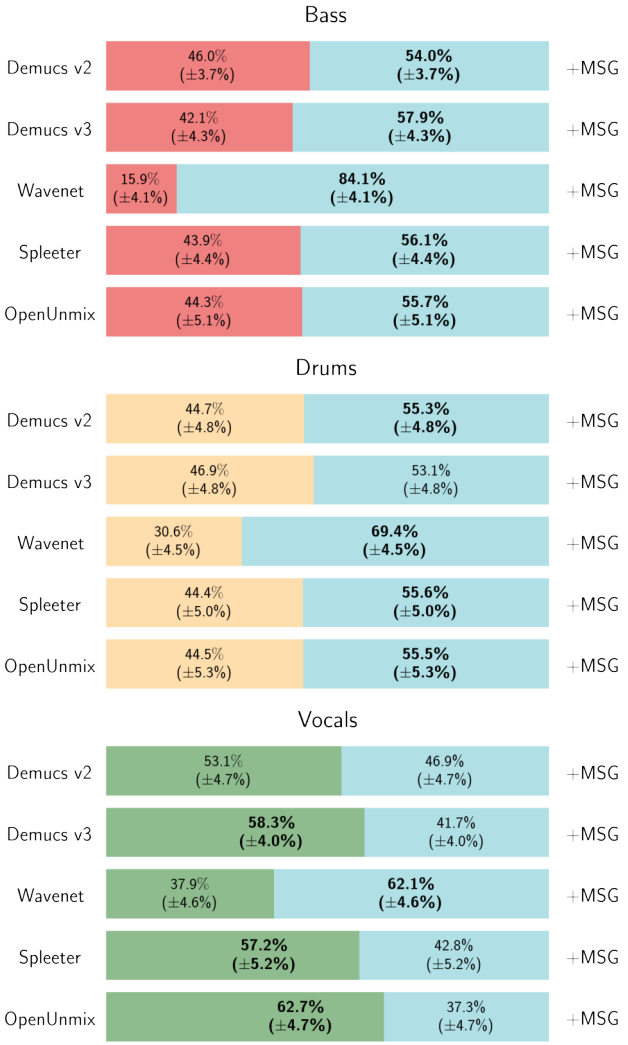

Figure 2: Subjective pairwise test results for bass, drums, and vocals. Each row contains the percent of listeners selecting that option as higher quality in a two-way forced choice listening test. A bold-faced value indicates a statistically significant difference.

recruited an additional 10 participants to see if a difference could be determined.

For each pairwise comparison, participants were given the following instructions, where <*source*> is one of "bass", "drums" or "vocals":

> Listen to both recordings of a <*source*>. After listening to both, select the recording that sounds like a higher-quality <*source*>. The higher-quality recording is the one that is more natural sounding, or has fewer audio artifacts (e.g., noise, clicks, or other instruments).

We used Reproducible Subjective Evaluation (ReSEval) [58] to set up our listener studies. We recruited participants via Amazon Mechanical Turk (MTurk). Our participants were US residents at least 18 years old that completed 20 or more tasks on MTurk with an approval rating

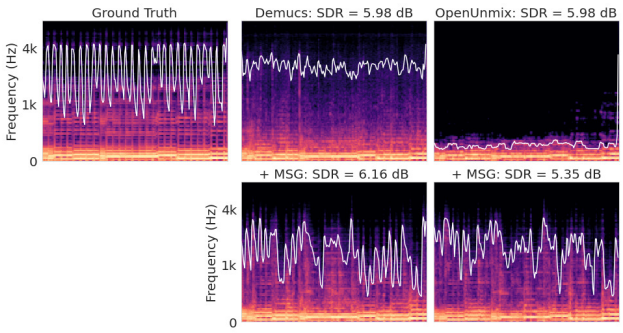

Figure 3: Spectrograms of the ground truth (left) and source estimates from Demucs v2 and OpenUnmix (top) and corresponding MSG output (bottom) for the bass source. The 98% spectral rolloff frequency is overlaid in white.

of at least 97%. Participants who passed the listening test and completed our evaluation were paid $3.00.

For each of the 15 tests, we collected between 308 and 696 pairwise evaluations from between 15 and 30 participants who passed the prescreening listening test. The number of evaluations is not a multiple of 25 because a few participants did not finish all 25 examples in their set of pairwise evaluations.

4.4.1 Subjective evaluation results

Each listening test evaluates one combination of source class and source separator. Figure 2 shows the results for each of the 15 tests. Listeners preferred the MSG output to the raw source separator output in 11 out of 15 combinations of separator and source. This difference was statistically significant (using a binomial test) in 10 of the 11 combinations. Listeners preferred the quality of separators with MSG on bass source estimates and had a moderate preference for MSG on drums. For vocals, listeners had a slight preference for the source estimate without MSG.

MSG performed best on the Wavenet separator, where it significantly improved the perceptual audio quality of all sources. MSG was also able to improve on the quality of source estimates of a separator not seen during training, Demucs v3, for bass sources—as well as an improvement on Demucs v3 drum sources that was not statistically significant. Note that Demucs v3 is a hybrid approach that operates in both the waveform and spectrogram domains. Our performance on vocals indicates that MSG is not able to enhance the quality of the source estimate of vocals. We are unaware of prior work that attempts to enhance source separation output, let alone a separated vocal source. Vocal separation has been optimized by many years of existing research, potentially leaving less room for a post-processing system to improve compared to, e.g., drum and bass sources.

5. FURTHER ANALYSIS

Our listener study indicates whether a separation is relatively "good" or "bad", but it does not clarify *why* one sep-

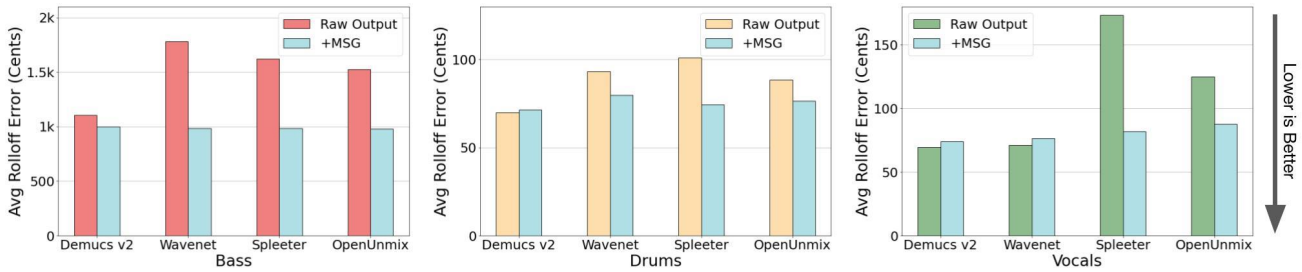

Figure 4: Mean spectral rolloff error for bass, drums, and vocals for separators with and without MSG post-processing.

arated source is better or worse than another. Similarly, the widely-used Signal-to-Distortion Ratio (SDR) [51, 52], as well as the related SIR and SAR, are not designed to capture the specific types of errors we focus on in this work. See, for example, the top row of Figure 3, which shows source estimates produced by Demucs v2 and OpenUnmix for the same bass source from the same mixture. Demucs adds additional high-frequency noise not present in the ground truth, while OpenUnmix removes many of the upper harmonics. Visually, the difference between these two systems is plain, however their SDR values (using `mus_eval` [59]) are equal to two decimal places: *5.98 dB!*

In this section, we examine the output of the four state-of-the-art separation systems used in the training of MSG models: (Demucs v2 [7], Wavenet [8], Spleeter [17], and OpenUnmix [16]), as well as the MSG-processed outputs for those four systems. As before, we use the MUSDB18 [49] test set, and we omit the "other" source.

Anecdotally, we have noted that waveform separators tend to add extra high-frequency noise and spectrogram separators tend to remove high-frequency partials, especially in bass estimates (see Figure 1). Spectrogram separators also tend to smooth out transients. While these are not the only issues that current separation systems exhibit, the rest of this section will be dedicated to analysis of these two issues.

5.1 Added and Missing Frequency Content

Following our anecdotal observation that waveform separators tend to add extra high-frequency noise and spectrogram separators tend to remove high-frequency partials, we seek to formalize these notions.

One statistic that can be a good proxy for whether a source estimate has excess high-frequency content or is missing desirable high-frequency content is spectral rolloff. For a given time frame in a spectrogram, the spectral rolloff at $X\%$ is the frequency below which $X\%$ of the energy of the signal lies. For example, the white line on each spectrogram in Figure 3 shows the spectral rolloff at 98%.

For every song in the MUSDB18 [49] test set, we compute the spectral rolloff at 98% every 32 ms (a hop size of 512 samples at 16 kHz) for every ground truth isolated source, every estimate produced by one of the four training separators and every MSG-enhanced source estimate. To calculate our statistics, we omit any frames that have an RMS less than -40 dBFS, in the ground-truth source, so as not to examine rolloff in relatively silent regions. We report the error between a source estimate's rolloff and a ground-truth source's rolloff in cents, which is $1200 \times (\log_2 x - \log_2 y)$, where x and y are rolloff frequencies in Hz. We chose to use cents over Hz because it better correlates to how humans perceive audio.

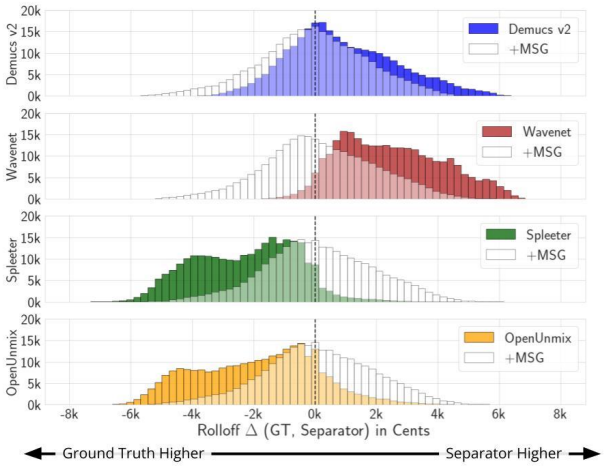

Figure 5: Histogram of the difference in spectral rolloff values between a given separator's bass estimate and ground truth bass source over the MUSDB18 test set. The vertical dotted line shows the desired difference of 0. MSG reduces the difference between the rolloff values of source estimate and ground-truth.

In Figure 4, we show the mean error, in cents, between the ground truth rolloff and the source estimate's rolloff. We see that the source estimates of vocals and drums have spectral rolloff errors on the order 100-200 cents, whereas source estimates of bass have errors of roughly 1000 cents. MSG reduces this error for all separators on bass sources, for three of the four separators on drums, and two of the four separators on vocals.

Because the bass estimates have such large errors, we examine them further in Figure 5, where we show a histogram of the per-frame differences between the spectral rolloff of source estimates and ground truth. The top two rows of the histogram show results for the two waveform separators (i.e., Demucs v2 and Wavenet), which each show an error distribution that is strongly skewed towards

positive error. This corroborates our observation of high-frequency noise introduced by waveform separators, as shown in the bass spectrogram in Figure 3. The bottom two rows show the error distribution for two spectrogram separators, Spleeter and OpenUnmix. Both exhibit an error distribution for spectral rolloff that is strongly skewed toward negative values. This quantifies the effect illustrated in Figures 3 and 1, where the spectrogram separators remove the higher partials of the bass source.

We further observe that, when MSG is applied to the output of all four separators, the resulting error distribution is less biased and, as was already shown in Figure 4, reduces the mean error magnitude. Figure 1 illustrates the effect of MSG on a single bass example, showing improved spectral rolloff reconstruction for both waveform and spectrogram models.

5.2 Improving Transient Reconstruction

While listening to the source estimates from spectrogram separators, we noticed that the transients of source estimates for drums and bass did not sound as clear as in the ground truth source estimates. To quantify these observations, we measure the location and strength of onsets in the estimated sources relative to the ground-truth. We use librosa's [60] `onset_strength()` function [61], which computes the spectral flux onset strength envelope at every frame in a spectrogram. We approximate an onset by identifying every frame with a strength above a certain threshold. We select an onset strength threshold via manual tuning. We set the threshold value to a constant value of 0.75 for both bass and drums on the MUSDB18 dataset. We manually tuned this threshold to find a value that best corresponds with our perception of relevant peaks in the signal. We chose to threshold `onset_strength()` instead of using librosa's `onset_detect()` because we found that matching up onsets between two signals using the latter method was hard to correctly tune.

We run this onset strength thresholding on both the ground-truth source and a source estimate and then calculate the F1 between the binary threshold arrays of the raw source estimate and the MSG post-processed estimate as a proxy for how well a separator preserves transients. A true positive (TP) is when a detected onset exists at the same spectrogram frame in the ground-truth and source estimate, a false positive (FP) is when an onset is detected at a frame in the source estimate but not the ground truth, and a false negative is when an onset is detected (FN) at a frame in the ground truth but not in the source estimate. We report the F1 score of onset reconstruction, $TP/(TP + \frac{1}{2}(FP + FN))$.

We report the F1 scores for onset detection on bass, drums, and vocals in Table 1. The results for vocals are not in favor of MSG for 3 of the 4 separators. We include the vocals results for completeness. Evaluating the transients for vocals might be slightly unusual, but the observed results align with the listener studies. In contrast with vocals, bass and drums both see improved F1 scores across multiple separators: MSG improves the F1 score in 7 out of the 8 combinations of source and separator, with the sole exception of drums separated by Demucs v2. This indicates that the ability to represent transients is generally improved by applying MSG-based post processing on bass and drums.

	Model	Type	Onset Strength F1 Raw	Onset Strength F1 + MSG
Bass	Demucs v2	Wave	0.52	**0.54**
	Wavenet	Wave	0.36	**0.44**
	Spleeter	Spec	0.36	**0.52**
	OpenUnmix	Spec	0.39	**0.49**
Drums	Demucs v2	Wave	**0.84**	0.82
	Wavenet	Wave	0.73	**0.74**
	Spleeter	Spec	0.78	**0.82**
	OpenUnmix	Spec	0.78	**0.79**
Vocals	Demucs v2	Wave	**0.58**	0.57
	Wavenet	Wave	**0.51**	0.49
	Spleeter	Spec	**0.71**	0.66
	OpenUnmix	Spec	0.41	**0.57**

Table 1: F1 scores for thresholded onset strength for bass, drums, and vocals for four separators with and without MSG post-processing. "Raw" means that F1 is computed between the separator's raw output and ground truth. "+MSG" means that MSG post-processing is applied to the raw source estimates. According to this measure, MSG is able to better preserve onsets in 7 out of 8 cases between the bass and drums sources, which most clearly demonstrate artifacts with transients.

6. CONCLUSION

State-of-the-art music source separators create audible perceptual degredations, such as missing frequencies and transients. In this work, we propose Make it Sound Good (MSG), a post-processing neural network that leverages generative modeling to enhance the perceptual quality of music source separators. In listening studies, users prefer bass and drum source estimates produced with MSG post-processing—even on a state-of-the-art separator not seen during training. We analyze the errors of waveform-based and spectrogram-based separators with and without MSG. Without MSG, we show that waveform-based separators induce high-frequency noise and spectrogram-based separators fail to reconstruct high-frequencies in the bass source, and have trouble reconstructing transients. We measure these artifacts via spectral rolloff and onset detection and show that, for both bass and drums, MSG generally improves reconstruction of spectral rolloff and onsets of the source estimate relative to the ground-truth sources. Fruitful directions for future work include using more modern techniques for sound enhancement (e.g., diffusion models [43]), making post-processors for the vocals and "other" sources, and deeper analyses of the issues with separation systems.

SAMPLEMATCH: DRUM SAMPLE RETRIEVAL BY MUSICAL CONTEXT

Stefan Lattner
Sony Computer Science Laboratories (CSL), Paris, France
stefan.lattner@sony.com

ABSTRACT

Modern digital music production typically involves combining numerous acoustic elements to compile a piece of music. Important types of such elements are *drum samples*, which determine the characteristics of the percussive components of the piece. Artists must use their aesthetic judgement to assess whether a given drum sample fits the current musical context. However, selecting drum samples from a potentially large library is tedious and may interrupt the creative flow. In this work, we explore the automatic drum sample retrieval based on aesthetic principles learned from data. As a result, artists can rank the samples in their library by fit to some musical context at different stages of the production process (i.e., by fit to incomplete song mixtures). To this end, we use contrastive learning to maximize the score of drum samples originating from the same song as the mixture. We conduct a listening test to determine whether the human ratings match the automatic scoring function. We also perform objective quantitative analyses to evaluate the efficacy of our approach.

1. INTRODUCTION

Machine-learning (ML) powered tools are increasingly finding their way into modern music production [1]. Commercial tools already use machine learning for different applications, like mixing/mastering [1] or data visualization. [2] In public perception, ML and artificial intelligence (AI) is often associated with *content generation*. Indeed, also in music production, generative AI models are about to transition from research labs to the studio, in the form of tools that integrate seamlessly into the artist's workflow, like Magenta Studio [3] and others [2–6].

Besides content generation, another frequent task in modern music production is *content retrieval*, where commercial solutions (based on expert systems) also already exist. [4] In manual content retrieval (i.e., content selection), artists select "loops" (short, typically bar-aligned audio files of any content) or "samples" (usually shorter, single notes or drum hits) that fit the current musical context. Content selection is a creative act in its own right, but it is challenging to browse through potentially large loop or sample libraries while – crucially – keeping the current context in mind.

To support the selection process, we envision a retrieval system that learns aesthetic principles of matching drum samples to musical context from data. As a result, it is able to sort a drum sample library according to a *score* it assigns to each sample. This lets users start their search with the most promising options first and may help turn a cumbersome curation process into a more artistic activity.

We use the cosine similarity in a learned latent space as a scoring function. Two encoders are trained with a contrastive loss to maximize the score between mixtures and drum samples originating from the same song. The encoders are trained with an electronic and acoustic data set of songs whose tracks are available separately. We perform a user study to evaluate if human listeners agree with our proposed scoring function. To that end, we test if participants prefer samples that obtain a high rating by the scoring function over randomly selected samples. Furthermore, we perform an ablation study to evaluate the different components of our method. In addition, we want to understand better how the learned space is organized. In particular, we want to gain some insights into the relationship of drum samples that fit well in the same context. For that, we perform a correlation analysis between audio features of samples that are close in the learned latent space.

The paper is organized as follows. Related works are discussed in Section 2, and Section 3 describes the used method. The used data and data preprocessing are described in Section 4. Section 5 explaines how the model training is performed. In Section 6, we introduce the performed experiments, including the objective evaluation, a user study and correlation analysis. We present and discuss the results in Section 7 and conclude in Section 8.

2. RELATED WORK

Self-supervised learning has been a hot topic in recent years, with well-known works in the visual domain, like MoCo [7] and SimCLR [8] that adopt contrastive learning approaches, and BYOL [9], or VICReg [10] that aim to eliminate negative samples. Examples for contrastive approaches in the speech domain are Wav2Vec [11], Wav2Vec 2.0 [12], as well as SpeechSimCLR [13]. Inspired by these works, self-supervised learning in non-speech (i.e., musical and

environmental) audio was also introduced with contrastive approaches [14,15], Audio2Vec [16] and Wav2Vec for non-speech audio using a conformer architecture [17]. An example for self-supervised learning for audio based on the BYOL method is [18]. Other audio-related contributions based on contrastive learning are multimodal contrastive learning (for audio and video) [19], as well as multi-format contrastive learning (between raw audio and spectrogram representations) [20]. We adopt ideas from self-supervised learning methods mentioned above, using a dictionary look-up approach like in MoCo [7], we adopt the variance- and co-variance regularization of VICReg [10], and we use decoupled contrastive learning, as proposed in [21].

Other works on drum sample retrieval involve the contrastive learning-based retrieval of single drum samples by their mixed versions [22] and retrieval by vocalization [23, 24]. Other academic works that tackle the task of matching artistic content based on *aesthetic principles* are the Neural Loop Combiner [25], and a stem mashup creation approach [26] (both based on contrastive learning). Other methods for computational mashup creation are based on optimization [27] or expert systems [28].

3. METHOD

3.1 Scoring Function

The goal of our proposed method is to estimate how well a given drum sample fits a specific musical context. This task can be modeled by contrastive learning as a dictionary look-up task, as described in [7]. A musical context $\mathbf{q}_i \in \mathbb{R}^m$ acts as a query, and drum samples $\mathbf{k}_j \in \mathbb{R}^m$ as keys. We define a scoring function $s(\mathbf{q}_i, \mathbf{k}_j)$ that outputs a high score if the sample fits the query. To that end, we use two encoders g_q and g_k to produce a query encoding $\mathbf{u}_i = g_q(\mathbf{q}_i), \mathbf{u}_i \in \mathbb{R}^d$ and a sample encoding $\mathbf{v}_j = g_k(\mathbf{k}_j), \mathbf{v}_j \in \mathbb{R}^d$. Finally, we define the scoring function as the cosine similarity $\mathrm{sim}(\cdot,\cdot)$ between the resulting encodings $s(\mathbf{q}_i, \mathbf{k}_j) = \mathrm{sim}(\mathbf{u}_i, \mathbf{v}_j)$. We train the encoders using a contrastive loss called NT-Xent in [8]:

$$\mathcal{X}(Z) = -\log \frac{\exp\left(\mathrm{sim}(\mathbf{u}_i, \mathbf{v}_j)/\tau\right)}{\sum_{l \neq j} \exp\left(\mathrm{sim}(\mathbf{u}_i, \mathbf{v}_l)/\tau\right)}, \qquad (1)$$

where $\{\mathbf{u}_i, \mathbf{v}_j\}$ is a positive pair, $Z \in \mathbb{R}^{n \times d}$ are all representations of a training batch, τ is the temperature parameter, and we adopt the decoupled contrastive learning variant, that has shown to work better for smaller batch sizes, by removing the positive pair from the denominator (i.e., $l \neq j$) [21].

3.2 Regularizations

Furthermore, we combine the contrastive loss with the variance and covariance regularization used in VICReg [10]. The variance regularization term is defined as a hinge function that penalizes variances of latent features along the batch dimension that are smaller than 1 as

$$\mathcal{V}(Z) = \frac{1}{d} \sum_{j=1}^{d} \max\left(0, 1 - S(\mathbf{z}_{:,j}, \epsilon)\right), \qquad (2)$$

where Python slicing notation is used, and S is the regularized standard deviation

$$S(x, \epsilon) = \sqrt{\mathrm{Var}(x) + \epsilon}. \qquad (3)$$

The covariance regularization penalizes non-zero off-diagonal entries in the covariance matrix of each batch, leading to a decorrelation of the latent dimensions:

$$\mathcal{C}(Z) = \frac{1}{d} \sum_{i \neq j} [C(Z)]_{i,j}^2, \qquad (4)$$

where C is the covariance matrix

$$C(Z) = \frac{1}{d-1} \sum_{i=1}^{d} (\mathbf{z}_{:,i} - \bar{z}_i)(\mathbf{z}_{:,i} - \bar{z}_i)^T, \; \bar{z}_i = \frac{1}{n} \sum_{j=1}^{n} z_{j,i}. \qquad (5)$$

Even though the cosine distance renders the norms of the network outputs irrelevant, they can still grow due to optimization dynamics. To keep the norms in a moderate range, we also add a norm regularization in form of a hinge function as

$$\mathcal{N}(Z) = -\frac{1}{n} \sum_{i=1}^{n} \min\left(0, c - ||\mathbf{z}_i||\right), \qquad (6)$$

where we fix $c = 4$ in our experiments (because most norms are smaller than 4 at initialization). Putting all the above terms together (and weighting the regularization terms with factors γ, δ and η), yields the final loss

$$\mathcal{L}(Z) = \mathcal{X}(Z) + \gamma \mathcal{V}(Z) + \delta \mathcal{C}(Z) + \eta \mathcal{N}(Z). \qquad (7)$$

4. DATA

We used a dataset of electronic music and pop/rock songs of 44.1 kHz sample rate for training and evaluation. The electronic music portion consists of 4830 so-called "remix packs", with durations ranging from several seconds to several minutes. Each remix pack consists of multiple audio tracks that contain the individual (mutually aligned) instruments (such as synth, bass, guitar, pad, strings, choir, brass, keyboard, vocals, and different percussion instruments).

The Pop/Rock dataset is a proprietary dataset of 885 well-known rock/pop songs of the past decades, including artists such as Lady Gaga, Coldplay, Stevie Wonder, Lenny Kravitz, Metallica, AC/DC, and Red Hot Chili Peppers. The stems (guitar, vocals, bass guitar, keyboard, misc, and different percussion instruments) are available as individual audio tracks for each song.

From every percussion track in the dataset, we extract so-called "one-shots", single hits with the respective percussion instrument. To that end, we picked those samples where the subsequent onset is of maximal distance (to retain most of the percussion's potential reverb). From the pop/rock songs, we extract 5 one-shots per percussion track, while from the electronic songs, we extract 1 one-shot per percussion track (as most of the time they are all identical). Altogether, this results in 63042 one-shot drum samples.

We categorize the extracted drum samples into 6 categories which are {kick, snare, hi-hat, ride, crash, toms}. The assignment is based on the filenames of the stems the samples originate from, using keyword dictionaries of typical drum-type expressions (like "hat" for hi-hat or "BD" for kick drum). We split the dataset in train / eval / test set with proportions $0.85/0.05/0.1$ (on a track level, meaning that samples of one track do not spread over different sets). All reported results are computed on the test set.

5. TRAINING

As an encoder, we use the EfficientNet-B4 [29], where we start training from weights that have been pre-trained on the ImageNet dataset. Even though ImageNet is far from the audio spectrum domain, it turned out that using ImageNet weights is crucial in our experiments (see Section 7.1, and it has also been shown in a previous study that cross-domain pre-training can be beneficial [30]).

The 1000 output units are reduced to 256 with a single linear layer. The EfficientNet expects a 2D input, which we provide by converting the audio signals into mel-scaled spectrograms with an STFT window length of 2048, a hop length of 512, and 128 resulting mel bins, considering the whole frequency range (fmax $=$ 22050). Also, we log-scale the values of the resulting mel spectrograms. We input the resulting spectrograms in each of the three RGB input channels of the EfficientNet (after normalization to the ImageNet color statistics).

A positive pair consists of an audio query and a corresponding drum sample. Given a drum sample, we select the stems of the corresponding song and remove the stem from which the drum sample was extracted. Then, we randomly choose at least 2, at most all of the remaining stems (the number of stems is uniformly sampled) and mix them on the fly during training (note that the mel spectrogram transformation is part of the model architecture using the *nnAudio* library). [5] All audio inputs are of length 4 seconds. If a drum sample is shorter than that, it is zero-padded. To obtain a query, we are cutting a 4-second-long snippet from a random position of the mixture.

The encoders are trained by the ADAM optimizer, with a batch size of 190, a learning rate of 3e-4, and a weight decay factor of 3e-5. The temperature parameter τ of the NT-Xent loss is set to 0.2. The factors for the variance and covariance regularization terms γ and δ are set to 1, and the norm regularization factor η is set to 10.

We use some data augmentation on both the queries and the drum samples. First, Gaussian noise is added (up to -12 dB). Furthermore, we perform time-stretch with a ratio between 0.9 and 1.15 of the original tempo. Another augmentation is reducing the gain down to a minimum attenuation of -6 dB, and we perform a time shift of up to 800ms to the right and 200ms to the left (to make the models invariant to the exact onset position of one-shot audios). All these augmentations occur with a probability of 50% for each instance.

6. EXPERIMENTS

In this section, we introduce the conducted experiments to validate our method including objective metrics (Section 6.1), the user study (Section 6.2), and we describe the method of the correlation analysis (Section 6.3).

6.1 Objective Evaluation

As the actual goal of the study is to sort the candidate samples given an audio query $\mathbf{q}_i$, the primary evaluation metric is the rank_i of the ground-truth samples for a given query (i.e., the samples that originate from the same song as the query). For that, we sort all drum samples in descending order according to the cosine similarity to a given encoded query and determine how early in the list a ground-truth sample is located. We also divide the rank_i by N list entries to obtain normalized ranks $\in (0, 1]$. As we can extract several queries (4-second-long random excerpts) for each song in the test set, and as there are several drum samples assigned to each song, we perform this test for every song in the test set 50 times (resulting in $|Q| = 27$k evaluations) and average the resulting ranks. The explanation above results in the Mean Normalized Rank summarized as

$$R_{\text{mn}} = \frac{1}{|Q|} \sum_{i=1}^{|Q|} \frac{\text{rank}_i}{N}. \tag{8}$$

In addition, we also report the *Median* Normalized Rank R_{md}, as this is an indicator of how well the model performs *most of the time*, ignoring possible outliers.

Besides also reporting the contrastive loss $\mathcal{X}$ (see Equation 1), we also evaluate how well the model has learned to cluster electronic and acoustic queries (i.e., mixtures) and keys (i.e., drum samples). To that end, we perform a binary (acoustic/electronic) k-nn classification (with $k = 50$) on the encodings separately for both the queries and the keys. From this classification task, we report the likelihood (L_q and L_k, respectively) of the data under the predictions.

In order to better understand the influence of different design choices, we perform ablation studies and report the metrics for each model and training variants. The different ablation scenarios are described in the following.

- `2Enc` denotes our proposed setup with 2 separate encoders instead of a shared encoder for both, queries and samples.
- `PTrain` denotes a variant that starts training from an EfficientNet that was pre-trained on ImageNet, instead of from randomly initialized weights.
- In `Aug`, data augmentation is used.
- `VCReg`, is using the variance and co-variance regularization terms (see Equations 2 and 4).
- In `SMix`, we randomly mix different numbers n of random stems to form a query (where $n > 1$). If `SMix` is not used, we always mix all stems of a song.

- For `QSInv`, in addition to sampling positive pairs from queries and corresponding samples, we also include as positive pairs two queries and two samples originating from the same song.

6.2 User Study

To evaluate the quality of the scoring function, we perform a user study in which we ask 10 experts (with musical education or concerned with music production) to rate the quality of selected drum samples given a musical context. More precisely, we test their preference between drum samples that scored well according to our system and samples that are randomly picked from the dataset. The possible choices are to select one of the two proposed mixtures, or "equal" (if there is no preference for one of the choices), or "skip" (if the samples to be rated are not of the expected class or any other problem occurred). Every participant obtains 12 single comparisons (presenting each of the 6 percussion types twice) and provides 12 ratings accordingly. After that, they can decide if they want to enter a further session (to provide 12 further ratings). Participants are asked not to perform more than 4 sessions to obtain a balanced result.

The procedure to obtain one comparison presented to a participant for rating is as follows. We pick a percussion type (e.g., snare) and a song from the test set that contains such a type as a single stem. We remove the stem containing that type, mix the remaining stems and pick ten 4-second-long excerpts from randomly sampled positions of the resulting mixture. All these excerpts are then fed through the query encoder, and the mean is taken from the resulting encodings. The resulting mean vector acts as the query encoding for the current song. Using this query, the cosine similarities to the latent representations of all 63k drum samples in the data set (obtained as described in Section 6) are computed, and the ten samples with the *highest similarities* are selected. Furthermore, ten drum samples of the corresponding percussion type are *randomly picked* from the data set. The thereby obtained samples are used to generate 20 new versions of the current song (a version for each sample).

To create a new version of a song, we perform an onset detection on the previously removed stem (containing the percussion type in question), position the selected samples in the estimated positions, and mix the resulting stem with the remaining stems (omitting the original stem of the percussion type in question). That way, we replace the original drum track with a track containing the drum sample to be evaluated. For a single user rating, we then contrast the mixtures of a *randomly picked* and a *highly rated* percussion sample and have participants indicate their preference between the two.

6.3 Correlation Analysis

In order to gain some insights into the latent space learned by the encoders, we perform a correlation analysis between audio features of neighboring data points. For that, different perceptual and spectral features are computed for the drum samples in the data set using the *Audio Commons timbre models* [6] for perceptual features (e.g., boominess, brightness, depth, hardness, roughness, warmth) and *librosa* [7] for spectral features (e.g., spectral centroid or spectral contrast). We also add an indicator if the respective drum sample originates from an electronic or acoustic song. In the former case, the "electronic" feature value is set to 1, in the latter case to 0.

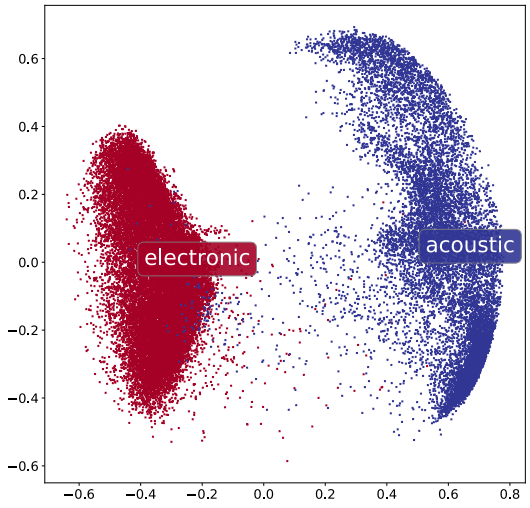

Figure 1: Principal Component Analysis (PCA) of drum sample encodings. Red dots indicate samples originating from electronic music and blue dots indicate samples originating from acoustic music.

The drum samples are mapped into the sample encoder's latent space, and k-means clustering is performed using $k = 24$. In each cluster, the mean of each audio feature is used as a specific observation of that audio feature variable. Then, the Pearson correlation coefficient is computed between all such variables (separately for every percussion type). As a result, we can derive statements like "whenever the loudness of a kick drum is high, the boominess of the snare tends to be low". Note that for computing the audio features, we normalize every sample to 0.5 seconds (i.e., cut or pad) so that the audio feature computation is not influenced by the length of the audio file (as some features are computed by averaging several spectrogram frames). To obtain the latent encodings used to compute the clusters, we use the regular 4-second-long samples.

7. RESULTS AND DISCUSSION

7.1 Objective Evaluation

In Table 1, we report the contrastive loss, the Mean and Median Normalized Rank, and the query and sample electronic/acoustic classification likelihood for different archi-

Table 1: Ablation study for different architectures and training scenarios tested on queries from full mixtures and queries from sparse mixtures (a sparse mixture is based on a random number n of stems, where $n > 1$). $\mathcal{X}$ denotes the contrastive loss and R_{mn} and R_{md} is the mean and median normalized rank, respectively, of ground truth samples. L_q is the likelihood of the binary k-nn (electronic/acoustic) classification task for query, and L_k for key encodings in the latent space.

tectures and training scenarios (as described in Section 6.1). For each run, we train for 600 epochs and pick the saved checkpoint of the epoch with the best performance (regarding the Mean Normalized Rank R_{mn}) on the evaluation set for evaluating the test set. We report the results when evaluating the models with queries that are drawn from mixtures where all stems of a song are used (denoted as "full mixtures") and mixtures with a random number n of stems (denoted as "sparse mixtures", where $n > 1$). The latter scenario is crucial in music production, where sample selection may occur at an intermediate state of the project, when several instruments are still missing.

The results show that our proposed architecture and training procedure (first row in Table 1) performs best in the mean and median rank metrics (R_{mn} and R_{mn}) for both query scenarios (note that the random guessing baseline is 0.5). It is somewhat surprising to us that `QSInv` (i.e., imposing additional invariance for queries/samples originating from the same song) does not improve but rather worsens the result (cf. row 2 of the table). Apparently, the relaxation of the space caused by not using this regularization helps to perform the main objective.

We can see for `SMix` that it is vital to mix different (numbers of) stems on the fly during training (cf. third row in Table 1 where this has not been done). `SMix` does not only help for the "sparse mixtures" scenario at test time (right part of the table) but also in the "full mixtures" scenario (left part of the table).

Using a pre-trained EfficientNet (`PTrain`) makes a considerable difference in the overall performance and training dynamics. In fact, when not using pre-trained weights, it is necessary to add `QSInv` in our experiments. Otherwise, the encoders do not learn at all (see row 6 in Table 1).

The last row of Table 1 presents the results of a scenario where all training optimizations (augmentation, variance, co-variance regularization, and sparse mixing) are turned off. It can be seen that the performance deteriorates substantially, particularly in the "sparse mixtures" test scenario.

Finally, the results of the classification likelihood (mostly around 99%) show that the models have implicitly learned to separate electronic and acoustic content (cf. Figure 1, showing a PCA of the drum sample encodings). Interestingly, this separation works consistently better if no data augmentation is used (see row 4 in Table 1). Electronic samples are generally "cleaner" than those extracted from acoustic music. Augmentation (e.g., adding noise) may remove some of these characteristics, making it harder to discriminate between the two classes.

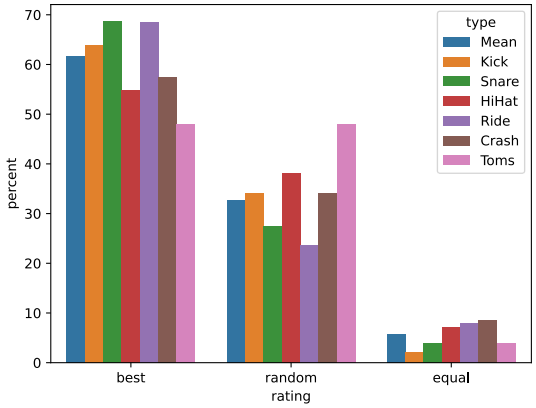

Figure 2: Preference ratings of participants in the user study, separated by percussion type (the blue bar "Mean" shows the mean of all ratings). "best" are mixtures with samples that *scored highest* by our method, and "random" denotes mixtures with *random samples* from the data set. An "equal" rating means no particular preference.

7.2 User Study

Figure 2 shows the results of the listening test (based on 300 ratings in total, omitting skipped ratings). On average ("Mean"), the samples that are ranked "best" by our method were preferred approximately twice as often as random samples (61.57% to 32.64%). It is also interesting that for most percussion types, the human preference for "best" is similar to or better than average (with Snare and Ride being the most salient), while human ratings disagree with our system's choices, particularly often for HiHat and Toms. A hypothesis why HiHats perform worse is that we merged both open and closed hi-hat in one group. When replacing the original hi-hats with the selected ones, there

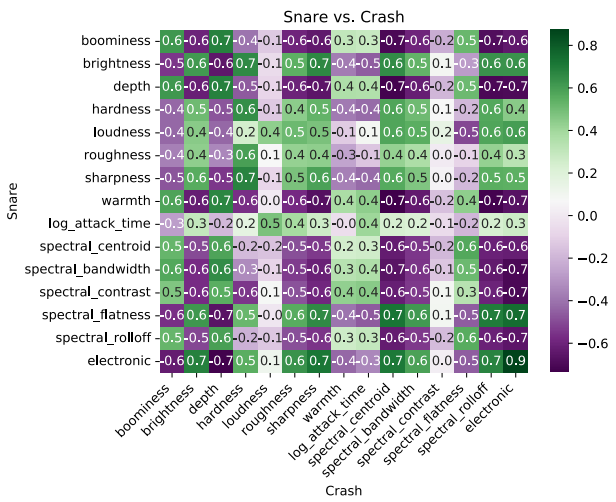

Figure 3: Correlations between perceptual and spectral features (and electronic / acoustic indicator) of Snare and Crash drum samples that are close in the latent space (i.e., scored to fit well in the same musical context).

is an equal chance that an open hi-hat is used for a rhythm that is meant to be instantiated with a closed hi-hat and vice versa. This is particularly problematic in electronic music, where closed hi-hats are often used with minimal temporal intervals. The reason why Toms do not work well is probably due to less available training data (many tracks do not have tom stems). Examples of how the user study was presented can be found on the accompaniment website. [8]

7.3 Correlation Analysis

Figure 3 shows the correlation coefficients between audio features of snare and crash drum samples over clusters in the latent space (as described in Section 6.3, note that the entirety of the percussion-type combinations is shown on the accompaniment website). [8]

To our knowledge, there is no theory about the aesthetic rules of drum sample selection. Therefore, this analysis is particularly informative. It is interesting to see that strong correlations exist at all between the audio features of snare and crash found in the same clusters of the latent space (as is true for most other percussion-type combinations). Consequently, the characteristics that make drum samples fit in the same musical contexts can (also) be explained by such lower-level features. Using such correlation coefficients makes it possible to understand how the learned space is organized. More importantly, it is also possible to derive rules and make the method explainable. For example, it is possible to extract statements like "if the snare of a song sounds warm, the crash should not sound bright" (because "warmth" of the snare and "brightness" of the crash are negatively correlated with a coefficient of -0.6).

When looking at the diagonal of the correlation matrix in Figure 3, we see that the perceptual features tend to be positively correlated (from "boominess" to "warmth"), while the spectral features tend to be negatively correlated (from "log attack time" to "spectral rolloff"). Possibly, as snare and crash have similar perceptual characteristics, they should not get into each other's way regarding their frequency ranges. Whenever the snare occupies the higher frequencies, the crash occupies the lower frequencies and vice versa (according to the "spectral centroid" entry of -0.6 in the diagonal).

Finally, the correlations with the "electronic" indicator are also informative. It shows that a snare (and partly a crash) in electronic music tends to be more intense than in acoustic music, with more brightness, loudness, and sharpness. At the same time (looking at the spectral centroid), in electronic music, a snare tends to occupy rather lower frequencies than in acoustic music, while the opposite is true for crash (where the spectral centroid is positively correlated with electronic snares - having a correlation coefficient of 0.7). The high correlation of "electronic" (0.9) in the diagonal shows that electronic snares and crashes tend to be in the same clusters of the latent space.

8. CONCLUSION AND FUTURE WORK

We introduced a method that automatically scores the fit of drum samples to a given musical context. As the method is thought to be used in a music production context, the audio queries used for training are based on "sparse mixtures", which allows scoring samples at different stages of the music production process. Results show that this form of data augmentation generally improves performance, also when queries are computed from complete mixtures at test time. Critically, the automatic system should agree with human judgment. Therefore, we performed a user study that tests this agreement. It could be shown that the drum samples that are highly rated by our system are also preferred by human experts approximately twice as often as randomly selected samples.

As the architecture and training procedure combine different ideas, we performed an ablation study, where it became clear that starting with a pre-trained model is crucial for a good final performance and that additional choices (like using variance and co-variance regularization, data augmentation, and on-the-fly sparse mixing) improve the results considerably. It was also shown that audio features of drum samples whose encodings are close in the latent space are highly correlated, and we demonstrated that the observed correlations can also be interpreted to derive rules.

Our proposed method is not limited to drum samples but can potentially be used to retrieve different kinds of musical material based on learned aesthetic principles. Also, in the future, we want to scale up the system by using bigger data sets and a more generic pre-processing strategy. Currently, single drum samples are extracted before training to obtain a controlled experiment setup and application scenario. Developing a system that uses stems directly would apply better to audio sources of any type and would therefore greatly increase the applicability of our method in music production.

A TRANSFORMER-BASED "SPELLCHECKER" FOR DETECTING ERRORS IN OMR OUTPUT

Timothy de Reuse **Ichiro Fujinaga**
Centre for Interdisciplinary Research in Music Media and Technology, McGill University
{timothy.dereuse, ichiro.fujinaga}@mcgill.ca

ABSTRACT

The outputs of Optical Music Recognition (OMR) systems require time-consuming human correction. Given that most of the errors induced by OMR processes appear "non-musical" to humans, we propose that the time to correct errors may be reduced by marking all symbols on a score that are musically unlikely, allowing the human to focus their attention accordingly. Using a dataset of Romantic string quartets, we train a variant of the Transformer network architecture on the task of classifying each symbol of an optically-recognized musical piece in symbolic format as correct or erroneous, based on whether a manual correction of the piece would require an insertion, deletion, or replacement of a symbol at that location. Since we have a limited amount of data with real OMR errors, we employ extensive data augmentation to add errors into training data in a way that mimics how OMR would modify the score. Our best-performing models achieve 99% recall and 50% precision on this error-detection task.

1. INTRODUCTION

An enormous amount of music scores exist only in the form of digital images, where its musical content is not machine-readable. Among the fields of research that that assist with large-scale processing of musical documents is Optical Music Recognition (OMR), which investigates how to transform images of music scores into symbolic music files (e.g., MusicXML files) that can be searched, played back, and edited. OMR has the potential to be a valuable tool for music archives and libraries, but it is not yet reliable enough; all methods require a human correction step after the OMR process, as the raw outputs of currently-available OMR algorithms contain too many errors to be acceptable for musicians or music researchers. This is an issue when using OMR on printed Western music notation, and is worse for other types of music notation, especially when training data is scarce. While custom interfaces exist for the purpose of facilitating human correction, such as the correction interface of MuRET [1], this is still a time-consuming task even for experts. While OMR speeds up symbolic encoding in many cases [2], the process of scanning documents, performing OMR, and correcting OMR is not always faster than that of transcribing pieces from scratch on complex, polyphonic scores [3].

We observe that OMR systems tend to introduce musically unlikely phenomena into scores. A typical example of the errors induced by the OMR process of PhotoScore [1] (a leading proprietary, commercial OMR software) is illustrated in Figure 1. In the OMR'ed score, consider the pattern of missing staccato articulations in measure 1, the eighth note misidentified as a sixteenth note in measure 2, the strangely placed grace note in measure 3, and the accidental misidentified as a grace note in measure 6. Also note how the slurs in each instrument of the OMR'ed score do not match up with each other, though the correct phrasing could probably be guessed from the melodic content alone. While not all of these phenomena are necessarily impossible in a string quartet, a human looking over the score would notice their presence.

Given the musical "incorrectness" of many of the errors introduced by OMR, we propose that a machine-learning algorithm could flag most OMR errors automatically given information on the conventions of the genre. This could reduce the correction time of a score; instead of checking every measure of OMR output against the corresponding measure in the score image, the user would only have to check those regions flagged by the algorithm as possibly erroneous. Even if the algorithm flags some non-erroneous regions of the score, it could potentially still exclude large portions of it from needing human review.

The reader may question why we aim for *detection* of errors as opposed to *correction* of errors outright; this could further reduce the time to correct OMR output even further, and there exists a large body of work on error correction for natural language that we could draw on. We posit, however, that any amount of correction that is not guaranteed to address nearly *all* errors in an OMR output would not significantly save time on the part of the human corrector, as they would still be required to manually review the result anyway. Current studies on correcting errors in polyphonic music (discussed in Section 2) do not attain high enough performance to meet this bar.

2. PREVIOUS WORK

There is little other research that seeks to detect or correct errors in symbolic music in the context of OMR. Most studies that discuss errors made by OMR systems seek to characterize them as a part of a method of evaluating their performance [4, 5]. As part of an end-to-end OMR system, Rossant and Blach [6] explicitly encode some musical rules (such as ensuring the number of beats in a measure matches the most recent time signature) that let them highlight areas that are likely incorrect, and also use confidence measures of detection steps from earlier in their OMR process to highlight areas that may have been detected incorrectly. More research focuses on error correction in music for other applications. McLeod et al. [7] focus on the task of analyzing errors in the output of Automatic Music Transcription (AMT) methods, introducing rule-based and machine leaning-based models to solve error detection and correction tasks, though these are intended as proof-of-concept baselines to define the tasks. Ycart et al. [8] compare a number of machine-learning models on the closely related task of Symbolic Music transduction, which involves processing the raw per-note probabilities output by an AMT model and producing a valid symbolic music file as output. Sidorov et al. [9] analyse music using formal grammars, taking the assumption that "correct" music tends to be highly compressible, and so any note whose presence alone significantly increases the amount of information in a piece is likely to be an error.

Significantly more literature exists in the fields of Grammar Error Detection (GED) and Grammar Error Correction (GEC) in natural language. The fields are far too broad to cover here; we direct readers to reviews on these subjects by Wang et al. [10], covering GEC, and Madi and Al-Khalifa [11], covering GED. Early models in both of these fields were rule-based, wherein every type of error had to be manually codified [12]. The current state of the art in these areas is in sequence-to-sequence deep-learning models similar to those used for machine translation, reaching human-level performance on common English-language GEC benchmarks [13]. To achieve this level of performance, however, a large amount of training data is required; there is much less research on GEC and GED in low-resource languages, the vast majority being on either English or Chinese [11]. Our task faces a similar issue; there exists orders of magnitude fewer training data for any one genre of music than there exists for the English language.

Data augmentation is commonly used in GEC and GED where data availability is low. Errors are added to correct examples and the models are then directed to correct those errors; we refer to errors created in this way as *synthetic errors* and errors created by the process of interest (e.g. errors induced by an OMR process) as *natural errors*. Early work on this process used simple statistics about distributions and types of errors to add errors semi-randomly [14, 15]. Later work, inspired by back-translation techniques from machine translation, trained models that *add* synthetic errors simultaneously with ones that *remove* them. Htut and Tetreault [16] evaluate a number of these models, finding that they provide significant improvements to training on natural errors when the dataset containing natural errors is small. Notably, they

find these gains in performance even when the synthetic errors are qualitatively different than the natural errors; that is, a GEC method can still perform well even when it is trained on grammatical errors that a human would never make. However, when a large dataset of natural errors is available, the improvements obtained by augmenting with synthetic errors are significantly diminished.

3. METHODOLOGY

In developing our method, we aim for it to have the following qualities:

- **High Recall Rate**: Our detection method should ideally make *no* false negatives; that is, whenever an error is present in its input, it highlights it. It is acceptable for the precision to be significantly lower than the recall as long as the user is assured that no errors lie outside the flagged regions.
- **Localization of Errors**: Within the constraint of having a high recall rate, the method should try to be as specific as possible when pointing out errors.
- **Trainable on a Small Dataset**: Many of the most common use-cases of OMR are on genres that do not have high-quality, large, digitized datasets on which we could train.
- **Takes Long Inputs**: Many errors introduced by OMR are unlikely to be identifiable in isolation from a small snippet of music, and may only be recognized on the basis of comparison with the rest of the piece.

3.1 Data Representation

What is "an error" in a musical score? Rigorously defining this notion requires some procedure to take the "difference" between two scores (in our case, an OMR output and a correct score). The characteristics of the errors that we find will depend heavily on the underlying representation we use. We also face the constraint that whatever representation we use must be suitable for input into a machine-learning model, preferably as a sequence; this disqualifies the use of methods that operate on hierarchically-structured MusicXML data [17, 18].

A piano roll-like representation, representing a snippet of music as a two-dimensional image, easily admits a difference operation by way of taking the pixel-wise difference of two two-dimensional piano rolls, but is memory-intensive for long inputs. Another possibility would be to use a token-based representation such as NoteTuple [19], which represents polyphonic music as an ordered list of multi-valued tokens; for example, a piece might be represented as a sequence of triples of the form `(MIDI Pitch, Onset Time, Duration)`. This kind of representation is common in deep learning applications, and there exist many notions of difference on one-dimensional sequences that could be adapted. However, to align with our goal of localizing errors, it would be better for each unit of our representation to contain as little information as possible, so that in calling a single element erroneous we pinpoint the location of the error down to a smaller region in the score.

To accomplish this, and to choose a representation that matches the domain of OMR, we opt to use an *agnostic representation* [20]. An agnostic representation of a musical score lists each of the symbols on a staff without considering their underlying musical meaning; this stands in contrast to *semantic representations* like MusicXML. An agnostic representation encodes less information per sequence element; a dotted eighth note with an accidental would typically be encoded by a single token in a representation like NoteTuple, whereas the accidental, the note, and the dot would each be a separate element in an agnostic representation, and each could be individually flagged as an error.

We write our own utility (included with the source code of this project) to convert Musicxml or Humdrum **kern files into an agnostic encoding by first parsing them with the `music21` package, and then heuristically defining an agnostic encoding that matches the resulting textttmusic21 stream. The encoding lists each symbol on a staff in order from left to right. When two or more symbols are in the same horizontal position (such as when multiple notes sound simultaneously) we list them in ascending order and add a caret symbol ^ between each of them. To handle multiple staves, we interleave them: a measure of the first violin, a measure of the second violin, the viola, the bass, and repeat. This scheme cannot encode all polyphonic musical scores into unique agnostic representations; staff lines where two rhythmically distinct polyphonic voices are notated on the same staff may contain unresolvable ambiguities, where it is not clear which notes belong to which voice. This is not an issue for our task, as we aim not to generate valid semantically-encoded scores from agnostic representations but only to *classify* notes in an existing score.

3.2 Sequence Alignment

To define a difference between two agnostically-encoded musical excerpts, we use the Needleman-Wunsch (NW) sequence alignment algorithm [21]. This algorithm takes as input two sequences and computes the shortest list of operations necessary to turn one into another, where an operation is defined as insertion, deletion, or replacement of a sequence element. By comparing a corrected score with its OMR'ed version, we can see *where* operations must be performed in order to correct it. Our strategy will be to train a model to answer the question: *Given a musical score that contains errors, where would we need to perform operations to correct those errors, according to a NW alignment?* We ignore information on *which* operations need to be performed. Preliminary experiments showed degradation in overall performance when our model was trained to identify the type of error along with its position. We surmise that to a human corrector, reliable detection of the location error itself is more important.

(b)

Figure 2: (a): A correct score (top) and version with OMR errors (bottom): Mendelssohn's Quartet No. 1 in E♭ Major Op. 12, Mvt. 2, measure 10, 2nd violin part. (b): The Needleman-Wunsch alignment between the agnostic encodings of the two scores on the left. The **Op.** column shows the operations needed to correct the OMR column: **I**nsertion, **R**eplacement, and **D**eletion. Note that during training, all these operations will simply be marked as Errors.

Figure 2a contains an illustration of two snippets of music: one original and one with OMR errors. Figure 2b shows the result of their alignment with the NW algorithm. Our training data will mark each note as an error if it has an operation assigned to it; for example, the eighth rest at the end of the OMR snippet in Figure 2a will be marked as an error in training, since it must be removed to correct the score. Under this scheme we have no way of flagging a note as an error if it is not present in the OMR output. As a workaround, we flag a symbol as erroneous in training if, to correct the input, it would be necessary to insert one or more items *after* that symbol in the sequence. For example, we would mark the very first barline of the OMR output in Figure 2b as an erroneous symbol, since there is a missing `8th.pos2.start` immediately succeeding it.

3.3 Dataset and Data Augmentation

Ideally, our dataset would comprise a large, well-curated corpus of symbolic music in a single genre, each with accompanying score files in some image format, and another dataset containing versions of those score images passed through an OMR process. We could match up each symbolic music file with its OMR'ed counterpart and perform an NW alignment between them. Then, during training, the OMR'ed symbolic music would be the input to our model, and the resulting alignment would be our target.

To our knowledge, there are no large, publicly available sources of data that match these requirements. Datasets intended for training OMR systems do not include erroneous OMR outputs, as their purpose is to aid in developing the OMR process itself. Given a set of scores in symbolic and image formats, we could automate a OMR application to process a new dataset in this way, but the commercial OMR software available to us does not have the requisite batch processing functionality that would make this feasible. Instead, we take a small dataset of symbolic music files paired with their OMR'ed counterparts, and supplement it with a large dataset containing music of the same genre, but without accompanying OMR'ed files. We add synthetic errors to this larger dataset to mimic the natural errors in the small dataset.

Our main dataset, from which we derive natural OMR errors, is a set of Mendelssohn's string quartets comprising 24 movements [22], containing a total of 175 thousand tokens when encoded agnostically. This dataset contains OMR'ed versions of each movement generated using the PhotoScore software, partially-corrected versions of the OMR'ed files for each movement, and fully-corrected versions of each movement. The OMR'ed files contain a high proportion of errors; the character error rate between the fully-corrected and uncorrected files is 0.29, and the same statistic for the partially-corrected files is 0.11 [2] . We supplement this with a corpus of the string quartets of Beethoven, Haydn, Mozart, and Schubert, taken from KernScores [3] and the Annotated Beethoven Corpus [23], comprising a total of 361 movements and a total of 9.25 million agnostic tokens. It would be ideal to focus specifically on a single era of music, but we posit that for the sake of ease of training, consistency in instrumentation (restricting ourselves to only string quartets) is a more important consideration.

To augment the dataset, we add errors to the agnostic representation of our dataset in a way that mimics how natural OMR errors are distributed in the smaller dataset. To this end, we set aside a small portion of the Mendelssohn string quartet dataset and run a NW alignment between these snippets and their manually-corrected versions. From these alignments we can obtain statistics

[2] This statistic may sound high compared to the number of errors shown in Figure 1. This is explained by the verbosity of agnostic encodings; something that *looks* intuitively like a single error on the page may actually constitute several.

Table 1: A table comparing precision scores for given recall (R) scores on our error detection task. The "Baseline" model uses an LSTUT, synthetic errors made with our data augmentation method described in Section 3.3, and a sequence length of 256. Each section of the table changes a single variable from the baseline.

on how each type of symbol tends to be affected by the OMR process. For example, in the OMR process, the symbol `rest.quarter` remains the same with probability 0.527, is deleted with probability 0.142, is replaced with an eighth rest with probability 0.013, and so on. We use these statistics as a probability distribution, sampling from it for every single symbol in an agnostically-encoded piece, and then apply the resulting operation to each symbol.

This is a highly simplified model of how OMR introduces errors. It does not take into account the effects of adjacent symbols on one another, or how errors tend to group together on parts of a page that are badly scanned or damaged. However, we have a small amount of real OMR data to work from, which we plan to use for validation and testing, so we cannot spare much for the purpose of training the error generator. A more sophisticated error-generation model would likely overfit on such a small fraction of this dataset.

We train with the large dataset augmented with synthetic errors, reserving our dataset of Mendelssohn string quartets containing natural OMR errors for validation and testing. Each batch of training data in agnostic format is tokenized and is augmented with errors. Then, each training example in the batch is NW-aligned with its correct version (Section 3.2), and the alignment results are used to create a sequence of binary flags (error or no error) the same length as the training example. We train the model using the synthetic training data as input and these binary flags as the target. Validation and testing follow the same process but use existing OMR'ed data instead of adding synthetic errors.

4. EXPERIMENTS

As a baseline model, we employ the Long Short-Term Universal Transformer (LSTUT) [24] as an encoder-only model. This architectre consists of a 4-layer Universal Transformer [25] (a Transformer network where all the layers share the same weights) with 5 self-attention heads, bookended by two bidirectional Long Short-Term Memory (LSTM) layers in lieu of the positional encoding scheme used by vanilla Transformers. This architecture was designed specifically to learn from short- and long-term repetitive musical structure, and outperformed other variants tested on our tasks. We use the linear self-attention mechanism by Vyas et al. [26], implemented as part of their `fast-transformers` package for use with the Pytorch deep learning framework; this is a modification to the vanilla Transformer network with memory usage that scales linearly with input size instead of quadratically. The source code for our full workflow is available on GitHub [4] .

We test on two alternate architectures: a bidirectional LSTM and a vanilla Transformer. In the baseline LSTUT, the LSTM layers and attention heads all have an internal hidden dimension of 128. The LSTM network uses four layers, each with a hidden dimension of 512, and the vanilla Transformer network has 6 layers each containing 4 self-attention heads, all with a hidden dimension of 128. All models end in a fully-connected layer that reduces each sequence element down to a single dimension. We designed these architectures such that all would have a similar number of trainable parameters (around 8 million).

We also test on different input sequence lengths, and the type of synthetic errors used for data augmentation; the "Random" run applies uniformly random deletions, insertions, and replacements in the training data, and the "50% fewer" run uses our statistically-informed data augmentation scheme but only adds half as many errors, which we use to see if it improves performance on partially-corrected OMR. All models were trained with early stopping based on validation loss, using four NVIDIA P100-PCIE GPUs with a combined 48 GB of memory. When testing dif-

[4] `github.com/timothydereuse/transformer-omr-spellchecker`

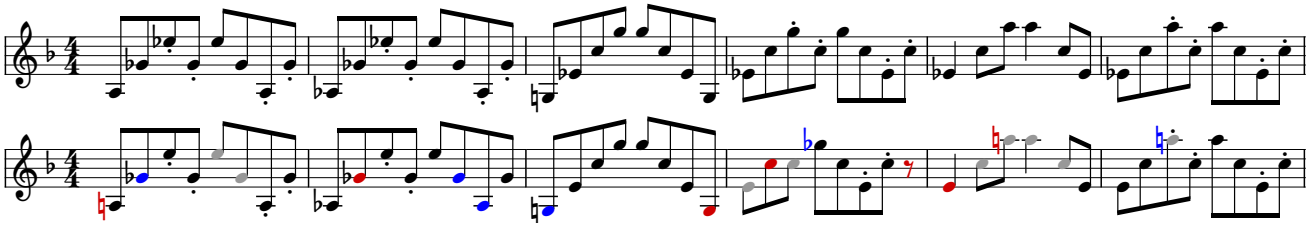

Figure 3: An excerpt from Mendelssohn's String Quartet in E♭ Major, Op. 12, Mvt 1, mm. 212-217 (1st violin part). The upper staff contains the original excerpt, and the bottom one contains OMR errors, along with the predictions of our model. Notes marked in red are errors that our model correctly identified, those marked in blue are errors that our model missed (false negatives), and those marked in grey are correct notes that our model marked as erroneous (false positives). Keep in mind that a correct note may be marked as erroneous if, to correct the score, one needs to insert a symbol *after* it.

ferent sequence lengths, we alter the batch size so as to always use the entirety of the available GPU memory. Lastly, we test on two different sets of data: one is the OMR'ed Mendelssohn quartets, and one is the same quartets after a single pass of human review. This second test set allows us to see if the model can detect the kinds of errors that humans miss when reviewing a score.

In testing, we must apply a threshold to the raw output of the network to turn it into a binary prediction. A common way to do this is to choose a threshold that maximises F1 score on the validation set and then apply that threshold to the test set. However, since we seek to maximise precision *given* a recall score near 1.0, we instead fix several scores for recall, and report the corresponding precision scores on the test set for those thresholds. We anticipate that in a real error-correction scenario, a user would be able to set a threshold themselves based on their tolerance for error; such forms of user interaction are common in high-recall information retrieval applications [27].

4.1 Results and Discussion

Table 1 shows a summary of our results. The Baseline model uses an LSTUT, synthetic errors generated with our data augmentation method, and an input sequence length of 256. We show the precision scores associated with different recall scores to represent different tolerances for missed errors. For example, our baseline model has a precision of 0.47 when the recall is 0.9, meaning that if a user wishes to be sure that 90% percent of the errors are caught, then 53% of the model's detections will be false positives.

The LSTUT model performs slightly better than the LSTM and the vanilla Transformer, though this performance difference is most notable at lower recall scores. Our statistically-informed error generation method outperforms the addition of random errors. At the highest recall score (R=0.99), our best precision score is 0.50, which we obtain at a sequence length of 1024. Precision drops only slightly as our target recall score increases, indicating that a significant fraction of each string quartet is deemed to be correct, and is ignored by the model with high confidence. Our models to perform well at identifying single errors surrounded by correct musical content, while long runs of errors, common in OMR'ed passages with tightly-spaced notes, are sometimes ignored. This may be a consequence of how our data augmentation method does not produce dense clusters of errors.

All models performed poorly on detecting errors in the partially-corrected files, though the vanilla Transformer network did marginally better. Examining our results, we note that our model struggles to notice the *absence* of elements like articulations and accidentals; these kinds of omissions comprise a majority of the errors in the partially-correct OMR files.

Figure 3 shows a violin passage from a Mendelssohn quartet and its OMR'ed version, indicating where our baseline model (at 0.90 recall) predicts errors. A common tendency of our method is illustrated here: when the model cannot pin an error to one single symbol definitively, it will mark a region around the error as erroneous (e.g., the many false positives in measures 4–5 of the excerpt). False negatives do happen (e.g., the missing staccato markings in measure 2), but when notes are missing or inserted, the model tends to make a detection that is at least in the vicinity of the true error.

5. CONCLUSION

For a machine-learning method to be useful in low-resource situations, such as those faced by many archivists and musicologists trying to make long-neglected music more accessible, it must perform a task consistently, given a small amount of data, and be easily generalizable. For this reason we have set ourselves a simple task, in hopes that we can perform it reliably. Even a low precision score may be helpful to a corrector if errors are rare; if our method flags 50% of the score as potentially erroneous, that halves the amount of material the human must check.

While our method achieves a reasonable amount of precision on Mendelssohn's string quartets, we have not proven that it can actually reduce OMR correction time. It would be useful to find ways of evaluating this type of system that speak more directly to its utility for human correctors; for example, by using the results of experiments by Pugin et al. [28] that test how long it takes to correct different types of errors. We plan to integrate our method into an existing notation application or correction interface, to see how it can best aid the symbolic encoding process.

ABSTRACT

This study explores the association between music preferences and moral values by applying text analysis techniques to lyrics. Harvesting data from a Facebook-hosted application, we align psychometric scores of 1,386 users to lyrics from the top 5 songs of their preferred music artists as emerged from Facebook Page Likes. We extract a set of lyrical features related to each song's overarching narrative, moral valence, sentiment, and emotion. A machine learning framework was designed to exploit regression approaches and evaluate the predictive power of lyrical features for inferring moral values. Results suggest that lyrics from top songs of artists people like inform their morality. Virtues of hierarchy and tradition achieve higher prediction scores ($.20 \leq r \leq .30$) than values of empathy and equality ($.08 \leq r \leq .11$), while basic demographic variables only account for a small part in the models' explainability. This shows the importance of music listening behaviours, as assessed via lyrical preferences, alone in capturing moral values. We discuss the technological and musicological implications and possible future improvements.

1. INTRODUCTION

The field of music recommender systems has a lot to gain from the fields of music psychology and sociology [1, 2], where researchers have found converging evidence that people listen to music that reflects their personality needs [3–7] and helps express their values [8–10]. For example, extroverted people tend to choose more energetic and rhythmic tunes, while listeners holding values of understanding and tolerance prefer more sophisticated and complex music. Indeed, operationalising knowledge of how personality traits relate to listener taste and preferences has already been shown to improve music recommendations [11, 12] and to make them more diverse [13]. Yet personality dispositions alone may not suffice to explain, and thus model, our music listening behaviours.

Aiming to advance an integrative view of the music listener, which may benefit music recommender system scenarios, we set to explore the less attended relation between moral values and music preferences. If personal values are conceived as intrinsic motivational goals, moral values reflect traits learned under the influence of society, culture, and religion, amongst others, which bond people together into groups. Considering music as an evolved tool of social affiliation and bonding [14, 15], it is reasonable to speculate that people may like certain music styles and genres because they provide stimuli that match their morality-related needs.

We further hypothesise that moral values are expressed more clearly in a verbal rather than non-verbal manner and examine their influence on musical taste through lyrics. When people listen to sung music, their preferences are driven by not only the audio content but also the content of lyrics [16]. Lyrics convey rich, multifaceted messages about societal issues such as love, life and death, but also political or religious concepts, often independently from melodic and other audio information [17]. Lyrical messages can support listeners' mental health [18]. Nonetheless, little is known about whether lyrical information manifests links between psychological traits and music preferences [19]. To what extent are moral values reflected in the lyrics of one's favourite songs? Do lyrics predict the moral traits of listeners?

To tackle these questions, we used data from the *LikeYouth.org* project, a Facebook-hosted application developed specifically for research purposes as a surveying tool and was mainly deployed in Italy. Upon providing their informed consent, participants completed validated psychometric questionnaires for personality, moral traits and basic human values, basic demographic information such as age and gender, while agreed to share their Page Likes (see [20] for a detailed description of the complete dataset). For the purpose of this study we only analysed moral values scores and Likes on music artist Pages. Combining these with information from the *genius.com* music database, we obtained the lyrics from the five most popular songs per artist. We performed both sentiment [21] and emotion [22] analysis on the obtained lyrics, assessed their moral narratives employing the MoralStrength lexicon [23], and examined themes and overarching narratives through topic modelling [24].

We built a series of regression models that infer moral traits from lyrical content, demographics, and Likes-based

features (e.g., artist popularity). Our findings show that peoples' worldviews and moral values are indeed reflected in their music preferences as modelled through lyrics, in line with recent literature [25, 26]. Extracting topic and moral features from lyrics specifically increased model performance over sentiment, emotion, and demographic features.

We contribute to the growing literature studying the interplay between music and psychology, with findings that clearly link the preferences of people to artists and songs that are in line with their moral values. Personalised recommendations for streaming on-demand music can be greatly enriched by including notions of moral worldviews about their listeners instead of only shallow psychological attributes [1, 5, 10]. Such knowledge can be directly implemented in psychologically aware music recommender systems, improving music streaming services and contributing to listener wellbeing [27]. On a different key, the relationship between moral worldviews and music preference is crucial to inform communication experts about their choice of the most appropriate music piece to accompany a social campaign.

2. BACKGROUND

We operationalise morality via the Moral Foundations Theory (MFT) [28], which expresses the psychological basis of moral reasoning in terms of five innate foundations, namely Care/Harm, Fairness/Cheating, Loyalty/Betrayal, Authority/Subversion, and Purity/Degradation. These can further collapse into two superior foundations: *Individualising* (Care and Fairness), indicative of a more liberal perspective, and *Binding* (Purity, Authority and Loyalty), indicative of a more conservative outlook.

Moral foundations are considered to be higher psychological constructs than the more commonly investigated personality traits [29]. They have been associated with attitudes towards complex situations such as politics [30, 31], climate change [32], and vaccination [33, 34].

However, moral values have attracted less attention from music scientists. Using data from an ad-hoc online survey comprising, among other items, MFQ scores and preferences ratings on 13 music genres, Preniqi et al. [25] found that people with higher levels of Binding foundations (e.g., more authoritarian individuals) tend to listen to country and Christian music, the lyrics of which often foster notions of tradition [3]. Those with lower levels of Binding traits tend to prefer music genres such as punk and hip-hop, where lyrics are known to challenge traditional values, and the status quo [8]. Individualising foundations were overall harder to predict (cf. [35]). Furthermore, including demographic information (e.g., age, gender, political views, education) improved MFT predictions marginally, indicating the ability of music preferences alone to explain one's moral values.

In the computational social science field, recent work has demonstrated the predictability of MFT traits from a variety of digital data, including gameplay [36], smartphone usage and web browsing [35]. Moral values can also be explained by verbal data, as they can be more clearly communicated through thoughts and opinions [23, 34, 37]. Several dictionary-based approaches for predicting moral values expressed in texts such as tweets and other social media posts have been proposed, including the Moral Foundations Dictionary [37, 38] and the MoralStrength lexicon [23]. Here we employ the latter to uncover moral narratives in song lyrics, which we then use to predict the moral traits of listeners.

		Census	**MFT All data** $n = 3,920$	**MFT & ≥10 Page Likes** $n = 1,386$
Gender	M	48%	54%	53%
	F	52%	46%	47%
Age	<25	23%	21%	29%
	≥25	77%	79%	71%

Table 1. Demographic breakdown of our data according to gender and age. The "Census" column reports the national distribution per attribute according to the statistics provided by the official census bureau [45].

The relation between lyrics and music preferences has only recently started to receive attention across music and social psychology disciplines. Some studies have suggested associations between the personality or mental health of songwriters and their lyrics [39, 40]. On the listener side, neurotic individuals tend to listen to songs with more complex and less repetitive lyrics that express negative emotions [19, 41]. More conscientious individuals tend to prefer lyrics talking about achievements [19] but also about love [42]. Importantly, preferences for lyrics are found to be predictive of personality traits distinctly from audio or melodic preferences [19, 42].

Concerning moral values, in recent work, they have been found to explain a unique and significant portion of the variance in the lyrical preferences of different metal music sub-genre fans that was not already accounted for by personality traits [26]. For example, preferring lyrics about celebrating metal culture and unity was related to higher levels of the Loyalty foundation and higher levels of extroversion. In U.S. popular music, an increase in lyrics related to self-focus and -promotion since the 1980s has been shown to manifest the increasing individualism of American society [43, 44].

3. DATA COLLECTION

The LikeYouth Facebook-hosted application was initially launched in March 2016, while the data used here were downloaded in September 2019. It was deployed mainly in Italy, where approximately 64,000 people entered the platform, from whom 3,920 users (90% geolocated in Italian territory) filled out the MFT questionnaire correctly.

Of those, 47% did not provide their age due to the facultative nature of LikeYouth. Because we wished to include age as a demographic predictor variable, we inferred the missing values from all (e.g., not just music artist related) Page Likes of the 3,920 users. Similar to [46] we created

a sparse matrix representation of Page Likes per user and applied sparse singular value decomposition to reduce dimensionality, while binning the age attribute (median $= 25$) as "younger" (< 25) and "older" (≥ 25) allowed to approximate the official census distribution [45]. We then employed an XGBoost classifier, to predict missing age values [35], with an estimated $AUROC = 0.79$ and standard deviation $= 0.018$. Acknowledging that age inference might add bias to our models, we only use age as a predictor in isolated experiments (see Table 4). We also run the same experiments keeping only users who provided their age. Predictions were similar for Binding and slightly lower for Individualising.

To ensure the stability of our regression models, we applied a simple activity threshold. After extensive experimentation we chose to drop users with less than 10 Facebook Page Likes related to music artists (Page category selection), resulting in a reduced final dataset of 1,386 users. Table 1 reports the demographic breakdown of our data sample in terms of gender and age, which follows closely the population distribution of the official Italian census [45].

For the final 1,386 users, we retrieved song lyrics corresponding to their music artist Page Likes using *genius.com*. Querying the Genius API, we initially obtained the 10 most popular songs per artist alongside the respective lyrics. We assume that if a user liked the Page of a specific artist, then that artist's most famous songs (as per Genius) reflect the music preferences of the user. We carried out predictive tasks using the $n = 10$, 5, or 3 most popular songs from an artist and found that $n = 5$ gave the best compromise in terms of predictions, computational resources, and within-musician variability in lyrical and audio content (see future work discussion) while maintaining an optimal number of musicians and songs for our lyrics data. Finally, we used the spaCy library [47, 48] to identify songs with English lyrics only, resulting in 3,179 artists and 15,895 songs.

We also considered two additional, more shallow digital trace features that can potentially convey information about user's music habits, namely the number of Page Likes per user (mean $= 35.11$, standard deviation $= 33.95$) and a built-in feature of artist popularity from LikeYouth, based on the number of Page followers.

We use LikeYouth because, to our best knowledge, it is the only dataset providing MFT scores of individuals alongside a potential proxy of their music preferences (e.g., artist Page Likes). A limitation of this approach is that the data provided by LikeYouth are static and may thus refer to a snapshot of music interests in time. Streaming platforms could offer richer information about habitual music listening [7, 42]. Nonetheless, there is substantial evidence that Facebook Page Likes can capture personality needs and personal values [5,20,46]. Another limitation is that LikeYouth user MFT scores and thus our predictive models cannot be made publicly available due to privacy implications [34]. Instead, we have shared the lyrics data and related source code for lyrical feature modeling in a GitHub repository. [1]

[1] https://github.com/vjosapreniqi/lyrics-content-features

Type	Method	Features
Topics	LDA	Death/Fear/Violence, Obscene, Romantic, World/Time/Life
Morals	MoralStrength	Care, Fairness, Loyalty, Authority, Purity
Sentiment	VADER	Negative, Positive, Neutral, Compound
Emotions	NRC	Anger, Disgust, Fear, Sadness, Anticipation, Surprise, Joy, Trust

Table 2. Summary of lyrical features used in this study.

4. LYRICS CONTENT ANALYSIS

We extracted a set of textual features related to each song lyrics' overarching narrative (topic modelling), moral valence, sentiment, and emotion. Based on the corresponding feature modeling method, we applied different levels of text preprocessing. Sentiment detection required only a general cleanup while keeping punctuation and capitalization within the text. For the other methods, we extracted Part Of Speech (POS) lemmas using the spaCy lemmatizer [47]. On average, each lyrics contained 273 words and 108 lemmas.

4.1 Topic Modelling

Initially, we aimed to uncover common patterns in the lyrics narratives by applying a topic modelling approach based on Latent Dirichlet Allocation (LDA) [24]. We used LDA due to its simplicity, high accuracy in topic modelling, and good computational efficiency [49]. The input of the LDA model is a term frequency matrix of the corpus created by the song lyrics. To eliminate very common terms that can lead to irrelevant topics, we ignored words with frequency higher than 90%.

To derive the optimum number of topics k, we optimized the topic coherency (C_v metric [50]) for models with $k \in [2, 16]$ using a step size of 2. The number of topics for which coherency was maximised was $k = 4$. For $k > 4$, we obtained topics that were either generic or hard to characterise due to the mixture of different words belonging to multiple topics. While for $k = 4$, the topics obtained were in line with previous literature [51,52]. Table 3 depicts examples of manually selected songs of 5 artists for each topic, ranked by descending weight in the specific topic.

4.2 Moral Valence

We assess the moral narratives by employing the MoralStrength lexicon [23], which holds the state-of-the-art performance in moral text prediction. This expands the Moral Foundation Dictionary by offering three times more moral-annotated lemmas. The lexicon provides, along with each lemma, the *moral valence score*, a numeric assessment that indicates both the polarity and the intensity of the lemma

Topic	Artist	Song Title	%
Romantic (0.39)	Mike Williams	Give it up	99
	Marc Anthony	I need to know	99
	NSYNC	I want you back	99
	Willie Nelson	Always on my mind	98
	Alexia	Because I miss you	97
Obscene (0.24)	Tyga	Rack city	98
	Fat Joe	Yellow tape	96
	Cardi B	Bartier cardi	95
	Chamillionaire	Ridin'	95
	21 Savage	Bank account	91
World/Time/ Life (0.22)	Holly Herndon	Morning sun	99
	Noisecontrollers	The day	97
	Nathan East	Finally home	96
	Dave Gahan	Tomorrow	94
	Gabrielle Aplin	Start of time	90
Death/Fear/ Violence (0.15)	Hatebreed	Destroy everything	99
	Fear Factory	Edgecrusher	97
	Eomac	Mandate for murder	95
	Destruction	Thrash till death	92
	Sabaton	Attack of dead men	91

Table 3. LDA topic modelling: overall topic prevalence (in brackets below topic descriptions) and 5 manually selected songs per topic as ranked by descending topic proportion.

in each of the five moral foundations (MFT traits). Moral valence is expressed on a Likert scale from one to nine, with five considered neutral. When lower than 5, scores reflect notions closer to Harm, Cheating, Betrayal, Subversion, and Degradation, while values higher than 5 indicate Care, Fairness, Loyalty, Authority, and Purity, respectively.

We obtained a moral valence score for each lemma in a song's lyrics and each MFT trait, which is then averaged across lemmas for each song. Negation correction was not applied, as moral foundation polarities do not directly translate as opposites (e.g., "not care" is not the same as "harm"). The MoralStrength lexicon has a limited linguistic coverage; as a result, we could not predict moral valence for 16% of the collected lyrics. Instead, we assigned them the value 5, the neutral point of the moral valence Likert scale. This approach pushes the observed mean towards the center of the scale, but captures the variability of the moral values across all the lyrical data.

4.3 Sentiment and Emotion Analysis

In textual data, emotions, as brief and preconscious phenomena, can be defined via descriptions of appraisal, physiological reaction, expressive display, feeling, or action tendency, while sentiments, as lasting and conscious emotional dispositions, tend to be modelled in terms of text polarity (positive, negative, neutral) [53].

We applied the commonly used VADER (Valence Aware Dictionary and sEntiment Reasoner) model [21] on the lyrical text to obtain information about the sentiment of each song. The VADER model is shown to perform well both with long and short text, providing for each song a score for positive, neutral, negative, and compound sentiment

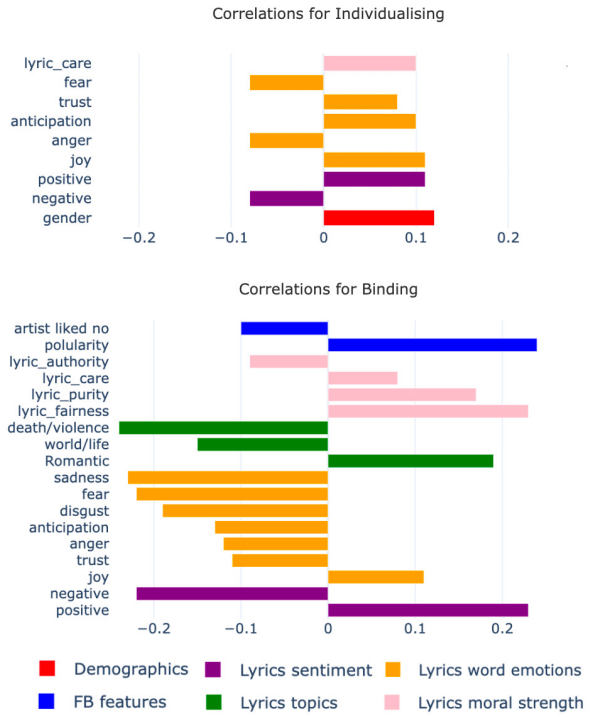

Figure 1. Spearman's Rank correlations of MFT super foundations with demographics, artist likes and lyrics features. We report only ones that were significant at $p \leq .01$. "Artist liked no" refers to the number of artist Likes per user.

(see Table 2). We also estimated the eight basic emotions defined in the Plutchik wheel of emotions [54] employing the NRC Word–Emotion Association Lexicon [22]. This lexicon was shown to be efficient with unlabeled data [55]. Each song lyrics was annotated with the eight emotions (see Table 2) by averaging its word emotion association scores.

5. EXPERIMENTS AND RESULTS

Initially, we explored the relationship between users' moral values as emerged from the self-reported questionnaires, basic demographic attributes, and their respective music preferences, as expressed in the linguistic components of the lyrics. Figure 1 depicts the statistically significant correlations ($p \leq .01$) obtained for the two superior foundations, namely Individualising and Binding. We observed that people who value more Individualising foundations prefer artists whose songs prevalently talk about anticipation and trust. On the other side, those concerned more about social order and Binding foundations tend to prefer artists who deal with more romantic topics in their songs instead of existential and social issues. Overall, participants with strong Binding foundations display a tendency to dislike songs with negative valence and emotions such as sadness, fear, or disgust. Yet both the Individualising and Binding groups resonate with positive and joyful songs, showing that despite often profound differences in sociopolitical stances, music is a shelter to everyone.

Next, we proposed a series of experimental designs to

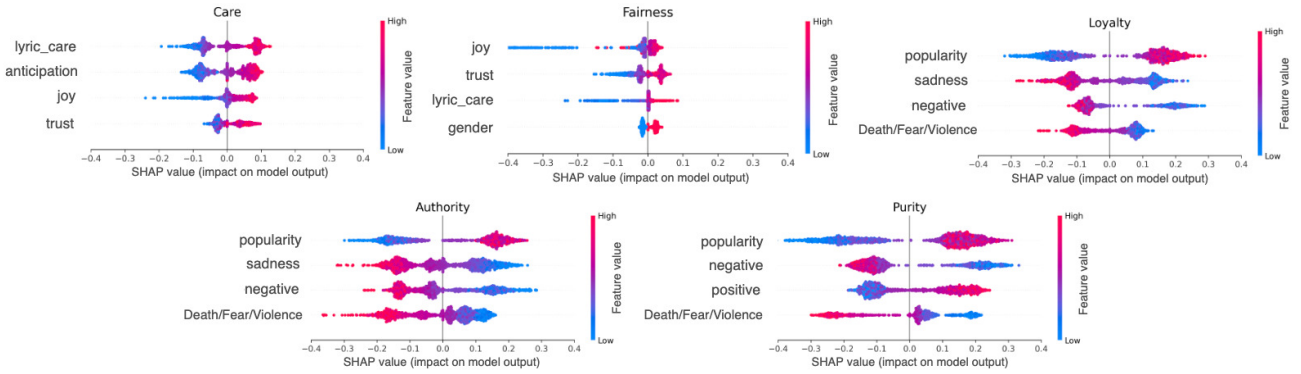

Figure 2. Top 4 individual feature contributions (via SHAP values) for the five basic moral foundations from experiment EX8 (see Table 4). The higher the SHAP value, the more the feature contributes to the prediction model.

ID	Features
EX1	Sentiment (VADER)
EX2	Emotions (NRC)
EX3	Sentiment + Emotions
EX4	Best of {EX1, EX2, EX3} + Morals
EX5	Best of {EX1, EX2, EX3} + Topics
EX6	Best of {EX1, EX2, EX3} + Morals + Topics
EX7	EX6 + Age + Gender
EX8	EX7 + Artist Likes + Artist Popularity

Table 4. Summary of performed experiments with corresponding features used as predictors.

infer moral values of the participants from their music preferences and the respective linguistic content. Table 4 summarises the performed experiments. We employed four algorithms, namely Support Vector Regressor, Random Forest, XGBoost, and ElasticNet, to predict moral values using a multivariate regression approach over a 5-fold cross-validation setting. For each participant, the features were aggregated and normalised. Here, we report only the results from the Random Forest since it slightly outperformed the rest. We used the Pearson's correlation coefficients between the predicted and actual moral values scores to measure the model's goodness fit. This metric was commonly used in papers that predicted personality based on users' music preferences and listening behaviours [5, 56].

To comprehend the general behaviour of our models and evaluate the importance of each feature, we estimated the SHAP values. SHAP (SHapley Additive exPlanations) is a game theory approach designed to illustrate the features' contribution to the final output of any machine learning model [57].

Following the incremental experimental design reported in Table 4, we trained one model per each moral foundation and presented the best results obtained by each feature in Table 5. In line with recent literature [25] that shows higher prediction accuracy for Binding rather than Individualising foundations, we noticed a similar behaviour also when inferring from linguistic features of song lyrics.

When adding demographics and artist Facebook information (EX8), the results slightly improved for both super foundations, implying that the more information we have about users' demographics and music preferences, the more precise our models become. Despite that, the model trained on just emotions, sentiment and moral information (EX4) achieved almost as good results as those who are aware of the demographics and the general artist information (EX7 and EX8). This highlights the importance of music preferences in portraying our goals and decisions whose motivations go far beyond basic demographic knowledge.

Figure 2 depicts the most important individual (only top 4 due to page restrictions) features for predicting each of the five moral foundations. While Figure 3 illustrates the impact individual (top 8) and grouped features in inferring the two superior foundations when considering all predictor variables (EX8). In line with observed correlations, feature importance representations for regression models show that lyrics linked to objective and subtle emotions (e.g., joy, trust, and anticipation) effectively predict Care and Fairness. Whereas more intense and opposite polarities of sentiment and emotions (e.g., fear, sadness, lyrics positive and negative valence) account for better predictions of Loyalty, Authority and Purity. We noticed that those who value more the Binding foundations appear to be sensitive to the popularity of the song, which reflects their worldview of prioritising group-focus over self-focus.

6. CONCLUSION

This paper discussed the link between lyrical information and moral values. We presented a wide range of lyrics processing techniques and features for measuring the power of linguistic aspects in predicting complex psychological traits such as moral values. Besides, we explored and compared the impact of user demographics and shallow digital traces in inferring moral foundations against the song lyrics components.

We noticed that Binders express their views throughout their music preference and lyrical styles. In contrast, Individualising views are more complex to be captured solely by people's music lyrics preferences. Thus, using the proposed framework, it was easier to infer moral values of Binding

	Moral Foundations - Regression Models

($.20 \leq r \leq .30$) between predicted and target values than Individualising foundations ($.08 \leq r \leq .11$).

We demonstrated that lyrics features extracted from the naturally emerging music preferences in social media, to some extent, allow for constructing reliable inferences of moral values. Considering the expanded presence of online music streaming services our findings may have direct implications for music recommendation and personalisation algorithms [1,5,58]. Since moral values are a key element of the decision making process in several societal issues [35, 59] and highly linked to political leanings [60], our research implications can help future studies to tackle aspects of why and how music is or can be used for mass stimulation and persuasion in social and political campaigns, raising awareness on what our digital music behaviours can reveal.

In future work, we intend to combine audio and lyrical content analysis together in a multimodal framework to further expand our understanding of music and moral affiliations, especially for Individualising foundations that remain hard to predict. Recent work highlights that preferences for both lyrics and audio features are important in predicting, often distinctly, personality traits [42]. We will also use additional data from LikeYouth to investigate if moral foundations can explain variance in music preferences that cannot be accounted for by personality traits and personal values (cf. [26]). We ultimately aim to integrate our findings into novel psychologically aware music recommender systems, but also beyond the music domain to other media.

7. ACKNOWLEDGEMENTS

This work was supported by the QMUL Centre for Doctoral Training in Data-informed Audience-centric Media Engineering (2021–2025) as part of a PhD studentship awarded to VP. KK acknowledges support from the Lagrange Project of the Institute for Scientific Interchange Foundation (ISI Foundation) funded by Fondazione Cassa di Risparmio di Torino (Fondazione CRT). We would like to thank the three anonymous reviewers and the meta-reviewer for their thoughtful comments.

ABSTRACT

Recent advances in deep learning not only facilitate the implementation of zero-shot singing voice synthesis (SVS) and singing voice conversion (SVC) tasks but also provide the opportunity to unify these two tasks into one generalized model. In this paper, we propose such a model that generate the singing voice of any target singer from any source singing content in either text or audio format. The model incorporates self-supervised joint training of the phonetic encoder and the acoustic encoder, with an audio-to-phoneme alignment process in each training step, such that these encoders map the audio and text data respectively into a shared, temporally aligned, and singer-agnostic latent space. The target singer's latent representations encoded at different granularity levels are all trained to match the source latent representations sequentially with the attention mechanisms in the decoding stage. This enables the model to generate unseen target singer's voice with fine-grained resolution from either text or audio sources. Both objective and subjective experiments confirmed that the proposed model is competitive with the state-of-the-art SVC and SVS methods.

1. INTRODUCTION

Singing voice generation is an innovative technology in contemporary music and multimedia content production. There are two major approaches to singing voice generation, which are 1) singing voice synthesis (SVS) [1–7] and 2) singing voice conversion (SVC) [8–12]. SVS features generation from a given musical score and lyrics (texts) and SVC from the given content (e.g., pitch, rhythm) of a source audio recording. Both approaches aim at imitating the performance style (e.g., expression, timbre) of a target singer's recordings in the generation result. In recent years, the SVS and SVC tasks have both witnessed a great improvement thanks to the advances in deep learning. Training a model that generates singing voice in different singer identities is no longer an issue. However, most of these works only support the generation of preset singers' voice, and learning the voices of new singers usually requires a sufficient amount of data to fine-tune the model [4, 7].

A practical singing voice generation system requires the capability to adapt to arbitrary singers, also known as the *zero-shot* scenario. Recent works on zero-shot SVC/SVS have utilized speaker encoders which pretrained on speaker verification tasks [13, 14] to generate speaker embeddings that enable the system to adapt to unseen singers' voices [15–17]. However, this approach has proven insufficient for unseen voice adaptation in recent speech generation studies. An advanced zero-shot voice conversion (VC) and text-to-speech (TTS) approach have utilized the attention mechanism to extract target speaker information from reference audio according to the desired content [18, 19], which outperforms the speaker encoder method [20, 21]. Such advances show potential in zero-shot singing voice generation, which is more challenging than VC and TTS due to the high variation of pitch, timbre, and expression in the singing voice, as well as the lack of publicly available datasets containing a large number of singers. These issues hinder a zero-shot singing voice generation model from sufficient generalization.

Recently, a semi-supervised SVS model combining an acoustic encoder and a phonetic encoder is proposed to deal with both audio and text inputs [7]. Jointly training the two encoders allows the SVS model to learn new singing voice identities in the fine-tuning stage with audios without text annotation. This approach provides new perspectives of zero-shot singing voice generation: from the aspect of technical concerns, joint training of both audio and phonetic encoders might improve the generalizability of zero-shot SVS/SVC; from the aspects of the application, SVS and SVC are no longer regarded as independent but unified into one task.

While [7] only supports SVS for preset singers' voice, in this paper we propose a unified model for SVC and SVS, which is able to generate arbitrary singing voice by either text or audio input. In addition, the system does not require well-aligned lyrics for synthesis since the phoneme duration is learned in a self-supervised manner. We utilize the attention mechanism to extract the target singer information, and introduce two variations of implementation, depending on the similarity or naturalness of the generated

audio. Results show that for both SVC and SVS on unseen singers, the proposed model outperforms state-of-the-art.

2. METHOD

Figure 1 illustrates the whole diagram of the proposed system. The left side of the diagram (blue part) is the source encoder, which encodes the content information of the desired output from either audio or text input. It contains an acoustic encoder (E_a) which encodes the spectrogram and a phonetic encoder (E_p) which encodes the phoneme sequence. The monotonic alignment search (MAS) module [22] encourages the output latent spaces of the two encoders to be in a similar distribution such that the phoneme embeddings are temporally aligned with the spectrogram. SVC or SVS can be achieved by choosing which encoder output to process. On the right side of the diagram, the target encoder (E_t) encodes the spectrograms of the target singer's audios into singer information, where the decoder (D) fuses it into the content information and generates the final output. The functions of all these building blocks will be introduced hereafter in this section.

2.1 Source encoder

Inspired by [7], our source encoder supports joint training for both audio and text inputs. The audio input $\mathbf{x}_s \in \mathbb{R}^{t_a \times n}$ is the log-scale mel-spectrogram of an input audio segment from the source singer s, where t_a is the number of frames and $n = 80$ is the number of mel-bands. The text input $\mathbf{p}_s$, which is corresponding to $\mathbf{x}_s$ is a phoneme index sequence with the length of t_p.

The acoustic encoder E_a maps $\mathbf{x}_s$ to a latent representation $\mathbf{z}_a \in \mathbb{R}^{t_a \times d}$ of source audio, where d is the dimension of this latent representation. Two methods are adopted to train the singer-agnostic $\mathbf{z}_a$. First, we employ a singer classifier C, which works as a domain confusion network [8] that attempts to predict the one-hot singer embedding s from $\mathbf{z}_a$ in a frame-by-frame manner by minimizing the loss function $\mathcal{L}_C := \text{CE}(C(\mathbf{z}_a), s)$, in which CE is the categorical cross-entropy. On the other hand, E_a is trained by maximizing $\mathcal{L}_C$ by using a gradient reversal layer. Second, after having $\mathbf{z}_a$ from E_a, we add Gaussian noise $\mathcal{N}(0, \alpha)$ to $\mathbf{z}_a$ to prevent E_a from overfitting the mel-spectrogram details and to encourage the stability of phoneme embedding [7]. We set $\alpha = 0.1$ in this paper.

The phonetic encoder E_p firstly maps $\mathbf{p}_s$ to a phonetic latent space $\mathbf{z}_p \in \mathbb{R}^{t_p \times d}$ at one of its intermediate layer. Then, the MAS module [22] is adopted to find the alignment between the acoustic embedding and the phonetic embedding and obtains the duration of each phoneme, which is required in the synthesis stage. Denote each frame of $\mathbf{z}_p$ as $\mathbf{z}_{p,i}$ for $i = 1, \cdots t_p$. Each $\mathbf{z}_{p,i}$ is fed into a linear layer which outputs a phonetic prior distribution $\hat{\mathbf{z}}_{p,i} \sim \mathcal{N}(\mu_i, \sigma_i)$. In the MAS process, the phoneme prior distribution sequence $\hat{\mathbf{z}}_p := \{\hat{\mathbf{z}}_{p,i}\}_{i=1}^{t_p}$ is aligned to $\mathbf{z}_a$ by finding the monotonic and surjective alignment path $A : [1 : t_a] \to [1 : t_p]$ such that the objective function

$$\mathcal{L}_{\text{mle}} := \sum_{j=1}^{t_a} \log \mathcal{N}(\mathbf{z}_{a,j}; \mu_{A(j)}, \sigma_{A(j)}) \tag{1}$$

is maximized. $\mathcal{N}(z; \mu, \sigma)$ is the likelihood function of a Gaussian variable z parametrized by μ and σ. In each training step, the alignment path is first searched by the Viterbi algorithm, and then the maximum likelihood estimation over this path updates the parameters. $\hat{\mathbf{z}}_p$ therefore approximates $\mathbf{z}_a$ iteratively along the training process. The optimal alignment path A^* indicates the temporal duration $d^* := \{d_i^*\}_{i=1}^{t_p}$ of every phoneme $\mathbf{p}_{s,i}$ in terms of frames, such that the texts could be well aligned with the log-scale mel-spectrogram.To avoid inaccurate pronunciation of the generated voice in some words, we duplicate expand $\mathbf{z}_{p,i}$ by d_i^* frames and pass it into the downstream layers of E_p, which finally outputs the phonetic latent representation $\mathbf{z}_p^* \in \mathbb{R}^{t_a \times d}$. To encourage the audio and the phoneme models to encode common information, the l_2 loss between $\mathbf{z}_p^*$ and $\mathbf{z}_a$ is minimized.

$$\mathcal{L}_{\text{enc}} := \|\mathbf{z}_p^* - \mathbf{z}_a\|_2^2 . \tag{2}$$

The final source embedding $\mathbf{z}$ is obtained by randomly switching between $\mathbf{z}_p^*$ and $\mathbf{z}_a$, that means,

$$\mathbf{z} = k\mathbf{z}_p^* + (1 - k)\mathbf{z}_a \tag{3}$$

where $k \sim \text{Bernoilli}(0.5)$.

To encode the pitch information, we extract the F0 contours of the source audio data using CREPE [23] and represent them in terms of MIDI pitch numbers. In preliminary experiments, we found that the output of CREPE caused inconsistent spikes in some audio segments. Therefore, we apply a median filter with the size of three to remove the noise, and obtain our input pitch sequence $\mathbf{f}_s$. $\mathbf{f}_s$ is then converted to a sequence of pitch embedding and concatenated with $\mathbf{z}$ as the decoder input.

2.2 Target encoder

Similar to E_a, the target encoder E_t is also constructed mainly with stacking three Conv Blocks (see Figure 1 for the diagram of a Conv Block). E_t takes the log-scale mel-spectrogram $\mathbf{x}_t$ of the audio segments from the target singer's corpus as input and then outputs timbre features with different granularity levels from each Conv Block. D then processes singer information following the order from the highest to the lowest level. Inspired by [19], these Conv Blocks in E_t are linked to the Style-Adaptive Layer Normalization (SALN) Feed Forward Transformer (FFT) blocks [24,25] in the decoder D (see Figure 2 Section 2.3), resembling the encoder-decoder pathway in the U-net [26].

2.3 Decoder

The decoder D incorporates two decoding steps. First, the *feature transformation module* fuses the target singer information into the content latent representation. Second, the *mel-spectrogram generator* reconstructs the log-scale

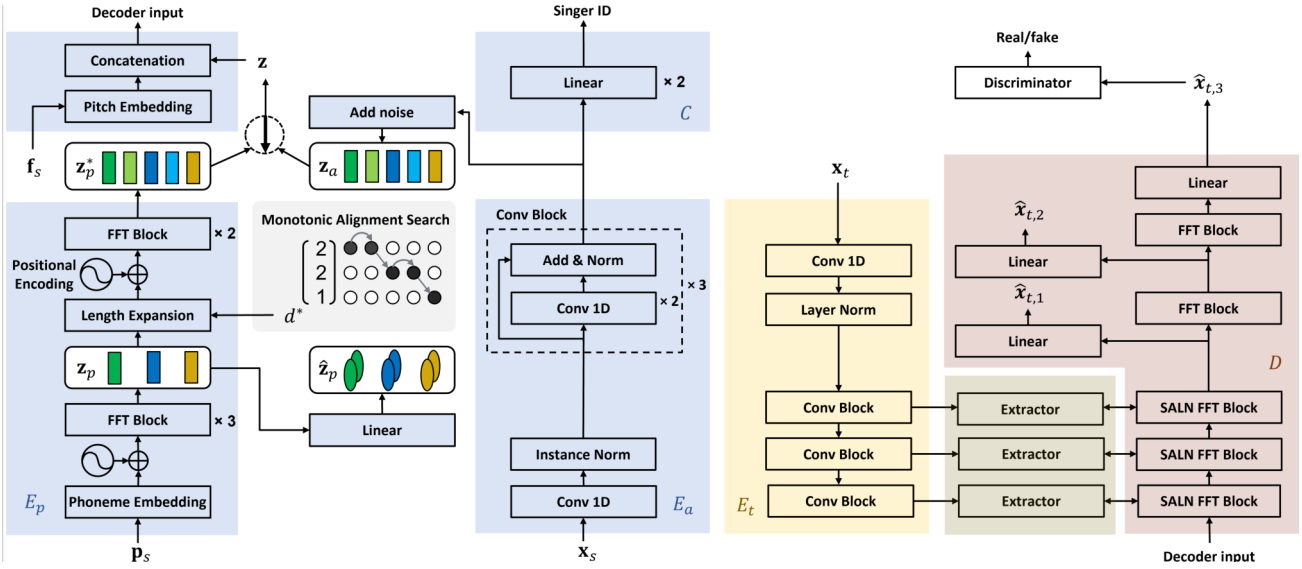

Figure 1. The architecture of the proposed model.

mel-spectrogram. The architecture of the feature transformation module is the same as in [25], in which the layer normalization layer in the FFT block [24] is replaced by a SALN layer [25]. Given an intermediate output h of the FFT and the target singer information w, the SALN operation can be formulated as follows:

$$y = g(w) \odot \text{LayerNormalization}(h) + f(w)\,, \quad (4)$$

where g and f are both linear layers and $\odot$ denotes element-wise multiplication.

The mel-spectrogram generator is comprised of two stacked FFT blocks and three output linear layers linked from the input/output nodes of the FFT blocks. This is similar to the idea of post-network [20, 27] using the FFT and linear layer [6, 24]. Each of the linear layers then outputs the log-scale mel-spectrogram. The outputted mel-spectrograms are denoted as $\hat{\mathbf{x}}_{t,1}$, $\hat{\mathbf{x}}_{t,2}$, and $\hat{\mathbf{x}}_{t,3}$. During training, suppose $\mathbf{x}_s$ is the ground-truth log-scale mel-spectrogram and the decoder is trained to minimize the average mel-spectrogram l_2 reconstruction loss:

$$\mathcal{L}_{\text{recon}} := \frac{1}{3}\sum_{i=1}^{3} \|\mathbf{x}_s - \hat{\mathbf{x}}_{t,i}\|_2^2\,. \quad (5)$$

2.4 Extractor

The extractor is an attention and layer normalization block [1] that connects each pair of Conv Block of E_t and the SALN FFT block of D, as shown in the right side of Figure 1. The extractor controls the mapping from the latent representation of the target singer outputted from the Conv Blocks of E_t to the latent representations of the source utterance such that they are structurally aligned. In other words, the attention mechanism guides E_t to extract the local timbre/style patterns that match the hidden latent states of D layer by layer in the training process [19].

[1] The affine transformation is removed in this block.

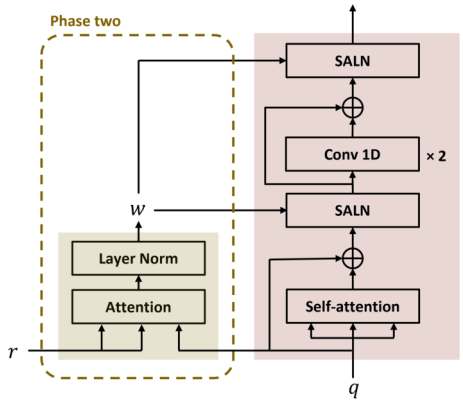

Figure 2. The SALN FFT block (right) with the Extractor (left). For the FFT blocks not using the SALN layers (e.g., the FFT blocks in E_p), the SALN layer is replaced by a layer normalization layer.

The processing of the extractor is illustrated in Figure 2. Let q be the input of one SALN FFT block of D and r be the latent representation of the target from its corresponding Conv Block of E_t. Each frame of q attempts to find local timbre/style patterns in r that have a similar structure to itself. And by aggregating them together, the extractor outputs an aligned local timbre/style representation w. More specifically, the attention mechanism is as follows:

$$Q = qW_q\,, \quad K = rW_k\,, \quad V = rW_v\,,$$
$$w = \text{softmax}\left(\frac{QK^T}{\sqrt{d}}\right)V\,, \quad (6)$$

where W_q, W_k and W_v are learnable parameters.

It should be noted that for each generated result, its corresponding w and also r are usually learned from the concatenation of multiple target audios, which is a strategy for training speech synthesis and conversion systems [18, 19]. However, such a strategy still tends to generate discontinuous outputs in SVS and SVC, especially when deal-

ing with unseen singers. This is because singing exhibits much more diverse and combined expressions than speaking. Under this situation, an effective extractor should be able to recombine the features of various expressions from different audio recordings into a sentence. The softmax function in (6), however, fails to achieve this since it tends to give parsimonious attention maps.

To alleviate the situation mentioned above, we adopt the idea from video style transfer [28], which used an alternative way of computing the attention map by changing the Softmax function in Equation (6) to cosine similarity. The cosine similarity attention can be represented as:

$$M_{i,j} = \frac{S_{i,j}}{\sum_j S_{i,j}}, \quad S_{i,j} = \frac{Q_i \cdot K_j}{\|Q_i\|\|K_j\|} + 1, \\ w = MV, \tag{7}$$

where Q_i and K_j are the ith frame of Q and jth frame of K respectively, and $M_{i,j}$ is the (i,j)th element of the resulting new attention map M. Since the softmax function may overemphasize the contents of vocal fragments with similar phonetic structures [28], using cosine similarity ensures that the model combines much more diversified timbre structures and generates a smoother output.

2.5 Discriminator

Over-smoothing of the mel-spectrogram predictions is a common problem in singing voice generation due to the use of the reconstruction loss [29]. Like many previous studies, we add a discriminator (denoted as Disc) at the output stage of our model to alleviate this problem.

The discriminator architecture we use is similar to [30] but with two slight modifications. First, we remove the conditional projections that were intended to make predictions for multiple singers, and second, we divide the number of channels by 4 to balance the generator and discriminator performances. The input of the discriminator is a 128-frame mel-spectrogram segment randomly sampled from $\hat{\mathbf{x}}_{t,3}$, and the output is a single value. It should be noted that $\hat{\mathbf{x}}_{t,1}$ and $\hat{\mathbf{x}}_{t,2}$ are not taken as the input of the discriminator in our experimental setting. Based on the principle of the Least Square Generative Adversarial Network (LSGAN) [31], the proposed model is trained with the adversarial loss $\mathcal{L}_{\text{adv}}$ while the discriminator is trained with the discriminator loss $\mathcal{L}_{\text{Disc}}$ ($a = 0.3$ in this paper):

$$\mathcal{L}_{\text{adv}} := (\text{Disc}(\hat{\mathbf{x}}_{t,3}) - a)^2, \\ \mathcal{L}_{\text{Disc}} := (\text{Disc}(\hat{\mathbf{x}}_{t,3}))^2 + (\text{Disc}(\mathbf{x}_s) - a)^2. \tag{8}$$

2.6 Two-phase training process and inference

We adopt the two-phase training process [7] to train the whole system. During phase one, the source encoder and D are jointly trained. Since E_t and the extractors are inactive in this phase, the latent representation of target singer w is set to a fixed-size 1-dimensional vector, which is derived from a singer embedding lookup table followed by two linear layers with ReLU activation. The 1-dimensional w is then expanded to t_a frames and fed into the SALN module. The total loss during this phase is as follows:

$$\mathcal{L}_{\text{Phase-I}} := \mathcal{L}_{\text{recon}} + \lambda_{\text{enc}}\mathcal{L}_{\text{enc}} - \lambda_{\text{mle}}\mathcal{L}_{\text{mle}} - \mathcal{L}_C, \tag{9}$$

where the last two terms of the equation use a minus sign to represent maximization, and $\mathcal{L}_C$ is also used for updating C. We set the loss weights with $\lambda_{\text{enc}} = 0.5$ and $\lambda_{\text{mle}} = 0.1$.

During phase two, E_t, D, and the extractors are jointly trained, while the parameters of the source encoder are fixed. For the input of E_t, we randomly sampled 5 utterances from the source singer s and concatenate their log-scale mel-spectrogram along the time axis as $\mathbf{x}_t$. The total loss for updating the model during this phase is as follows:

$$\mathcal{L}_{\text{Phase-II}} := \mathcal{L}_{\text{recon}} + \mathcal{L}_{\text{adv}}, \tag{10}$$

and the discriminator Disc is updated by $\mathcal{L}_{\text{Disc}}$.

The process of randomly switching (see Equation (3)) is applied in both phases, and for the utterance without textual notation, we directly pass $\mathbf{z}_a$ as $\mathbf{z}$, letting the corresponding loss functions $\mathcal{L}_{\text{enc}}$ and $\mathcal{L}_{\text{mle}}$ not counted.

During inference, we specify either $\mathbf{z}_p^*$ or $\mathbf{z}_a$ as $\mathbf{z}$, depending on whether SVS or SVC is to be performed. $\mathbf{x}_t$ can be multiple utterances of a target singer. Since the input pitch $\mathbf{f}_s$ may not be within the target singer's pitch range, we shift $\mathbf{f}_s$ by the difference in median pitches:

$$\mathbf{f}_{\text{shift}} = \mathbf{f}_s - \text{median}(\mathbf{f}_s) + \text{median}(\mathbf{f}_t), \tag{11}$$

where $\mathbf{f}_t$ is the pitch sequence of $\mathbf{x}_t$ and $\mathbf{f}_{\text{shift}}$ is the shifted pitch for model input [15]. We take the last layer output $\hat{\mathbf{x}}_{t,3}$ of the model as the resulting mel-spectrogram.

Dataset	d	p	d/p	Type	Text
MPOP600	10	4	150	singing	✓
Musdb-V	2.3	86	1.6	singing	✗
NUS-48E	2.8	12	14	singing/speech	✓
VCTK	44	109	24.2	speech	✓

Table 1. The datasets employed in this paper. From left to right: dataset name, total duration (d, in hours), number of speaker/singer (p), average duration per speaker/singer (d/p, in minutes), type of content (singing, speech, or both), and the availability of text labels.

3. EXPERIMENTAL SETUP

3.1 Datasets

Four public datasets are used in our experiment. First, the MPOP600 [32] dataset contains 600 Mandarin pop songs sung by two male and two female vocalists. Second, the NUS-48E [33] dataset consists of 48 English popular songs performed by 12 singers. Third, the VCTK corpus [34] is a multi-speaker speech dataset for TTS and voice conversion tasks and has been widely used in many singing voice generation systems.Finally, Musdb-V is the vocal tracks manually collected from MUSDB18 [35], a dataset for music

source separation, containing 150 songs in different genres along with their isolated drums, bass, vocals, and other stems.Details of these datasets are listed in Table 1. The total duration of the data achieves 59.1 hours.

We randomly select 10 singers from Musdb-V as our test set; they are the so-called unseen singers during training. The remaining data are then partitioned into training and validation sets by 95:5 for each singer/speaker. All the audios are resampled to 24kHz, and the log-scale mel-spectrograms with 80 bins are computed by short-time Fourier transformation (STFT) using the size of Fast Fourier Transform, window size, and hop size of 2,048, 1,200, and 300, respectively. For MPOP600 and VCTK, we convert the text into phoneme sequence using pypinyin [2] and phonemizer [3], respectively. As for NUS-48E, we use the phoneme labels provided in the dataset.

3.2 Implementation details

The dimension of all hidden layers is set as 128 for the source encoder and 256 for both D and E_t. In each block, the kernel size in the two-layer 1D-convolution are set to 3 and 1, respectively, and the kernel sizes in the first 1D-convolution layer of E_a and E_t are both set to 3. The number of attention heads is set to 2. We use the AdamW optimizer with $\beta_1 = 0.9, \beta_2 = 0.999, \epsilon = 10^{-8}$, and follow the same learning rate schedule in [19]. Both phase one and phase two are trained for 250k steps with batch size being 8, and the discriminator joins the training process of phase two after 150k steps. We use Parallel WaveGAN (PWG) [36] to convert log-scale mel-spectrograms to waveforms. The PWG [4] is trained for 1M steps using MPOP600, NUS-48E and Musdb-V.

3.3 Evaluation methods

We conduct the evaluation with four scenarios: 1) **Unseen SVC**, conversion between singers in the test set; 2) **Seen SVC**, conversion between singers in the training set; 3) **Unseen SVS**, synthesizing singers in the test set from the utterance in the validation set; [5] and 4) **Seen SVS**, synthesizing singers in the training set from the utterance of another speaker/singer also in the training set. In addition, the VCTK and the speech part of NUS-48E are excluded from the evaluation. For each round of generation, one utterance of the source singer and five utterances of the target singer are randomly selected.

For objective evaluation, we use a speaker verification (SV) system [37] to evaluate the similarity between the target singer and the generated singing voice. The SV system [6] is trained from scratch using all four datasets for 500 epochs. The loss function and the model we use is AM-Softmax and ResNetSE34L, respectively. The resulting model takes an utterance as input and outputs a fix-dimensional embedding. We then compute the cosine similarity between the embedding of the generated singing voice and the average embedding of the five target utterances. The averaged cosine similarity of the randomly generated 1,000 utterances is then reported.

For subjective evaluation, we conduct a Mean Opinion Score (MOS) test. For each evaluation scenario, 50 utterances are randomly generated for evaluation. Each participant was asked to listen to the source utterance, target utterances, and the generated audios , and rated the generated singing voice in terms of two metrics: perceptual naturalness and similarity to the target. Both metrics are rated from 1 to 5, with 5 representing the best performance and 1 being the worst. We report the averaged scores with the 95% confidence intervals for each model.

Model	Unseen		Seen	
	SVC	SVS	SVC	SVS
Baseline SVC	0.059	–	0.213	–
Baseline SVS	–	0.084	–	–*
Fragment SVC/SVS	0.129	0.122	0.237	0.244
Proposed (S)	**0.294**	**0.232**	**0.536**	**0.479**
Proposed (S\Disc)	0.257	0.232	0.420	0.398
Proposed (C)	0.115	0.079	0.451	0.446

Table 2. Result of objective evaluation. *Result of seen Baseline SVS is not counted due to the inconsistency of training data (not supporting text-free training) compared to other seen SVS models.

Datasets	SVC	SVS
All	0.290	0.233
w/o MPOP600	0.292	0.225
w/o Musdb	0.178	0.145
w/o MPOP600 and w/o Musdb	0.194	0.149

Table 3. Objective similarity scores with reduced training data. All four settings are trained with Proposed (S) under the unseen-to-unseen scenario.

3.4 Models for comparison

Three variants of the proposed model are considered in the evaluation. They are the model using the softmax-based attention in the extractor (denoted as **Proposed (S)**), the model using cosine similarity attention (denoted as **Proposed (C)**), and the model without the discriminator while using softmax-based attention (denoted as **Proposed (S\Disc)**). These model variants are used to compare how the attention types and the discriminator affect the performance. Besides, three baseline models are considered and described as follows.

Fragment (SVC/SVS) is adapted from FragmentVC, a state-of-the-art voice conversion model which also employs the softmax attention in the extractors [19].In our implementation, we simply replace the pretrained Wav2Vec [38] source encoder in FragmentVC with our pretrained source encoder. The remaining architecture and the train-

Task	Model	Unseen singers		Seen singers	
		Similarity	Naturalness	Similarity	Naturalness
SVC	Baseline (SVC)	3.14 ± 0.17	3.29 ± 0.16	3.20 ± 0.18	3.21 ± 0.16
	Proposed (S)	$\mathbf{3.61 \pm 0.16}$	3.27 ± 0.17	3.63 ± 0.16	3.27 ± 0.16
	Proposed (C)	3.56 ± 0.17	$\mathbf{3.53 \pm 0.17}$	$\mathbf{3.70 \pm 0.16}$	$\mathbf{3.46 \pm 0.16}$
SVS	Baseline (SVS)	3.14 ± 0.18	2.98 ± 0.16	$\mathbf{3.88 \pm 0.15}$	$\mathbf{3.39 \pm 0.16}$
	Proposed (S) w/o Musdb-V	$\mathbf{3.18 \pm 0.17}$	$\mathbf{3.06 \pm 0.17}$	3.87 ± 0.15	3.32 ± 0.17

Table 4. Subjective test of both the SVC and SVS tasks. MOS and the 95% confidence interval are shown for each case.

ing process follow the original implementation.

Baseline (SVC) is adapted from [15], the state-of-the-art zero-shot SVC model, which is an adaptation of AutoVC [20] and uses the WORLD vocoder [39] to synthesize the singing voice. In our modification of [15], we replace the WORLD vocoder with the PWG vocoder by changing the output layer to generate mel-spectrogram and concatenating a pitch embedding with the same dimension of the content encoding. This is to ensure fair comparison since WORLD vocoder may lead to sound quality degradation in comparison with PWG [40]. During training and inference, the singer embedding is generated by feeding the five target utterances to the speaker encoder and averaging the resulting embeddings.

Baseline (SVS) is adapted from the singing model of DeepSinger, also a state-of-the-art SVS model [6]. In our implementation, we change the output layer of this model to generate mel-spectrograms, and the phoneme duration is extracted by a commonly used open source tool [41]. The major difference between Baseline (SVS) and our proposed model is that the baseline model needs phoneme duration provided by another speech-text alignment system, while our model estimates phoneme duration directly from our self-supervised source encoder.

For the objective test, the six models described above are all compared under the four scenarios. As for the subjective test, to reduce participants' loading, we only compare Baseline (SVC), Proposed (S), and Proposed (C) for SVC, and compare Baseline (SVS) and Proposed (S) (w/o Musdb-V) for SVS. it should be noted that in SVS, Proposed (S) is particularly trained without Musdb-V; this is again for a fair comparison since Baseline (SVS) does not support training with text-free data. [7]

4. RESULTS

Table 2 shows the objective evaluation results in terms of similarity score. The three proposed models generally outperform the baselines. The effectiveness of using the attention-based extractor is verified by comparing Baseline SVC/SVS to the other four models. Also, the advantage of the SALN layer is shown by comparing Fragment SVC/SVS and Proposed (S). The improvement using the discriminator is also shown. The softmax-based attention achieves higher similarity than cosine similarity attention.

Table 3 compares the objective similarity scores trained on reduced sizes of data for the unseen-to-unseen case. It shows that the Musdb-V dataset plays a crucial role in improving the similarity score, and implies that a training dataset with more singers might benefit from singing voice generation more than a large dataset in zero-shot singing voice generation.

Table 4 shows the MOS results responded by 62 subjects for both the SVC and SVS tasks. For the SVC task, both Proposed (S) and Proposed (C) outperform the Baseline (SVC) considerably in terms of perceptual similarity for both seen and unseen cases. As for naturalness, Proposed (C) outperforms both Baseline (SVC) and Proposed (S) substantially. The cosine similarity attention achieves better naturalness and verifies the argument that it can better combine timbre structures and generate smoother outputs, while softmax-based attention achieves better similarity, in line with objective evaluation (see Table 2).

For the SVS subjective test, our degenerated model (Proposed (S) without Musdb-V) shows results comparable to Baseline (SVS) in general, while it still slightly outperforms the baseline for both similarity and naturalness in the unseen-to-unseen case. Such a comparable result can be explained by the finding in Table 3: having a singer-diverse dataset (e.g., Musdb-V) is critical for zero-shot singing voice generation. Since lyrical annotations are not always available for such datasets, a unified model that supports both audio- and text-based training is apparently more flexible, and could also jointly improve the performance of the SVS and SVC models.

5. CONCLUSION

We have presented a unified model which jointly supports the zero-shot SVC and SVS tasks, and has achieved state-of-the-art performance on both tasks. Our experiments also show that the design of the attention mechanism determines the trade-off between perceptual similarity and naturalness, and that a dataset containing a large number of singers is critical in improving zero-shot SVS and SVC. These two directions are suggested for future research on zero-shot singing voice generation.

[7] Since our proposed model allows either audio or text input, we can surely incorporate the text-free Musdb-V set but train the model for the SVS task. In our pilot study, we also observed that incorporating Musdb-V did improve the perceptual quality of SVS results. Such improvement with Musdb-V is also seen in the ablation study (Table 3). However, in order not to take advantage of the Baseline (SVS) model, we opt to degenerate Propose (S) (i.e. without Musdb-V) in our subjective test.

SEMANTIC CONTROL OF GENERATIVE MUSICAL ATTRIBUTES

ABSTRACT

Deep generative neural networks have been successful in tasks such as composing novel music and rendering expressive performance. Controllability is essential for building creative tools from such models. Recent work in this area has focused on disentangled latent space representations, but this is only part of the solution. Efficient control of semantic attributes must handle non-linearities and holes that occur in latent spaces, whilst minimising unwanted changes to other attributes. This paper introduces SeNT-Gen, a neural traversal algorithm that uses a secondary neural network to model the complex relationships between latent codes and musical attributes. This enables precise editing of semantic attributes that adapts to context. We demonstrate the method using the dMelodies dataset, and show strong performance for several VAE models.

1. INTRODUCTION

Deep generative models show promise for music, with systems that can compose melodies and accompaniments, render expressive performances, or synthesise instrumental sounds and singing voices [1, 2]. While many of these work as "black boxes," *controllability* is an essential factor in creative tools for musicians. This raises important challenges such as controlling musically meaningful aspects of the composition, balancing creativity versus imitation, providing interactivity and refinement, and producing a convincing temporal structure that has a sense of direction [3].

In generative applications a neural network is trained to find a low-dimensional representation for complex data. A common approach uses a Variational Auto-Encoder (VAE) in which an *encoder* learns to transform the data space X into a simpler "latent space" Z. For music X is a representation of a score such as a piano-roll that defines the pitch and duration of notes over time. A *decoder* recovers the original representation from the latent samples. In learning the latent representation the network identifies the essential attributes needed to construct the melody. The dimensions of the latent space represent semantic attributes such as note density [4], syncopation [5], genre [6] or arousal [7]. Novel melodies can be generated by decoding samples drawn from the latent space. Moving in the latent space adjusts the semantic attributes, for example: to smoothly "morph" between two melodies by interpolating a path between their latent positions.

Recent work on control of generative music has focused on regularisation of the latent space, and disentanglement of the semantic attributes. The aim is to relate each semantic attribute of the melody to a unique dimension of the latent space, which allows attributes to be adjusted by adding an "attribute vector" [8, 9] in latent space. This approach involves some challenges. First, there is often a tradeoff between regularisation of the latent space and reconstruction quality. Second, effective disentanglement can only be achieved through supervision [10] and unsupervised approaches are sensitive to inductive biases in both the data set and learning model (such as network model, hyperparameters, random seeds). Third, the relationship between the latent dimension and corresponding semantic attribute value may be non-linear. Fourth, latent spaces may contain "holes" where the decoder produces invalid results [11] and these must be avoided when adjusting attributes, or interpolating paths in the latent space. This means that some additional work is required beyond disentanglement to properly control the values of semantic attributes.

This paper proposes a new method to efficiently traverse latent spaces frequently used in generative music. We introduce the Semantic Neural Latent Traversal method for Generative models (SeNT-Gen), which employs a secondary neural network to model the complex relationship between latent codes and semantic attributes. The SeNT-Gen traversal function predicts the new latent position given a starting position and attribute change, supporting non-linear relationships and adapting to the context of the traversal. We evaluate the performance of SeNT-Gen for musical control using the dMelodies [12] data set.

Our key contributions are:

1. A neural method to traverse the latent space, targeting precise changes to musical attributes, and supporting non-linear contextual relationships between the VAE latent space and semantic attributes;

2. Experiments and analysis of the proposed method using the established dMelodies data set. The method is independent of learning model, and shows best performance for strongly regularised models;

Le, S. Gupta, S. Venkatesh, "Semantic Control of Generative Musical Attributes", in *Proc. of the 23rd Int. Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

3. Objective quantitative metrics to measure performance of the method through targeted attribute changes, which improves on notions of "controllability" that are tied to interpolation heuristics.

2. RELATED WORK

Control of generative music is usually based on latent space representations. Some of these approaches are surveyed here, while alternative approaches for images do not directly translate between image and musical domains [12]. Music-VAE [5] uses a hierarchical recurrent VAE to model temporal structure in music. Attribute vectors are shown to partially control attributes such as *note density*, *melodic interval* and *rhythmic syncopation*. MIDI-VAE [6] learns songs using a a parallel VAE with shared latent space, and an attached style classifier enables a chosen *style* (classic, jazz, pop, Bach, Mozart) to be applied to the output. GLSR-VAE [4] uses a novel regularisation method to control *note density* of chorale-style melodies. Music FaderNets [7] proposes a Gaussian mixture VAE for learning piano performance, with control over the *arousal* or "energy level" based on rhythm and note density. AR-VAE [13] defines a supervised regularisation method which is applied to controlling *rhythmic complexity*, *pitch range*, *note density*, and *contour* for melodies trained from chorales and folk tunes. Kawai and colleagues [14] use a VAE with adversarial classifier-discriminator to condition the decoder on semantic attributes. This model is trained on folk tunes to control orthogonal attributes such as *number of notes*, *pitch variability*, *chromatic motion* and *amount of arpeggiation*.

Apart from latent space approaches, other methods generally require ad-hoc modifications to the probability distribution of a model. Transformers are used to generate music with long-term structure [15], but control is limited to providing a prompt stimulus for the system to extend. Pop Music Transformer [16] uses a Transformer-XL model to learn expressive piano performances. Control over *tempo* and *chord* is achieved by masking out corresponding event probabilities in the model output. Coconet [17] uses a convolutional model to generate chorales in the style of Bach. Cococo [18] adds "semantic sliders" for *conventional/surprising* and *happy/sad* output using "soft priors" to modify the model's sampling distribution.

Several factors make it difficult to compare the results of these studies. Firstly, there are a wide variety of model architectures, and each implements its own encoding of the training data into a form suitable for model training. This in turn depends on the data-sets used, which vary from simple scores in ABC notation, to traditional scores, to MIDI transcriptions of actual performances either recorded from a digital keyboard or automatically extracted from audio recordings. Secondly, while there is a focus on disentangled representations, these are not in themselves control methods. Even in a disentangled latent space, more work is required to accurately achieve a specific value of an attribute, dealing with potential non-linearities and holes in the latent space. In the absence of a particular control algorithm some works assess "controllability" through interpolation [7, 11, 14] though there is no consistency in the metrics used.

Feature	Values	Description
Tonic	12	Notes C, C#, D ..., B
Octave	3	Octave 4, 5, or 6
Scale	3	major, minor, or blues
Rhythm Bar 1, 2	28	$\binom{8}{6}$ codes for 6 note onsets
Arp Chord 1, 2, 3, 4	2	arpeggio direction up or down

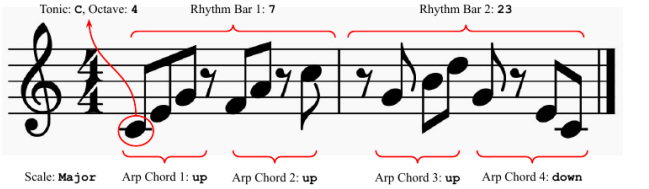

Figure 1. Each dMelodies two-bar melody is described by 9 attributes. *Tonic*, *Octave* and *Scale* apply to the entire melody. Separate *Rhythm* attributes apply to each bar. *Arpeggio* attributes apply to each of the 4 chords. The table (top) shows the number of values for each attributes, and an example from [12] is shown below.

The dMelodies dataset [12] has been proposed for evaluation of musical disentanglement learning, similar to dSprites in the image domain [19]. dMelodies includes 1,354,752 unique two-bar melodies, algorithmically constructed with independent factors of variation, with each comprised of 4 arpeggios in a I-IV-V-I chord pattern (see Table 1). Attributes are discrete, and most (except for *Tonic* and *Octave*) are categorical. dMelodies provides three unsupervised reference models including β-VAE [20], and a subsequent paper [11] adds three supervised models: I-VAE [21], AR-VAE [13], and S2-VAE [22]. Three measures of disentanglement are implemented [12]: *Mutual Information Gap* [23], *Modularity* [24], and *Separated Attribute Predictability* [25]. On these measures, supervised learning is shown to give better disentanglement, without sacrificing reconstruction quality [11].

2.1 Metrics

Suppose the VAE decoder $\mathcal{G}$ generates an object $x = \mathcal{G}(z)$ for latent sample z, and let $c = [c_1, c_2, ..., c_K]$ be the K semantic attributes of x. Disentanglement is formalised through the concepts of *consistency* and *restrictiveness* [26] and establishes a relationship between a latent dimension z_i and a corresponding semantic attribute c_i. *Consistency* says that when z_i is fixed, c_i of the generated x never changes. *Restrictiveness* says that when only z_i is changed, the change is restricted to c_i and there is no change to other attributes c_j for $j \neq i$.

Attributes may be controlled through a traversal function $\mathcal{T}_k(z, c_k, c_k^*)$ which predicts the latent value z^* required to change attribute k of z from c_k to c_k^*. The accuracy of $\mathcal{T}_k$ can be evaluated for a set of changes (z, c_k, c_k^*) by measuring the deviation of the result from the target, and any side effects on non-target attributes. Alternative approaches assess "controllabilty" in the absence of such a traversal function. Instead, interpolation is used to tra-

VAE	To	Oc	Sc	R1	R2	A1	A2	A3	A4

Table 1. Latent Density Ratio (LDR) for four dMelodies VAE models. Attributes are Tonic (To), Octave (Oc), Scale (Sc), Rhythm Bar (R) and Arp Chord (A).

verse from a position z in the latent space, along the corresponding dimension z_d between a minimum and maximum value over a number of steps. This is repeated over a small batch of points. Three measures are defined by [7] based on the work of [26]: *Consistency* measures how constant the attribute is across the batch for the same value of z_d, *Restrictiveness* measures how constant other attributes are when z_d changes, and *Linearity* measures how linear the attribute is with respect to the latent dimension z_d. An *attribute change matrix* $A(d, n)$ is proposed by [11] which computes the net change in the n^{th} attribute while traversing regularised dimension d. When an attribute is well controlled A should be high on the diagonal, and low elsewhere, and these relationships can be inspected by visualising the matrix. Another measure of controllability is the correlation between the interpolated value z_d and the resulting attribute [14], which measures linearity but not restrictiveness.

Another important factor is the *Latent Density Ratio* (or *LDR*), the proportion of a batch of random latent samples that decode with valid attributes [11]. As shown in Table 1, errors in dMelodies occur most frequently with the *Scale*, *Rhythm Bar* and *Arp Chord* attributes. If notes are generated that are outside the three defined scales (major, minor, blues) the *Scale* attribute is invalid. If a bar does not have exactly 6 note onsets the *Rhythm Bar* attribute does not match one of the 28 codes, and is invalid. If the chord notes are not consistently ascending or descending, the *Arp Chord* attribute is invalid. A traversal function should aim to be more accurate than these base-line LDR rates.

3. METHOD

3.1 Neural Latent Traversal

This section describes SeNT-Gen as applied to musical VAE models. Further details are available for a GAN-based image synthesis application [27].

Let x be a sample of the data space $X = \mathbb{R}^N$, a piano-roll encoding of a melody. Let z be a sample of the latent space $Z = \mathbb{R}^D$ of the VAE model. Let $c = [c_1, c_2, ..., c_K]$ be the vector of K semantic attributes of x, and $R_1(.)$, ..., $R_k(.)$ be K functions that compute the value of attribute k of x in the normalised range $[0, 1]$: $c_k = R_k(x)$. Let $\mathcal{F}(.)$ be the encoder, and $\mathcal{G}(.)$ be the decoder of the VAE, so that $\mathcal{G}(\mathcal{F}(x)) \approx x$. We use x^* for the *target value* of x, and $\hat{x}$ for its *predicted* or *achieved* value.

Given a sample x, we aim to find the modified x^* such that the value of attribute k is changed from c_k to c_k^* while all other attributes remain unchanged: $c_i^* = c_i, i \neq k$.

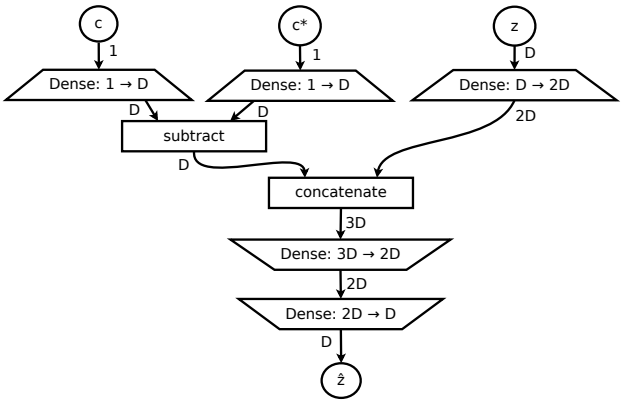

Figure 2. Implementation of SeNT-Gen neural traversal function $\mathcal{T}_k(z, c_k, c_k^*)$. Input is the latent code z, and the desired attribute change from c_k to c_k^*. Each Dense layer includes ReLU activation, except for the Tanh activation on the final layer. Output is the latent code $\hat{z}$ which approximates the solution z^*.

This adjustment will be done in the latent space. Given the latent encoding $z = \mathcal{F}(x)$, we seek a modified z^* that generates $x^* = \mathcal{G}(z^*)$, with the desired attribute value $c_k^* = R_k(\mathcal{G}(z^*))$.

SeNT-Gen implements contextual traversal of the latent space for each of the attributes. The traversal function $\mathcal{T}_k$ predicts the new value $\hat{z}$ given the old value z, and the old and new values of the attribute c_k and c_k^*:

$$\hat{z} = \mathcal{T}_k(z, c_k, c_k^*)$$

The traversal function $\mathcal{T}_k$ is implemented by training the neural network shown in Figure 2 which outputs the value $\hat{z}$, an approximate solution for z^*.

Three constraints are imposed during training. The first constraint is to minimise the perceptual loss by ensuring that the changed attribute value $\hat{c}_k = R_k(\mathcal{G}(\hat{z}))$ is close to the target c_k^*:

$$\mathcal{L}_c = \mathbb{E}_{z \sim P(Z)} \left[\| R_k(\mathcal{G}(\hat{z})) - c_k^* \|_2^2 \right] \quad (1)$$

The term $\| R_k(\mathcal{G}(\hat{z})) - c_k^* \|_2$ represents the deviation between $\hat{c}_k$ and the target c_k^*, and is in the range [0,1]. When R_k is invalid for $\mathcal{G}(\hat{z})$ a deviation of 1 is used instead.

The other two constraints are required to align the attributes of the traversal function with the relevant dimensions of the latent space. In a disentangled latent space each semantic attribute corresponds to one latent dimension, but in general there will likely be a small number of relevant dimensions that are strongly related to each attribute. For *relevant* dimensions r, $\hat{z}_r$ should be be close to the correct solution z_r^*. For the other *irrelevant* dimensions i, $\hat{z}_i$ should be close to the original location z_i.

Relevance is expressed using the vector $\rho_k \in \mathbb{R}^D$, which is 1 for relevant dimensions and 0 otherwise. Under supervised training, this relation will be known and for a consistent numbering of attributes and dimensions $\rho_k[i] = 1$ for $i = k$, and 0 for $i \neq k$. Otherwise, for unsupervised models ρ_k can be calculated using mutual

information as described below. The two remaining loss functions are thus:

$$\mathcal{L}_I = \mathbb{E}_{z,z^* \sim P(Z)} \left[\| {\rho_k}^T (\hat{z} - z^*) \|_2^2 \right] \quad (2)$$

$$\mathcal{L}_{\neg I} = \mathbb{E}_{z,z^* \sim P(Z)} \left[\| (1 - \rho_k)^T (\hat{z} - z) \|_2^2 \right] \quad (3)$$

Equation 2 pulls $\hat{z}$ towards z^* for relevant dimensions, and Equation 3 pulls $\hat{z}$ towards z for irrelevant dimensions.

When ρ_k is not known a-priori it can be calculated using the mutual information (MI) between the dimensions $d \in \{1, ..., D\}$ of z and the c_k values:

$$\rho_k = \text{threshold} \left(\text{softmax}(\text{MI}(z_d, c_k)), \gamma \right) \quad (4)$$

Where γ is a hyper-parameter controlling the number of latent dimensions related to each semantic attribute. Equation 4 selects γ dimensions of z that have the most mutual information with each attribute c_k.

3.2 Latent Traversal Training

The traversal function $\mathcal{T}_k$ is trained on similar pairs of latent vectors (z, z^*) which differ only in attribute c_k. Such pairs are good examples of attribute modifications. We sample pairs of the data space (x, x^*), and compute their attributes (c_k, c_k^*), where $c_k = R_k(x)$, and $c_k^* = R_k(x^*)$. We use the encoder compute their latent representation (z, z^*), where $z = \mathcal{F}(x)$ and $z^* = \mathcal{F}(x^*)$. We discard pairs where there is a significant difference in attributes other than k. A training pair is considered valid if:

$$\sum_{j \neq k} \| c_j - c_j^* \|_2 \leq \epsilon, \quad \text{for } j \in \{1, ..., K\} \quad (5)$$

Where $\epsilon \geq 0$ is a slack parameter. One implementation is to enumerate all pairs from a set of candidate samples, and adjust ϵ to be as small as possible while also yielding enough similar pairs.

After generating the training pairs, we train the traversal model $\mathcal{T}_k$ by minimising the loss:

$$\mathcal{L}_k \triangleq \lambda_1 \mathcal{L}_I + \lambda_2 \mathcal{L}_{\neg I} + \lambda_3 \mathcal{L}_c \quad (6)$$

where λ_1, λ_2, and λ_3 are hyper-parameters that balance perceptual loss versus semantic relevance.

4. EXPERIMENTS

We train each of the four dMelodies learning models (β-VAE, AR-VAE, I-VAE and S2-VAE) for three different hyperparameter settings and 3 different random seeds, a total of 36 models. Input is a two-bar melody, with a latent space of $D = 32$ dimensions. For β-VAE we vary $\beta \in \{0.2, 1, 4\}$, and for the other models we vary the regularisation strength $\Gamma \in \{0.1, 1, 10\}$ for $\beta = 0.2$. The default settings use 1016k melodies (75%) for training the original models, which leaves 338k melodies (25%) as candidates for training and testing the SeNT traversal function $\mathcal{T}_k$. Setting $\epsilon = 0$ yields between 42k and 157k pairs (see Equation 5) and from these we allocate 80% for training and 20% for testing. Since dMelodies is generated by combinatorial expansion, attributes with the most states (*Tonic*, *Rhythm Bar*) have the most pairs, while those with the fewest states (*Arp Chord*) have the least. Latent codes z are normalised to the range $[-1, 1]$, and attributes c_k to $[0, 1]$. Neural traversal is trained for $\gamma = 3$ (see Equation 4), $\lambda_1 = \lambda_2 = \lambda_3 = 1$ (Equation 6).

4.1 Performance Metrics

Performance of the traversal function $\mathcal{T}_k$ is evaluated by measuring accuracy on a set of attribute changes. A set of testing pairs (z, z^*) is generated using the same method that generated the training pairs (see Equation 5). These define a starting state z and an attribute change from c_k to c_k^* that leaves other attributes unchanged. Using the traversal function we predict the new latent code $\hat{z} = \mathcal{T}_k(z, c_k, c_k^*)$, and compute its attributes $\hat{c}_i = R_i(\mathcal{G}(\hat{z}))$ for all i. This approach ensures that only feasible attribute changes are tested, and that these have been unseen during training.

For a targeted change of an attribute, the important measures are: (1) How far is the edited attribute value $\hat{c}_k$ from the desired target c_k^*? and (2) How far are the unedited attributes $\hat{c}_u$ from the original values c_u? The *target deviation* Δ_k for target attribute k is defined as:

$$\Delta_k = |\hat{c}_k - c_k^*| \quad (7)$$

where $\hat{c}_k = R_k(\mathcal{G}(\hat{z}))$. The *non-target deviation* ∇_u for non-target attribute u is defined as:

$$\nabla_u = |\hat{c}_u - c_u| \quad (8)$$

When Δ_k is low, the traversal achieves the desired attribute k value. When ∇_u is low, the traversal avoids unintended changes to other attributes u. When combined, these measures are similar to the attribute change matrix of [11], except that Δ_k is with respect to specific target values, rather than arbitrary interpolation points.

Occasionally errors occur in the generated melodies, due to the decoder quality and the proximity of samples to holes in the latent space. Ideally $\mathcal{T}_k$ should avoid these holes, and to measure this we define the *Target Density Ratio* (or TDR) to be the proportion of the decoded target $\hat{z}$ values with valid attributes. We aim for TDR to be substantially higher than the underlying LDR (defined in 2.1).

5. RESULTS

For brevity we summarise the 36 models by selecting the best performing hyper-parameters, and aggregate over the three random seeds. For supervised models these are the settings with the most regularisation $\Gamma = 10$, and for β-VAE, the median $\beta = 1$. Source code is available online with further results and technical details. [1]

Figure 3 shows Mutual Information between semantic attributes (vertical axis) and latent dimensions (horizontal axis). The supervised S2-VAE (top) shows good disentanglement, with each attribute uniquely related to one

[1] https://github.com/stewartgreenhill/sentgen

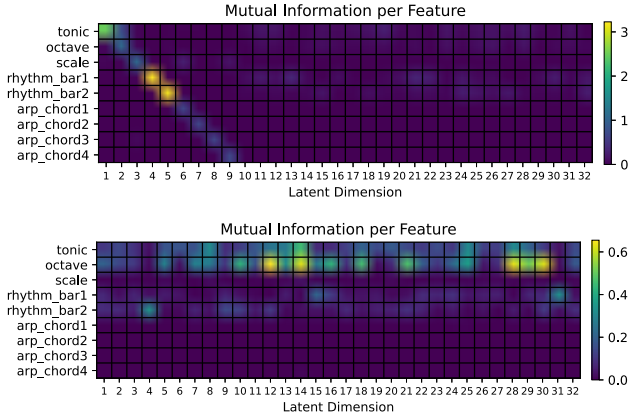

Figure 3. Mutual Information between semantic attributes and dimensions of the latent space for supervised S2-VAE (top), and unsupervised β-VAE (bottom).

of the first 9 latent dimensions. The strongest relationships are for the attributes with the most states: *Tonic* and *Rhythm Bar*. The unsupervised β-VAE (bottom) shows some strong but less well separated relationships, and some very weak relationships: *Scale*, *Arp Chord*. Mutual Information is important in SeNT-Gen for determining ρ_k which aligns semantic attributes to the latent space (Equations 2–4).

Figure 4 shows SeNT-Gen traversal accuracy for the S2-VAE. The bottom chart shows mean target deviation Δ_k for target attributes k. Smaller deviations are better. For most attributes the deviation is 2% or less, and the worst performance is 8% for attribute *Tonic*. The top chart shows the mean non-target deviation ∇_k, with non-target attributes on the vertical axis, and target attributes on the horizontal axis. The *Scale* attribute is most influenced by changes to other attributes, particularly *Tonic*, and *Octave* where the influence approaches 60%. This makes sense since these attributes are both changing the overall pitch of the melody, and it only requires one transposition "error" amongst the 12 melody notes to cause the scale to be invalid or altered. To a lesser extent the *Arp Chord* attributes are also susceptible for the same reason. Changes to *Arp Chord* attributes are the most accurate, with no deviation in the target or non-target attributes other than *Scale*.

Figure 5 shows SeNT-Gen traversal accuracy for the β-VAE which is the worst performing model. Rhythm attributes show a good target deviation of 3%, with the pitch based attribute deviations ranging from 7 to 22%. Non-target errors are lowest for changes to *Rhythm Bar 1 & 2*, but are generally much higher than for the S2-VAE. Here *Scale* and *Arp Chord* attributes are most influenced by changes to other attributes. This is expected since these attributes are only weakly related to dimensions of the latent space (see Figure 3) so are essentially invisible to the traversal constraints.

Another way to evaluate traversal accuracy is to look at correlation R^2 between target and achieved attribute values. Figure 6 shows the target c_k^* value (horizontal) versus the achieved $\hat{c}_k$ (vertical) for rhythm_bar1, the attribute

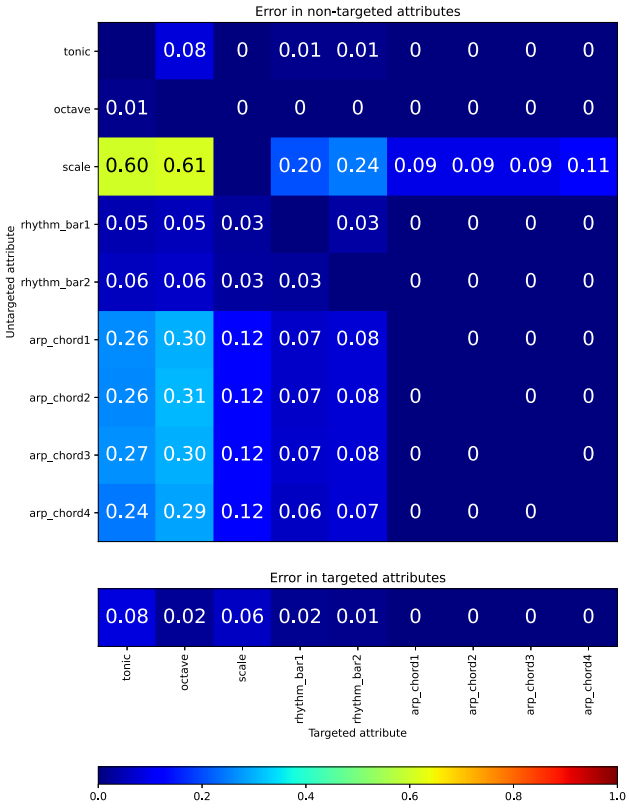

Figure 4. Accuracy of S2-VAE traversal, showing *target deviation* Δ (bottom), and *non-target deviation* ∇ (top). Target attributes are on the horizontal axis, and non-targets on the vertical.

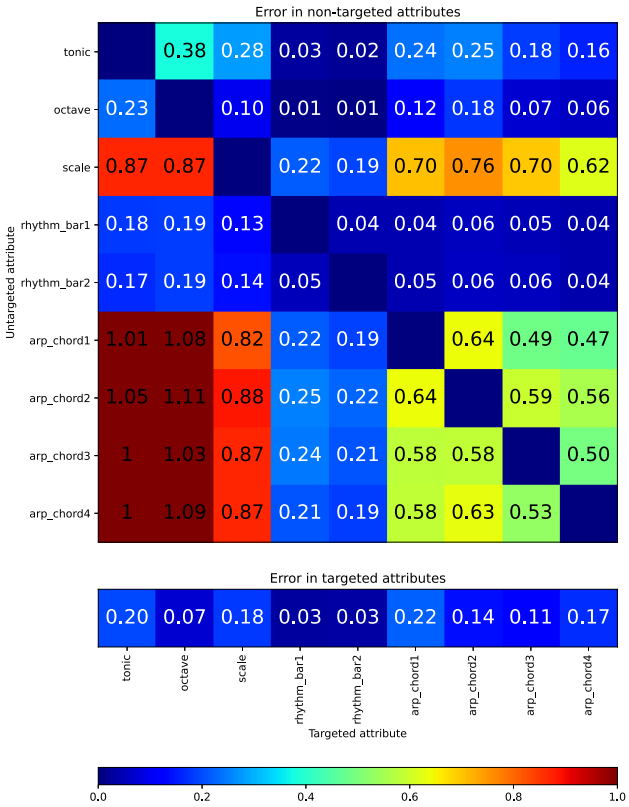

Figure 5. Accuracy of β-VAE traversal, showing *target deviation* Δ (bottom), and *non-target deviation* ∇ (top). Target attributes are on the horizontal axis, and non-targets on the vertical.

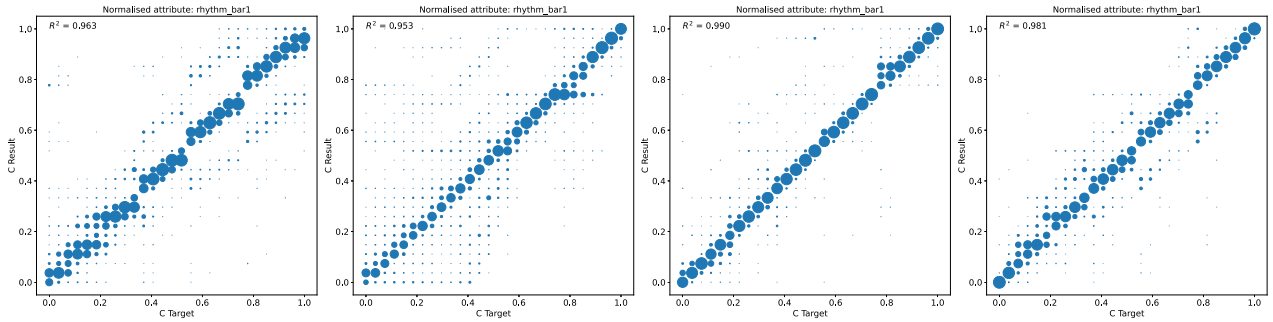

Figure 6. Correlation R^2 between normalised target c_k^* (horizontal axis) and result $\hat{c}_k$ (vertical axis) for $k = \text{rhythm\_bar1}$. Dot area is proportional to number of samples. Models are (left to right) β-VAE, AR-VAE, I-VAE, and S2-VAE.

Table 3. Target Density Ratio (TDR) for four dMelodies VAE models. See Table 1 for Latent Density Ratio (LDR).

with the most states. The frequency and location of errors can be visualised by inspecting the off-diagonal elements. Table 2 shows the R^2 values for each of the attributes over four dMelodies VAE models, excluding samples which yield invalid results. As expected, this measure shows high correlations where target deviation Δ is low. The three supervised models show strong control over the *Rhythm Bar* and *Arp Chord* attributes with weaker control over *Tonic*, *Octave* and *Scale*.

Table 3 shows the Target Density Ratio (TDR), the proportion of the decoded targets $\hat{x} = \mathcal{G}(\hat{z})$ that have valid attributes, thus avoiding potential holes in the latent space. The best performer from this perspective is the I-VAE which exhibits good TDR for all attributes. All models score better than the corresponding latent density ratio (LDR, Table 1). Notably, the AR-VAE shows good control over *Arp Chord* with TDR=0.73 despite scoring very low LDR=0.02 for these attributes.

6. CONCLUSION

This paper presents a novel algorithm to control musical attributes of deep generative models. The SeNT-Gen method implements a neural traversal function $\mathcal{T}_k(z, c_k, c_k^*)$ that predicts the latent position z^* required to change attribute k of z from c_k to c_k^*. Previous works in this field focus on disentanglement but do not implement traversal functions and instead assess controllability via latent space interpolation which does not allow the specification of a particular target value c_k^* for the controlled attribute.

The SeNT-Gen method is demonstrated using the dMelodies data set and various VAE models. Performance is strongest for highly regularised models. The best performance was obtained using the S2-VAE model, which shows strong control over most attributes, and few side-effects except for *Scale*. Some attributes that depend on note pitch (*Scale* and *Arp Chord*) are significantly less stable when adjusting overall pitch via *Tonic* or *Octave*, and also show low LDR scores. The definition of these attributes may be fragile to small changes in the melody notes. The Target Density Ratio (TDR) measures the robustness of the method to holes in the latent space, aggregating factors related to the latent space regularisation, the traversal algorithm, and the fidelity of the decoder. TDR for I-VAE and S2-VAE is good for most attributes, and AR-VAE shows very strong improvement over a poor baseline LDR.

Although each SeNT-Gen traversal function controls only one attribute, more complex operations involving multiple attributes could be performed using a sequence of separate attribute changes. Future improvements to the algorithm could include better support for categorical variables, as well as mixtures different variable types. Categorical variables would normally be one-hot encoded, but alternative distance metrics might be required, for example Jaccard distance where Euclidean distance is currently used (Equations 1 and 5).

While demonstrated here using VAE models, SeNT-Gen can also be used in other latent space models such as Generative Adversarial Networks (GAN). There is an underlying assumption that the relationship between semantic attributes and the latent dimensions will be fairly sparse. This is normally true for supervised models, but can also apply in other models too. In any case the hyper-parameter γ should be chosen to reflect this. An extensive study of the other hyper-parameters λ_1, λ_2, and λ_3 was outside the scope of this work, but fine-tuning these values through meta-optimisation may improve the overall performance.

ABSTRACT

This paper revisits the idea of music representation learning supervised by editorial metadata, contributing to the state of the art in two ways. First, we exploit the public editorial metadata available on Discogs, an extensive community-maintained music database containing information about artists, releases, and record labels. Second, we use a contrastive learning setup based on COLA, different from previous systems based on triplet loss. We train models targeting several associations derived from the metadata and experiment with stacked combinations of learned representations, evaluating them on standard music classification tasks. Additionally, we consider learning all the associations jointly in a multi-task setup. We show that it is possible to improve the performance of current self-supervised models by using inexpensive metadata commonly available in music collections, producing representations comparable to those learned on classification setups. We find that the resulting representations based on editorial metadata outperform a system trained with music style tags available in the same large-scale dataset, which motivates further research using this type of supervision. Additionally, we give insights on how to preprocess Discogs metadata to build training objectives and provide public pre-trained models.

1. INTRODUCTION

Developing robust representations is crucial to improving the performance of existing supervised Music Information Retrieval (MIR) tasks on datasets with few annotations. While conventional approaches are based on classification [1–3], other directions include self-supervised strategies [4–9] including leveraging generative models [10], supervision by editorial metadata [11–15], playlist co-ocurrences [16], co-listen statistics [15], natural language text [17], or combinations of them [10, 14–16]. While self-supervised systems are narrowing the performance gap with the supervised approaches, the latter seem to be reaching a performance ceiling in the academic research, partially due to the tremendous difficulty to collect larger annotated datasets.

Using editorial metadata as a source of supervision was already considered in other domains, for example, in scientific publication classification [18] or film recommendation [19]. Likewise, music is naturally rich in metadata. For example, physical formats typically contain detailed editorial information on their covers, digital audio files support containers such as ID3 for this purpose, and most streaming platforms offer album or artist-level browsability. Most music digital service providers routinely require such metadata from content uploaders, and therefore it is often available for music collections in the industry by default. Furthermore, editorial metadata does not suffer from the subjectivity problems common for music tags and tends to be more consistent. Because of these reasons, such metadata allows the creation of potentially larger and less noisy datasets than tag annotations.

Park *et al.* showed that certain types of editorial metadata (artist name) could be used to learn music representations using the triplet loss [11]. Motivated by their study and following the recent success of unsupervised representation learning approaches such as SimCLR [9, 20], we are interested whether modifying such systems to operate with similarity relations based on editorial metadata improves the learned features.

Our proposal differs from previous works on metadata-based music representation learning in two aspects. First, we use editorial metadata from Discogs, [1] a website containing an extensive metadata database including the artists, year, country, record label, and genres/styles of each release. Discogs publishes monthly dumps of their data under the Creative Commons CC0 license that we use to label 3.3 million tracks from our in-house data collection, allowing us to extract conclusions about systems trained on large datasets. Second, we adopt a contrastive approach already performant in a self-supervised setup instead of siamese networks. Specifically, we choose COLA [21] for its simplicity, operating directly on spectral representations, and requiring no data augmentation, which makes it efficient and suitable for large-data regimes. COLA works by maximizing the bilinear similar-

ity between a pair of mel-spectrogram patches (anchor and positive) cropped from the same audio clip while minimizing it for the rest of the patches in the batch. We propose to modify this self-supervised approach by constructing the anchor/positive pairs according to the different types of metadata considered (i.e., same track, release, artist, and record label). Additionally, we explore whether different metadata associations generate complementary information by combining the embeddings produced by their respective models and creating multi-task systems jointly optimized to learn them.

To summarize, we propose investigating the usability of metadata as an inexpensive source of supervision to train contrastive feature extractors for music classification. On top of the original self-supervised COLA approach, we experiment with associations based on editorial metadata to construct the positive pairs. We report results on public benchmarking datasets to facilitate comparison with the SOTA and provide publicly available pre-trained embedding and downstream models.

2. RELATED WORK

This paper combines three ideas: supervision based on editorial metadata, usage of the Discogs database, and the recent advances in contrastive learning for MIR. In this section, we review relevant works on these topics.

2.1 Metadata-based music representation learning

Park *et al.* shows that the artist name can be used as training target, with the resulting features being close in performance to those obtained from systems trained on crowdsourced tags [11]. As the artist information is too sparse to be learned efficiently in a classification setup, they approached it as a metric learning task by creating triplets with anchor and positive samples belonging to the same artist and a negative sample belonging to a different one. In a posterior study, they extend the approach to learning track-, album-, artist-level associations, and a combination of all, finding that the latter two provide the best representation [13].

Kim *et al.* propose dealing with the high dimensionality of artist vectors by summarizing them into Latent Dirichlet Allocation topics [22] to create targets suitable for a traditional classification setup [12]. Other works exploit editorial metadata (release year) among other learning sources in multi-task setups [14].

2.2 Discogs in MIR research

The Discogs database has already been used for research. Bogdanov *et al.* propose using it in the context of music recommendation [23], MIR, and computational musicology [24]. The former study proposes a recommendation system based on the similarity between artist representations in the form of a tag cloud of the associated genre, style, record label, and release year and country metadata. The latter illustrates the potential uses of the database on various cultural analysis examples including the evolution of physical distribution formats, genre and style trends, and their co-occurrences. Similarly, some studies analyze music artist collaboration networks [25–28].

In the context of music genre classification, the AcousticBrainz Genre dataset contains mappings across different music genre taxonomies, including the one from Discogs [29]. Hennequin *et al.* use the genre and style labels from Discogs for genre tag disambiguation [30].

2.3 Contrastive Learning in MIR

The MIR community has lately adopted contrastive learning approaches, both supervised and self-supervised. Regarding supervised methods, Favory *et al.* use a contrastive objective to align embedded representations of tags and audio [31, 32]. In a subsequent study, the system is enriched with playlists-track interactions as an additional modality to align [16].

On the self-supervised side, several contrastive systems from the computer vision domain have been adapted and evaluated for music-related tasks. CLMR [5] adapts SimCLR [20] to operate on waveforms using musically-meaningful augmentations. BYOL-A [6] relies on the BYOL [33] framework and adapts it to the audio domain by proposing specific augmentations and evaluating it on several audio tasks, including instrument classification. S3T [8] combines the MoCo framework [34] with Swin Transformers [35] to learn music classification features. Wang *et al.* [9] modify SimCLR by using a normalization-free SlowFast [36] backbone and improve the performance in several audio tasks, including music-auto-tagging. PEMR [7] deals with the lack of temporal resolution of existing systems by learning to mask important or irrelevant parts of the mel-spectrogram to produce self-augmented positive/negative samples. COLA [21] is a simple contrastive model for audio that takes random mel-spectrogram patches of the same clip instead of augmented versions of the same patch as anchor/positive pairs. It relies on the bilinear similarity to compute a distance matrix between all the anchors and positives and uses the categorical cross-entropy loss to maximize the similarity between correspondent anchor/positive pairs while using the rest of the positives in the batch as negatives.

We follow a straightforward implementation of COLA, but instead of relying on the same audio clip (purely self-supervised), we form the anchor/positive pairs according to relationships from the metadata. The complete pipeline is represented in Figure 1 (left). This is, to the best of our knowledge, the first usage of this framework in the context of MIR.

3. METHODOLOGY

We are interested in assessing the representation power of features derived from associations of commonly available editorial metadata. This goal is motivated by previous works that already showed the usability of the track, artist, and album similarities as supervision targets [13]. As these works already studied the influence of the dataset size and

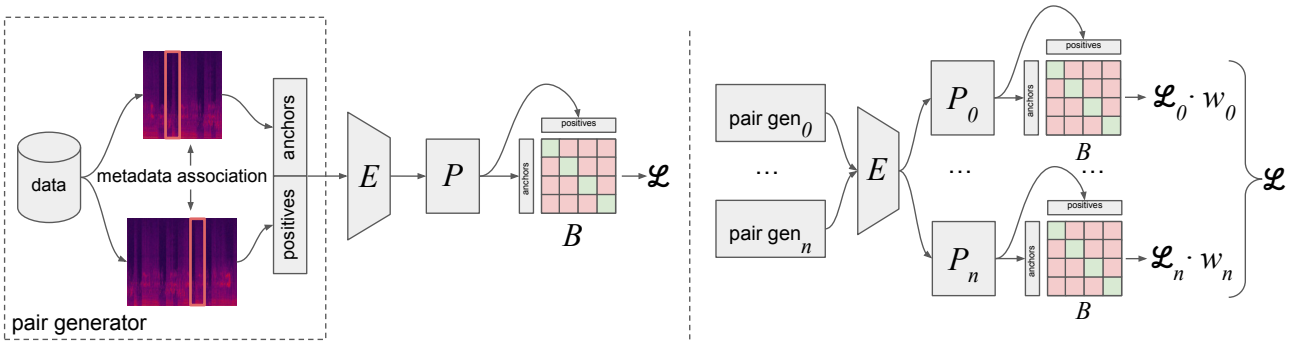

Figure 1. Overview of the proposed pipelines for a single (left) and multiple tasks (right). *E* is the encoder, *P* the projection head, *B* are the weights for the bilinear similarity, and $\mathcal{L}$ is the loss term. In the multi-task setup, tasks go from *0* to *n*.

showed a positive correlation with the downstream metrics, we will only perform full-size experiments and focus on unexplored aspects.

In particular, we are interested in imposing tight constraints on the pair generation process to emphasize the differences between the different associations. To formalize our problem, we consider a collection of music where each song has a track ID (*t*) and appears in one or more releases (*R*). Each release is produced by one or more artists (*A*) for one or more record labels (*L*). We define one self-supervised and three metadata-based associations:

- *track association*, the anchor and positive samples come from the same track (self-supervised),

$$t_a = t_p$$

- *release association*, t_a and t_p have at least a release in common,

$$|R(t_a) \cap R(t_p)| > 0$$

- *artist association*, t_a and t_p have at least an artist in common, but they do not appear in the same release,

$$|A(t_a) \cap A(t_p)| > 0, \text{ and } |R(t_a) \cap R(t_p)| = 0$$

- *label association*, t_a and t_p have at least a record label in common, but they do not share any artist,

$$|L(t_a) \cap L(t_p)| > 0, \text{ and } |A(t_a) \cap A(t_p)| = 0$$

Note that this approach considerably limits the number of pairs that can be matches and presumably leads to sub-optimal representations. However, our goal is to limit the number of overlapping pairs to emphasize the differences between associations. For instance, the release associations would be broadly a subset of the artist ones without the proposed constraints.

For each association, we generate a dataset of anchor/positive pairs. We initialize a pool with all the songs in the music collection. For each song, we pick a random pair that complies with the association's condition and remove both from the pool. While this approach does not exploit every possible association, it gives each track one association attempt, which provides us with sufficient training data for the scope of this work. We also considered a balanced version of the algorithm (e.g., same number of tracks per artist) that we discarded as the performance dropped due to the reduced dataset size without providing additional insights.

Following our contrastive paradigm, we do not need to create explicit anchor/negative pairs. For a given anchor, the rest of the positive samples in the batch are considered negatives (see Figure 1). While this naive approach implies that two pairs of tracks associated with the same artist will be respectively used as negative examples, there is a small probability of having repeated artists in a batch, and we ignored this issue. [2]

4. EXPERIMENTS

We pre-trained different contrastive systems following the proposed similarity notions. To evaluate the quality of the learned representations, we trained shallow classifiers on different multi-class and multi-label classification tasks. Additionally, we conducted experiments to understand the complementarity of such representations.

4.1 Contrastive targets based on Discogs' metadata

The Discogs database provides publicly available dumps of their *release* data that we used to create our training targets. According to Discogs, a release is "a broad term for any audio product that is made for general public consumption"; albums, singles, or compilations are examples of releases. Each release entry contains lists of the artists and record labels involved, the year and country of release, and a list of music genres and styles according to the Discogs' taxonomy. We matched our in-house audio collection to releases and master releases (groupings of different versions of a release) in the Discogs metadata dump resulting in 4 million tracks, with 58.2% of the tracks belonging to more than one release. A track may be linked to many releases for multiple reasons, including remasters, reeditions, or compilations containing it. For each track, we generated lists of artists and record labels by pooling the metadata on the

[2] For example, considering a dataset of one million tracks, a batch size of 200 pairs, and an average of 6 tracks per release, the probability of having two pairs from the same release in the batch is $6e-4$, which we consider an affordable false-negative rate.

Association	Pairs	Diversity	Time	Acc.
track	3.3M	3.3M	63h	88.7
release	846K	2.0M	21h	35.7
artist	1.2M	257K	33h	41.1
label	1.1M	142K	48h	24.7

Table 1. Statistics for the metadata association and their respective models. We show the number of pairs used, association diversity (number of different tracks, releases, artists, and record labels, respectively), training time (hours), and validation accuracy (%).

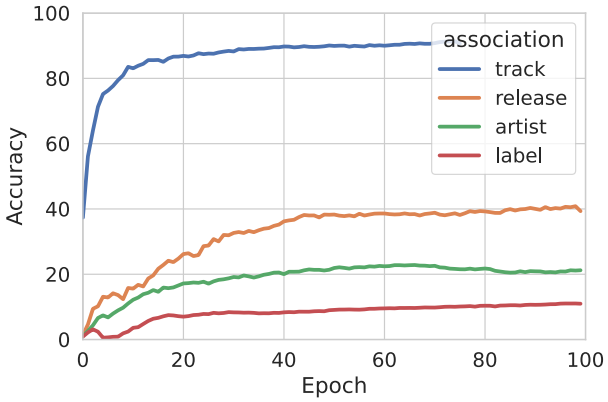

Figure 2. Training accuracies over the epochs for the different associations.

releases linked to it. We observed that different versions of a release could contain very different information, so for us, this was a simple way of maximizing the amount of information available per track.

We selected the subset with the top-400 most popular music styles resulting in 3.3 million tracks to train a baseline model with a multi-label classification objective (Style tags model). We reserved subsets of 50,000 tracks without artist overlap and a minimum frequency of 50 releases per music style tag for testing and validation. These sets were used as data pools to generate training, validation, and testing sets for the considered metadata associations following the methodology presented in Section 3. Note that we did not apply any data cleaning or deduplication, meaning that there may be room for improving the proposed representation models. Table 1 contains the resulting number of pairs and association diversities for each association, as well as the training time, and the accuracy obtained by their respective models. [3]

4.2 Pre-training the embedding models

We used an EfficientNet v1 on its B0 configuration as a backbone CNN to learn the embedding representations [37]. Our models operate on 2-second patches of mel-spectrograms with 96 bands extracted with the same parametrization as for MusiCNN [38] using the Essentia library [39]. [4]

Due to the massive dataset size, we stored the features as half-precision (16-bit) floats, and split the data into three machines with two GeForce RTX 2080 Ti GPUs each to parallelize the training. Every epoch, we fed the model with a random 2-second crop of the mel-spectrogram from each track in the training set. We also used a random patch per track for validation, but in this case, we used the same offset on every epoch to get more stable metrics. We relied on the Adam optimizer with an initial learning rate of $1e{-}3$ and a scheduler that reduced the learning rate by a factor of 10 if the validation loss had not decreased in 10 epochs. We trained the models for 100 epochs and considered two versions. The first one had the weights from the epoch where the lowest validation loss was achieved. The second model was obtained with stochastic weight averaging [40]. For the last 25 epochs, we imposed a learning rate of $1e{-}3$ and kept a moving average of the weights. As the latter version only reported minimum improvements in specific tasks, we decided to present the results of the former only.

As a baseline, we trained a model targeting the top-400 Discogs music styles with the multi-label soft-margin loss by connecting a fully-connected layer to the flattened output of the last convolutional block with 1280 units (embedding layer). As discussed on the Discogs website, [5] music styles usually go beyond purely stylistic descriptions and encode cultural, temporal, or geographical information, so we hypothesize that the learned representations are valuable beyond the task of genre recognition.

For the contrastive objectives, we used a fully-connected projection head with 512 dimensions on top of the same embedding layer, followed by a normalization layer and a *tanh* activation. We used the bilinear similarity ($a^T Bp$) and the cross-entropy loss as in the original implementation. While the authors of COLA showed that larger batch sizes improved the performance, we could only afford a batch size of 200 pairs due to the memory size of our GPUs. We parallelized the training so that each optimizer step aggregated six batches computed by different GPUs. This setup was close to the optimal number of pairs per optimizer step found in the original publication but used a larger ratio of positive samples.

To get additional insights into the models, we computed the top-1 accuracies by taking the *arg max* of the similarity matrices. Table 1 shows the training times and validation accuracies obtained by the model of each metadata association, and Figure 2 shows the evolution of the training accuracies over the epochs. The accuracies show that the associations have different difficulty levels, which aligns with our expectations.

All the pre-trained models are publicly available for feature extraction within the Essentia library. [6]

[3] The high number of releases is partially due to albums with multiple reeditions. On average, each track in our dataset is linked to 5 releases.

MTAT	25,860	50	Multi-label
FMA	8,000	8	Multi-class

Table 2. Considered downstream datasets.

4.3 Downstream datasets

We evaluated our models as frozen feature extractors following a transfer learning setup. We consider three well-known music auto-tagging and classification datasets: FMA-small [41] (*FMA*), MagnaTagATune [42] (*MTAT*), and the MTG-Jamendo Dataset [43]. The latter contains different subsets for *Genre*, *Instrument*, and mood/theme (*Mood*) tags, as well as the top-50 tags in the dataset (*Top50*) that we treated independently. For *FMA* and *MTAT*, we used the splits proposed by the authors [41] and the 12:1:3 partition [44] respectively. In the MTG-Jamendo tasks, we used the sets defined by its *split-0* similarly to previous works [17, 45]. Table 2 shows the size of the considered datasets.

4.4 Transfer learning evaluation setup

As for the pre-training stage, we trained the downstream models with 2-second patches randomly cropped on each epoch. For validation, we averaged over the activations from the half-overlapped patches of the entire tracks. We passed the patches through the frozen backbone and used the flattened output of the last convolution layer as the input to a multi-layer perceptron with a single hidden layer of 512 units with a *sigmoid* or *softmax* activation for the multi-label or multi-class tasks. We used the cross-entropy loss and the Adam optimizer with a starting learning rate of $1e-3$ and added a weight decay of $1e-5$. A scheduler divided the learning rate by half if the loss had not decreased in five epochs. We trained the models for 30 epochs and used the weights from the epoch achieving the lowest validation loss to evaluate the test set.

4.5 Stacks of embeddings

Apart from evaluating the embeddings obtained from every association individually, we were interested in understanding their complementarity. We wanted to understand if the individually-learned representations could be combined to boost the performance, and if so, which were the best combinations. To investigate this, we ran stacks of embeddings through the presented evaluation protocol. First, we evaluated the stack of the Track, Release, Artist, and Label features for all the datasets. Additionally, we performed a systematic evaluation considering all the possible combinations of the four contrastive models plus the model trained on tags on *MTAT* considering two, three, four, and five embeddings.

4.6 Multi-task model

We also considered training a multi-task model to learn the metadata associations jointly. The architecture of the proposed system is depicted in Figure 1 (right). For each association, we have a separate pair generator and projection head. To perform an optimization step, we ran a batch of pairs from each association through the shared encoder and its specific projection head and computed a weighted sum of the losses. The loss weights were empirically selected prioritizing associations with better single-model performances (*track*: 0.1, *release*: 0.15, *artist*: 0.6, and *label*: 0.15). Additionally, we initialized the encoder with the weights of the model based on artist associations on its 20th epoch to speed up the training. While we experimented with multi-task models based on two association types, we did not find additional insights and decided to omit those results. Due to the additional model size, we had to reduce the batch size to 50 pairs per association.

4.7 Results and discussion

Table 3 reports the metrics obtained by our models and selected works from the literature. In descending order, the five groups in the table contain SOTA models trained from scratch without additional data, SOTA embedding models, baseline embedding models trained by us, our proposed embedding models trained on metadata associations, and models combining metadata associations. In the first group, we include MusiCNN [38], Harmonic CNN [45], and the winning submission of the 2021 Emotion and Theme Recognition challenge (team Lileonardo) [46] [7] as the best models from the literature in *MTAT*, *Top50*, and *Mood*, respectively. Similarly, MuLaP [17] reports the best performance as a frozen embedding extractor in *Genre*, *Mood*, *Top50*, and *FMA*, and the same applies to CALM [10] in *MTAT*. Note that comparisons against these reported metrics may be unreliable due to differences in training and evaluation settings.

We computed three baselines based on audio embeddings from an EfficientNet architecture with random weights, an EfficientNet architecture trained on music style tags as described in Section 4.2, and the VGGish model with its pre-trained weights [47].

Concerning our contrastive models, we observe that the model based on track associations (Track model) achieves competitive performance in some tasks, especially in *Top50*. Nevertheless, the models using metadata associations show better or equivalent performance despite seeing fewer pairs of tracks in the pre-training stage. In particular, we find that model based on artist associations (Artist model) is the best-performing with a few exceptions, which aligns with previous studies in metadata-based music representation learning [13].

Instrument and *MTAT* are the tasks where our models are further from the SOTA. For *MTAT*, we attribute this to the fact that CALM has 1,000 times more parameters, and

Table 3. ROC-AUC, PR-AUC, and accuracy metrics for the downstream datasets. The five horizontal groups represent SOTA models from the literature trained from scratch, SOTA feature extractors from the literature, baseline feature extractors trained by ourselves, the proposed feature extractors based on metadata associations, and the proposed feature extractors combining associations. (*) results were computed in a clean version of *MTAT* and are not directly comparable.

that the authors report the best metrics from a grid search over shallow classifiers and hyperparameters. Also, we observed that models operating in the full *MTAT* previews tend to report higher PR-AUC performances [8, 10] than models operating in short chunks [5, 38].

The Stack is obtained by concatenating the embeddings from the models based on single associations as input for the MLPs. Except for *MTAT*, we do not get improvements over the best single model in any dataset despite the additional input dimensionality (5,120). Table 4 shows the top-5 results of models trained on combinations of embeddings for *MTAT*. The representations from the Artist and Style tags models are the only ones present in all the top-5 combinations, suggesting that these are the representations with the most valuable information. This observation aligns with the results from Table 3.

Similarly, our Multi-task model is not superior to the best single model in any dataset, but generally it is close in performance to the Artist model. We observe that Multi-task only overcomes Artist in the datasets where other associations perform better (i.e., *Instrument* and *FMA*), which shows its capability to pick the best information from different association types.

5. CONCLUSIONS

In this paper, we studied the usage of editorial metadata as a source of supervision for contrastive feature extraction models intended for music classification. We contributed to the previous work on metadata-based feature learning by scaling up the experiments in terms of dataset size, considering additional editorial metadata notions, and by experimenting with a new contrastive learning setup. We could validate that some of the observations from previous studies still hold for models trained on 10 times more data. Namely, we observed that some metadata-based representations are superior to their tag-based counterparts and that artist associations provide the best representations. Additionally, we found that the features learned from different metadata notions can be combined or jointly learned, showing slight performance improvements for particular tasks. To the best of our knowledge, this is the first study using Discogs' metadata to train music feature models. We did this by generating pairs of tracks according to metadata notions with simple matching rules, which leaves room for experimentation with the dataset.

In future research, we will explore more complex relationships in the metadata. For example, we could rely on metadata co-occurrences (e.g., record labels sharing many artists) to create more detailed associations. Another direction is to combine our approach with more sophisticated contrastive learning paradigms, which opens up a possibility for performance improvements. Finally, we will consider extending the evaluation to additional tasks such as music recommendation or arousal and valence regression.

6. ACKNOWLEDGEMENTS

ABSTRACT

This paper proposes a novel Transformer-based model for music score infilling, to generate a music passage that fills in the gap between given past and future contexts. While existing infilling approaches can generate a passage that connects smoothly locally with the given contexts, they do not take into account the musical form or structure of the music and may therefore generate overly smooth results. To address this issue, we propose a structure-aware conditioning approach that employs a novel attention-selecting module to supply user-provided structure-related information to the Transformer for infilling. With both objective and subjective evaluations, we show that the proposed model can harness the structural information effectively and generate melodies in the style of pop of higher quality than the two existing structure-agnostic infilling models.

1. INTRODUCTION

In recent years, machine learning techniques have been widely applied to symbolic music generation. A large number of models attain *sequential generation* by accounting for only the *past context*, i.e., the generated music depends on only the preceding musical content [1–14]. While sequential generation can find useful use cases, it does not align with typical human compositional practices which can be non-sequential in nature. Musicians often write motifs or small pieces to get inspiration first, before working on the middle parts to connect them.

Hence, we focus on the scenario when both the past and *future* contexts are given, which is called *music score infilling* or inpainting [15]. As shown in Figure 1(a), the task is to let models fill in the missing part between the two given segments. Prompt-based conditioning approaches [15–23] have been applied to such a task in recent years, treating the two given segments as the "prompt." Among them, the variable-length infilling model (VLI) [20] obtains promising results by adding special positional encodings to XLNet [24], a permutation-based language model that is naturally suitable for generative tasks with given bi-

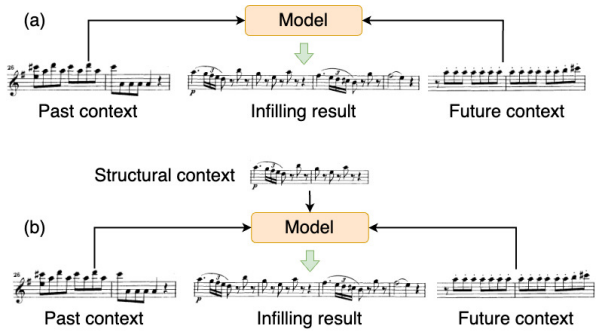

Figure 1: Comparison between (a) structure-agnostic and (b) structure-aware approaches for music score infilling.

directional contexts. The experiment of VLI shows that their model is capable of connecting the past and future contexts smoothly locally for infilling solo piano passages of up to 4 bars (measures).

Considering composers usually write musical pieces in a hierarchical manner [25], we note that prompt-based conditioning approaches have a strong limitation: they generate results with only consideration of local smoothness among the past context, future context, and result, without taking care of the overall musical *form* or *structure* of the music. For instance, a composer may like to write a song in a musical form of `ABA′B′`. If we consider the concatenation of the segments corresponding to `A` and `B` (i.e., `AB`) as the past context, and the segment corresponding to `B′` as the future context, and feed them to an existing infilling model, the model may generate a sequence that consists of similar melody and chord progression as the segments corresponding to `B` and `B′`, not the intended repetition or variation of the segment corresponding to `A`.

To address this issue, we propose in this paper a novel **structure-aware** setting for music infilling. As shown in Figure 1(b), besides the past and future contexts exploited by conventional structure-agnostic, prompt-based models, out approach additionally capitalizes for the infilling task the *structural context*, a music segment corresponding to a certain part of the whole music that is supposed to share the same *structure label* (such as `A` or `B`) with the missing segment. Accordingly, besides local smoothness, the model also needs to consider the similarity between the infilled segment and the structural context. Here, we assume the structural context is provided by a user, not generated by a model. For example, the user may designate the segment corresponding to `A` as the structural context, thereby

Su, and Yi-Hsuan Yang, "Melody Infilling with User-Provided Structural Context", in *Proc. of the 23rd Int. Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

inform the model with the intended musical form.

We improve upon the VLI model [20] in the following ways to realize structure-aware infilling. First, we use the classic Transformer [26–28] instead of the more sophisticated XLNet [24] as the model backbone, to make it easier to add a conditioning module to exploit the structural context. To improve the capability of the Transformer to account for bi-directional contexts, we propose two novel components, the *bar-count-down technique* (Section 3.2) and *order embeddings* (Section 3.3), which respectively give the model an explicit control of the length of the generated music, and a convenient way to attend to the future context. Second, being inspired by the Theme Transformer [29], we use not a Transformer decoder-only architecture but a sequence-to-sequence (seq2seq) Transformer encoder/decoder architecture, using the cross-attention between the encoder and decoder as the conditioning module to account for the structural context. Moreover, we propose an *attention-selecting module* that allows the Transformer to access multiple structural contexts while infilling different parts of a music piece, which can be useful both in the training and inference time (Section 3.4) .

For evaluation, we compare our model with two strong baselines, the VLI [20] and the work of Hsu & Chang [21], on the task of symbolic-domain melody infilling of 4-bar content using the POP909 dataset [30] and the associated structural labels from Dai *et al.* [31]. With objective and subjective analyses, we show that our model greatly outperforms the baselines in the structure completeness of the generated pieces, without degrading local smoothness.

We set up a webpage for demos [1] and open source our code at a public GitHub repository. [2]

2. RELATED WORK

Generating missing parts with given surrounding contexts has been attempted by early works. DeepBach [17] predicts missing notes based on the notes around them. They use two recurrent neural networks (RNNs) to capture the past and future contexts, and a feedforward neural network to capture the current context from notes with the same temporal position as the target note. COCONET [16] trains a convolutional neural network (CNN) to complete partial musical scores and explores the use of blocked Gibbs sampling as an analog to rewriting. They encode the music data with the piano roll representation and treat that as a fixed-size image, so the model can only perform fixed-length music infilling. Inpainting Net [15] uses an RNN to integrate the temporal information from a variational auto-encoder (VAE) [32] for bar-wise generation, Wei *et al.* [23] build the model with a similar concept as Inpainting Net and use the contrastive loss [33, 34] for training to improve the infilling quality. Some Transformer-based models have also been proposed to achieve music infilling. Ippolito *et al.* [18] concatenate the past and future context with a special separator token. They keep the original positional encoding of the contexts and the missing segment, which again limits the length of given contexts and generated sequence to be fixed. We see that these infilling models impose some data assumptions and thereby have certain restrictions, e.g., the length of the input sequence cannot be arbitrary, or the missing segment needs to be complete bars. The work of Hsu & Chang [21] is free of these restrictions. They use two Transformer encoders to capture the past and future context respectively and generate results with a Transformer decoder. The VLI model [20] can also realize variable-length infilling. However, to our best knowledge, no existing models have explicitly considered structure-related information for infilling.

Structure-based conditioning has been explored only recently by Shi *et al*. [29] in their Theme Transformer model for sequential music generation. They use a seq2seq Transformer to account for not only the past context but also an additional pre-given theme segment that is supposed to manifest itself multiple times in the model's generation result. The present work can be considered as an extension of their work to the scenario of music infilling.

3. METHODOLOGY

Given a past context C_{past} and a future context C_{future}, the general, **structure-agnostic music infilling** task entails generating an *infilled segment* T that interconnects C_{past} and C_{future} smoothly, preferably in a musically meaningful way. When using an autoregressive generative model such as the Transformer as the model backbone, the training object is to maximize the following likelihood function:

$$\prod_{0<k\leq|T|} P(t_k|t_{<k}, C_{\text{past}}, C_{\text{future}}) \,, \tag{1}$$

where t_k denotes the element of T at timestep k, $t_{<k}$ the subsequence consisting of all the previously generated elements, and $|\cdot|$ the length of a sequence.

Extending from Eq. (1), we propose and study in this paper a special case, called **structure-aware music infilling**, where an additional segment G representing the *structural context* is given, leading to the new objective:

$$\prod_{0<k\leq|T|} P(t_k|t_{<k}, C_{\text{past}}, C_{\text{future}}; G) \,. \tag{2}$$

As depicted in Figure 2(a), our model is based on Transformer with the encoder-decoder architecture. It uses the decoder to self-attend to the prompt (i.e., C_{past} and C_{future}) and the previously-generated elements (i.e., $t_{<k}$), and the encoder to cross-attend to the structural context G. We provide details of the proposed model below.

Note that we do not require the length of all the involved segments to be fixed; namely $|T|$, $|C_{\text{past}}|$, $|C_{\text{future}}|$ and $|G|$ are all variables in our setting.

3.1 REMI-based Token Representation

To incorporate structure-related information to our representation of the music data, we devise an extension of the REMI-based representation [8] that comprises five types

[1] https://tanchihpin0517.github.io/structure-aware_infilling
[2] https://github.com/tanchihpin0517/structure-aware_infilling

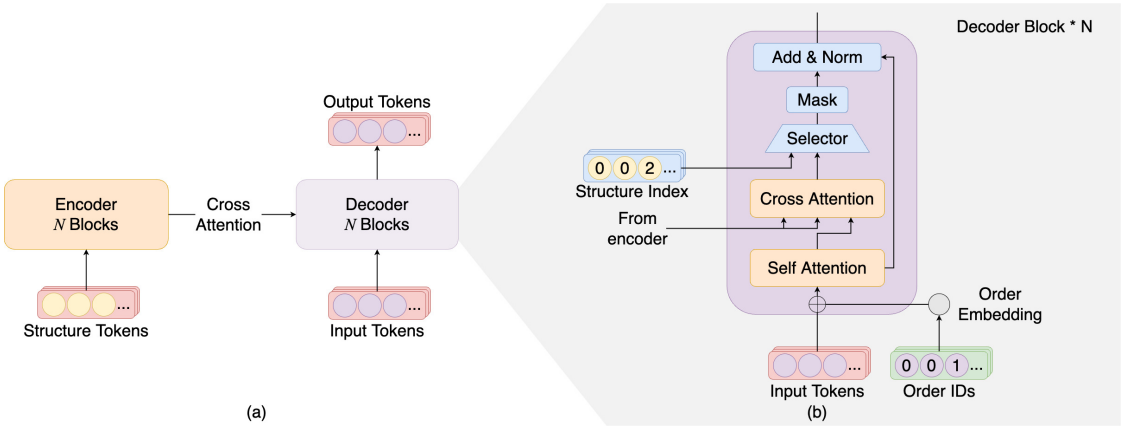

Figure 2: Schematic diagram of (a) the proposed seq2seq Transformer model for structure-aware infilling, and (b) a zoom-in of the decoder highlighting how the decoder utilizes the *order embedding* and *structure index*.

Token type	Voc. size	Values
`Bar`	32	1, 2, ... , 32
`Struct`	16	0, 1, ... , 15
`Tempo`	47	28, 32, ... , 212
`Position`	16	0, 1, ... , 15
`Pitch`	86	22, 23, ... , 107
`Duration`	16	1, 2, ... , 16

Table 1: The vocabulary of the token representation.

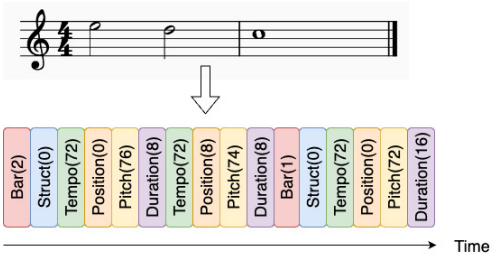

Figure 3: An example of representing a two-bar segment with our adapted REMI-based token representation. With the bar-count-down technique, `Bar(2)` and `Bar(1)` are used for the first and second `Bar` tokens, respectively.

of tokens: `Bar`, `Struct`, `Tempo`, `Position`, `Pitch` and `Duration`. Table 1 lists the vocabulary of our token representation. `Bar` consists of numbers from 1 to 32, standing for the number of remaining bars on the generation process. A music form, e.g., `ABA′B′`, consists of multiple groups of similar phrases or sections (each of multiple bars), e.g., {`A`, `A′`} and {`B`, `B′`}, where each group can be said to be associated with the same *structure label*. We use `Struct` to indicate the structure label for each bar. `Tempo` and `Position` are related to the musical metre. `Tempo` is the current tempo of beats per minute (BPM), and `Position` is the temporal distance between the onset of a musical note and the beginning of its bar, denoted by the number of 16-th notes. `Pitch` and `Duration` are related to musical notes, which are the MIDI pitch number and duration in 16-th notes, respectively. We show an example of how we encode the musical content in Figure 3.

3.2 Bar-Count-Down Technique

The work of Hsu & Chang [21] uses special `BOS` and `EOS` tokens as the "signal" to start or stop the generation process. At inference time, the infilled segment generated by their model comes to an end when the model generates an `EOS` token. While this may work fine in certain cases, doing so cannot give us an explicit control of the number of bars to be generated for the infilled segment. Such a control is preferable when we want to make sure that the previous context and the future context are a certain number of bars apart, which is highly needed for structure-aware infilling. For example, a user may want to specify the music form as `A8B8A′8B′8`, meaning that all the four sections `A`, `B`, `A′`, `B′` are eight-bar long each.

To have such a control, we employ a special token representation technique called "bar-count-down." For each infilled sequence T, we adjust the suffix number of `Bar` tokens to match the length of T. Take Figure 3 as an example: The number in `Bar` tokens are counted down from two because the sequence in Figure 3 is 2-bars long. Once training a model with this setup, the length of T can be controlled effectively by the number of remaining bars associated with the first `Bar` token given on generation.

3.3 Order Embedding

Transformers with causal masking are mainly designed for sequential generation. To apply the model to infilling tasks where the missing part is in the middle of the input sequence, the model proposed by Hsu & Chang [21] attends to bi-directional context from two encoders with cross-attention. As we want to instead use only the self-attention of the decoder to exploit bi-directional information, we reorder the sequence $\{C_{\text{past}}, T, C_{\text{future}}\}$ to $\{C_{\text{past}}, C_{\text{future}}, T\}$. Doing so would however change the original positional relationship among C_{past}, T, and C_{future}.[3] As depicted

[3] The principal idea of the attention mechanism [26] is to use the token embeddings of two tokens to compute their correlation, leading to the so-

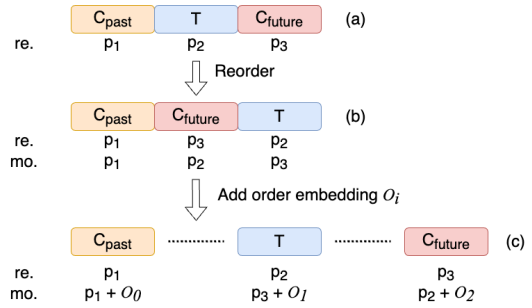

Figure 4: Illustration of the order embedding, where $re.$ and $mo.$ stand for the *real position* and *model-viewed position*. Conceptually, we shift the model-viewed position by O_i to make it consistent with the real position.

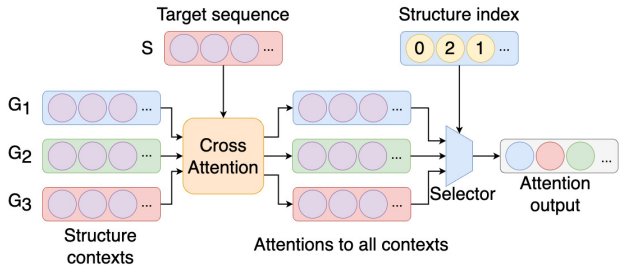

Figure 5: The schematic of attention selecting. Multiple structural contexts G_1, G_2, G_3 are passed to the cross-attention block simultaneously, and the output is filtered by the *selector* with the *structure index*.

in Figure 4(b), the *real* positional relationships among the segments entails associating the tokens in T with positional embeddings corresponding to a set of positions p_2 that signifies the model the segment T is after C_{past} (i.e., $p_1 \prec p_2$) and is before C_{future} ($p_2 \prec p_3$).[4] After reordering, however, using the typical way of computing the positional embeddings from left to right by the Transformers, T would be assigned with positional embeddings corresponding to p_3, meaning that by the *model-viewed* positional relationships, T is after both C_{past} and C_{future}. The real and the model-viewed are mismatched.

We introduce a new position-related *segment embedding* called "order embedding" to tackle this issue. Specifically, for the positional embeddings for all the tokens in C_{past}, we add to them the same additional embedding corresponding to a positional "offset" or "order," denoted as O_0. We similarly incorporate O_1 and O_2 to the positional embeddings for the tokens in T and C_{future}. As long as the "offset" is big enough, we can have $p_1 + O_0 \prec p_3 + O_1 \prec p_2 + O_2$, ensuring that the real and model-viewed positional relationships are matched, as depicted in Figure 4(c).

We note that, as the same order embedding is added to the positional embeddings of all the tokens in a segment, the proposed idea works nicely regardless of whether the segment lengths $|C_{\text{past}}|$, $|T|$, $|C_{\text{future}}|$ are fixed or not.

3.4 Attention-Selecting Module

While the formulation of Eq. (2) considers only one structural context G, in practice, we may want to designate multiple structural contexts $\{G_1, G_2, \ldots, G_N\}$ for infilling, with each segment G_n corresponding to a certain structure label such as `A` and `B`. This is useful, for example, when the first part of the infilled segment T is meant to be similar to phrase `A`, while the latter part similar to phrase `B`. To indicate which G_n a specific token t_k of T should refer to, we define the *structure index* $y_k \in \{0, \ldots, N\}$, for $k = \{1, \ldots, |T|\}$. The structure indices are also given by the user when the user specifies the intended musical form. With all these, we extend Eq. (2) to:

$$\prod_{0<k\leq|T|} P(t_k|t_{<k}, C_{\text{past}}, C_{\text{future}}; G_1, ..., G_N, y_k)\,. \quad (3)$$

We use $y_k = 0$ to indicate the case where t_k is supposed to follow none of the structural contexts (e.g., when t_k is part of the bridge). When $y_k \neq 0$, t_k follows only one of the structural context G_{y_k}. In our implementation, for tokens whose $y_k = 0$, we only use the self-attention to attend to the prompt and $t_{<k}$, leading to a formulation akin to Eq. (1). When $y_k \neq 0$, we have a "selector" that picks by y_k the structural context G_{y_k} to be attended to via cross-attention, resulting in a formulation akin to Eq. (2). This is depicted in Figure 2(b) and Figure 5.

Figure 5 also shows that, in our implementation, instead of computing the cross attention between the target sequence with a specific structural context G_{y_k}, we actually compute the cross attention between the target sequence with every structural contexts $\{G_1, G_2, \ldots, G_N\}$ and let the selector pick the right one. While this seems a waste of computing, we find doing so faster when GPUs are used.[5]

4. EXPERIMENTAL SETUP

We collect the melody data[6] from the POP909 dataset compiled by Wang *et al.* [30]. POP909 contains 909 MIDI files of pop piano performances, though we discard 8 of them due to errors encountered in the preprocessing stage. We split all remaining songs into 811 (90%) songs for training and 91 (10%) songs for testing. The 16-th note is set as the minimal temporal resolution to quantize the tempo, beat, and duration for reducing the vocabulary size.

Dai *et al.* [31] publicly share the *structural information* of songs in POP909 with letters and integers to indicate the structure labels and their lengths in bars, such as

`i4 A8 B8 x4 A8 B8 B8 X2 c4 c4 X2 B9 o2`, (4)

called attention score. However, using the token embeddings alone fails to consider the position-related relations of the two tokens (e.g., whether they are neighbors or distant apart). Accordingly, in practice, people add token-wise positional embeddings to the token embeddings before computing their attention [35–37].

[4] We use $p \prec q$ to denote that any elements in the set p is smaller, or "temporally before," any elements in the set q.

[5] There is another implementation detail: actually, not only the tokens in T but also those in C_{past} and C_{future} would go through the Transformer's self- and cross-attention blocks. This is to get the latent vectors for the tokens in C_{past} and C_{future}. In doing so, we calculate and employ the structure indices for C_{past} and C_{future} as well.

[6] Please note that the "melody" data in this paper is not exact monophonic music. We merge two midi tracks, "MELODY" and "BRIDGE" of the MIDI files of POP909 [30] to generate the melody data, which is monophonic most of the time but not always.

where the music phrases labeled with the same letter are considered to share the same structural context.[7] [8] Besides, the musical phrases with the labels `i`, `x`, and `o` are respectively the introduction, bridge, and ending, which do not have structural context in our setting. For each song, we use the phrases corresponding to the first occurrence of the structure labels such as `A` and `B` as the structural contexts G_1, G_2, etc. For example, we choose bars 5–12 (i.e., the `A8` phrase after `i4`) and bars 13–20 (i.e., the `B8` phrase before `x4`) in the example shown in Eq. (4) as the structural contexts for `A` and `B` since they are the first music phrases in the song with the corresponding labels.

The training data is generated with the following steps: (i) iterating through all labels except for the first and last ones in the structural information, (ii) choosing their corresponding music phrases as the infilled sequences T, and (iii) concatenating T with their preceding and following 6-bars music segments to get $\{C_{\text{past}}, T, C_{\text{future}}\}$, yielding 8,607 data in total. Before feeding the training data into the model, we reorder the input sequences and insert additional special tokens, `BOS`, `SEP`, and `EOS`, to change them into $\{\texttt{BOS}, C_{\text{past}}, \texttt{SEP}, C_{\text{future}}, \texttt{SEP}, T, \texttt{EOS}\}$. The reordered input sequence and structural contexts are transformed to the embeddings with size 512. The model consists of an encoder and a decoder, where both of them consist of six 8-head self-attention layers with intermediate layers of dimension 2,048. Each layer of the encoder and decoder is connected with an 8-head cross-attention, as shown in Figure 2. The output from the model is transformed back to a probability distribution of the vocabulary with the softmax function. At inference time, we use nucleus sampling [38] to sample the output tokens with the threshold value of 0.9.

For evaluation, we create the testing data by: (i) searching from the testing songs all the 4-bar phrases that correspond to only a structure label, (ii) keeping only the phrases that share the same structure label with one of its two neighboring phrases but a different structure label with the other neighbor, and (iii) setting the 4-bar phrase as the target T and concatenate them with their preceding and succeeding 6-bar music segments, which are set as the past context C_{past} and future context C_{future}, respectively. We get 156 test cases of $\{C_{\text{past}}, T, C_{\text{future}}\}$, each with 16 bars (i.e., $6+4+6$). All the cases have the form of, e.g., `AA'B` or `ABB'`, and the target lengths are **4 bars** with arbitrary number of notes (hence *variable* sequence lengths). In this setting, the attention selection mechanism is used only for training, since the target sequence T in our testing data only have one structural context to refer to.

We consider VLI [20] and the model from Hsu & Chang [21] as the baselines. By design, only our model has access to an external structural context. However, we consider the comparison as valid, since C_{past} and C_{future} are presumably long enough to provide sufficient context, and at least one of them has the same structure label as T. Besides, in our implementation, we found the model Hsu & Chang [21] rarely generates infilled segments with the desirable number of bars. Therefore, we slightly improve their model by incorporating the bar-count-down technique.

[7] The lower-case and capital letters indicate respectively *non-melodic* and *melodic* phrases (i.e., where a clear melody is present, mostly a vocal line or an instrument solo), but we do not use this information.

[8] Depending on the underlying musical form of a song, different songs may have different numbers of phrase groups. For example, a song with a simpler form may only have phrase groups `A` and `B`, while other songs have much more. In the POP909 dataset, a song can contain up to 9 unique phrase groups, which are labeled as `A`, `B`, `C`, `D`, etc.

	$H \downarrow$	$GS \uparrow$	$D \downarrow$
Ours	**2.75**$\pm$0.80	**0.70**$\pm$0.08	**25.73**$\pm$19.45

Original	2.78$\pm$0.89	0.70$\pm$0.09	0.00$\pm$ 0.00

Table 2: Objective evaluation results. H: pitch class histogram cross entropy, GS: grooving pattern similarity, D: melody distance (↑/↓: the higher/lower the better).

5. OBJECTIVE EVALUATION RESULTS

We propose three new metrics for objective evaluation, all of which have not been used in the literature of music infilling. The first two metrics, **pitch class histogram cross entropy** (H) and **grooving pattern similarity** (GS), are extensions of the ones proposed by Wu & Yang for sequential generation [10] to our infilling task, evaluating respectively the consistency in terms of pitch class distribution (which is related to tonality) and rhythmic pattern. For H, we compute per test case the pitch class histogram of T, and that histogram of the concatenation of C_{past} and C_{future}, and then report the cross entropy between these two histograms. For GS, we use per bar a 16-dim binary vector indicating where there is at least a note onset for every position in a bar, calculate one minus the normalized XOR difference between every pair of bars [10], one from T and the other from either C_{past} and C_{future}, and then report the average per test case. The third metric, **melody distance** (D) measures the melody distance (dissimilarity) between the infilled segment T and the ground truth one (denoted as $T\#$) using the algorithm proposed by Hu *et al.* [39]. Lower H and higher GS may imply that T connects C_{past} and C_{future} smoothly, while lower D indicates that the generation result is similar to a human-made one.

Table 2 shows that our model achieves the best result in all the three metrics, followed by VLI and then the model of Hsu & Chang. Besides being consistent with the contexts, the infilling result of our model is closest to the ground truth one $T\#$, demonstrating the effectiveness of exploiting the structural context. Figure 6 exemplifies how the infilled bars by our model fit the desired musical form.

6. SUBJECTIVE EVALUATION RESULTS

We conduct additionally an online user study for subjective evaluation. We have 91 anonymous volunteers, where 12 of them are marked as professionals according to the question about their musical background. Each subject is pre-

Figure 6: Results generated by (a) our model and (b) VLI. The structural relations of bars 4-5 (green area) and bars 8-9 (red area) are preserved well in (a) but not in (b).

sented with 3 out of 15 sets of music segments randomly sampled from the testing data. We inform them that the first and last 6 bars are the given prompts, and the middle 4 bars are the music generated by a model. Each set of music contains in random order 4 music including 3 generated by the models and 1 from the real data. The subjects rate each of the 4 music in a 5-point Likert scale (the higher the better) according to their (i) **melodic fluency**: do the pitches of notes go in the right tonality and connect the contexts fluently? (ii) **rhythmic fluency**: are the notes played on the right beats? (iii) **structureness**: how is the generated part of the music similar to its contexts? (ix) **overall**: how much do they like the music?

Table 3 shows the mean opinion scores (MOS) of the user study. Echoing the result of the objective evaluation, the proposed model outscores the baselines by a large margin in all the four subjective metrics, and is close to the real music with a small gap. The same observations can be made from either the average result of all the subjects, or only that from the 12 professionals.

However, we notice that our model may overly imitate the given structural contexts in some cases, as exemplified in Figure 7. When this happens, the generated music sounds rigid and non-creative. We conjecture that this can be attributed to the limited diversity of our training data—the melodies corresponding to the same structure label in POP909 appear to be too similar to each other, which may not be uncommon for pop songs. To study this, we implement additionally a 'Copy' baseline that simply copies the structural contexts as the result, and include its infilling result to the demo website. Our own subjective listening of its result confirms that the proposed method still outperforms the 'Copy' baseline most of the time, as the connections between the targets and their contexts are considered by our model, but not by the 'Copy' baseline.

7. CONCLUSION

In this paper, we have proposed a new structure-aware conditioning approach for music score infilling. To help Transformers exploit bi-directional contexts, we employ the order embedding to shift the position viewed by the model. Besides, we introduce a new attention-selecting mechanism to account for multiple structural contexts. Evaluations on 4-bar melody infilling validate the superiority of the proposed model over two existing Transformer-based structure-agnostic infilling methods [20, 21].

We can extend this work in three ways. First, instead of relying on user inputs, we may build models that generate the musical form automatically and predict the structural context for a specific infilled segment to refer to. Second, we like to expand our work to other music genres and polyphonic music. Finally, we like to study how the attention-selecting mechanism can be applied to sequential generative tasks such as theme-based generation [29].

8. ACKNOWLEDGEMENT

We are grateful to Shih-Lun Wu for sharing the unpublished idea of the bar-count-down technique, Ping-Yi Chen and Chin-Jui Chang for the assistance with experiments and discussion, Shan Lee for the help of figure drawing, and Chun-Wei Lai and Sophia Lin for the help in finding volunteers for the user study. We also thank the anonymous reviewers for their valuable feedbacks. Our research is funded by grants NSTC 109-2628-E-001-002-MY2 and NSTC 110-2221-E-006-137-MY3 from the National Science and Technology Council of Taiwan.

ROBUST MELODY TRACK IDENTIFICATION IN SYMBOLIC MUSIC

ABSTRACT

Melody tracks are worthy of special attention in symbolic music information retrieval (MIR) because they contribute more towards music perception than many other musical components. However, many existing symbolic MIR systems neglect the preprocessing of melody track identification (MTI). Moreover, existing MTI methods often deal with MIDIs of the same genres and follow specific track configuration. This limits their generalization and robustness to unseen data. To address these challenges, we propose a CNN-Transformer-based MTI model designed to identify a single melody track for arbitrary MIDI files robustly. To accommodate longer inputs, We also employ a sparse Transformer, speeding up attention computation. Our experiments show that our proposed model outperforms state-of-the-art (SOTA) algorithms in accuracy and benefits downstream MIR tasks.

1. INTRODUCTION

Listeners' perception of musical works is greatly shaped by the melodic lines of those works [1]. Human listeners can usually easily distinguish the melody from other musical components such as harmonic lines [2]. It is, however, not as easy for machines. Melody is also a major focus of many music information retrieval (MIR) tasks. These tasks fall into three categories: 1) Melody as a target, where the system seeks to output a suitable melody. Examples of this task include melody segregation [3, 4] and melody generation [5, 6]. 2) Melody as a requirement, where the model takes in an explicitly-identified melodic line as an input. Such tasks include lyrics generation from music [7, 8] and singing synthesis [9, 10]. 3) Melody as a dependency, where the melody is not explicitly provided as input but still heavily influences the results. Examples include genre classification [11] and music similarity measurement [12].

However, for melody-as-a-target tasks, the data of annotated melody labels can be difficult to obtain. Thus, an automatic MTI model can create more data for their training. The melodic line is the decisive factor for these melody-as-a-dependency tasks [13, 14]. However, current studies on melody-as-a-dependency tasks often neglect to intelligently identify the melodic lines of music. For example, a music embedding learning model, PiRhDy [15], simply regards the track with the highest average pitch as the melody. Existing genre classifiers treat all tracks equally rather than give special emphasis to the melodic line [11]. On the one hand, melody plays fundamental role in music perception [16]; studies have shown the success of attention and self-attention mechanisms in sequence modeling [17, 18]. On this basis, we hypothesize that melody-as-a-dependency tasks' performance would likely improve if the data are available with identified melodic lines. This preprocessing of MTI would also help melody-as-a-requirement applications. For instance, some stylistic music generation systems can only accommodate specifically formatted melody note sequences as input, demanding musicians' manual annotation [19]. Equipped with a MTI module, it could eliminate the dependence on manual processing.

There are two main challenges in developing a robust Melody Track Identification (MTI) model for symbolic music. First, many existing methods either rely on normative composition theories [20]. They assume that the input MIDIs are highly-formatted (i.e., one channel has only one track) and usually in limited genres [21, 22]. This assumption limits their generalization and robustness in dealing with more diverse or "dirtier" samples. Second, while local and global musical features are both significant for MTI, architectures such as CNNs and RNNs are not ideal in capturing short-and-long-term features simultaneously.

To address the above challenges, we propose a CNN-Transformer model to identify one single track as the melody for a given input MIDI file. This architecture effectively captures local musical features at the level of a measure (or a frame) while also making predictions over the whole piece based on global aggregations of those local features. We also utilize sparse attention in the Transformer [23] to speed up computation and reduce memory requirements so longer musical works can be processed.

We conduct the MTI experiment on a manually annotated dataset of 11,625 MIDIs. The results show that the proposed model makes a breakthrough in the accuracy of MTI. We also evaluate our proposed model as a preprocessing plug-in in the three types of melody-sensitive tasks. The results indicate that our proposed model is easy to incorporate and effectively improves their performance. This work includes a dataset with 13,100 widely used MIDIs whose melody tracks have been labeled. This dataset will be an asset to other MIR studies in the future.

2. RELATED WORK

2.1 Melody-Sensitive Tasks

Many studies have been done on MIR tasks which are heavily influenced by melody. Whether any specific such task has melody as a target, melody as a requirement, or melody as a dependency, accurate identification and knowledge of melody can help solve that task.

2.1.1 Melody as a Target

Tasks which set the melody as a target seek to output a melody. These tasks include generating melodies, extracting melodies from existing music, and converting one melody into another. Most existing systems for these tasks require annotated melodic lines as labels. For instance, MSNet is an encoder-decoder network designed for melody extraction from audio [4]. It takes an audio spectrum as input, extracts a salience map via UNet-like networks, and then estimates the audio's melodic line. Another system treating melody as a target developed a LSTM-GAN model conditioned on lyrics to generate symbolic melody sequences [5].

2.1.2 Melody as a Requirement

Tasks which take melody as a requirement, by definition, require an explicitly labeled melodic line as an input. The aforementioned PiRhDy is a model designed for one such task: it needs an explicitly labeled melodic line so that it can predict a MIDI file's melodic notes by the contexts and thus learning the representation of the music [15]. Similarly, Melody2Vec [24] can only utilize MIDIs with labeled track names of "melody" or "vocal" as training data. Another example is AI-Lyrics, a system which automatically generates lyrics to parallel an input musical piece's style and syllable alignment [8]. This generator requires a syllable template which can only be extracted from the melody track of the input MIDI files. Other lyric generators and singing synthesis systems also require vocal melody to be explicitly identified as inputs [7, 9, 10]. Currently, the melodic lines in MIDI files must be manually labeled for those files to work with these systems, which hinders the systems' practical applications.

2.1.3 Melody as a Dependency

Tasks which use melody as a dependency do not require MIDIs with explicitly labeled melodic lines, but they are dependent on melody information nonetheless. For instance, MuSeReNet is a genre classifier for symbolic music which extracts latent features of MIDI files with CNNs and then feeds them into a Multilayer Perceptron (MLP) to identify their genre [11]. Genre is heavily influenced by melody, so better knowledge of melody would no doubt help improve this system's accuracy. Another example is MusicBERT, which is a large-scale pre-trained model for music understanding, resembling the BERT from the field of Natural Language Processing (NLP) [25, 26]. It pre-trains the Transformer encoder [18] by solving a pretext task where it learns a music embedding by reconstructing notes' eight music elements such as tempo, pitch, velocity, and many others. Considering these elements are influenced by melody, we believe the knowledge of melody would likely help the learning.

2.2 Melody Identification

Melody extraction and identification problems can also be subdivided based on the different source and target data forms. The aforementioned MSNet is designed to extract melodic lines from acoustic audio, but though it achieves SOTA performance, it is sensitive to pre-defined settings such as input frame length and is not robust to inputs which do not match with those settings. Other models attempt to perform melodic line extraction from symbolic music [2, 3]. Namely, they output a note sequence representing the melodic line of an input MIDI. Hsiao et al., for instance, uses 1D-CNN networks to extract contextual information and further predict the probability of every pair of notes belonging to the same track. However, this model requires a lot of computation and thus have difficulty handling scaled up data size in a short time.

Rather than generating a note sequence as the melodic line, MTI systems aim to simply label the track which contains the melody. The Skyline algorithm, for instance, picks the track with the highest average pitch as the melody track [27]. There also exist Bayesian approaches which estimate a track to be a melody track if that track maximizes an accumulated probability derived from features such as note velocity, pitch values, and so on [28]. There are few deep learning approaches seeking to identify a single track of a MIDI file as the melody track. However, the emergence of self-attention mechanism makes the deep-learning-based models more powerful to cope with short term and long term musical structures simultaneously. And this motivates us to develop our CNN-Transformer model for this problem.

3. METHOD

In this section, we formulate the MTI problem, then present the data representation and the architecture design.

3.1 Problem Formulation

First, we define robustness of a MTI model for symbolic music in four aspects. A robust MTI model should be capable of identifying the melody tracks from MIDI files that 1) do not follow pre-defined track configurations (i.e., the first channel contains the melody track, the melody track is named as "Melody", etc.), 2) have several melodic and non-melodic tracks within one channel, 3) consist of various musical parameters (instruments, tempos, velocities and time signatures), and 4) diverse in genres, styles, and sentiments.

An arbitrary piece of symbolic music in MIDI format is denoted as $\mathcal{S} = \{Tr_N\}$, where N denotes its number of tracks, each track $tr_i \in Tr$ is a sequence of MIDI events, which trigger control demands or music notes. Namely,

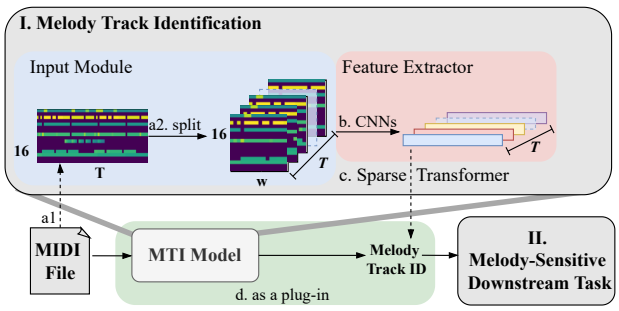

Figure 1. Dataflow of our method. (a) MIDI quantization and split. (b) CNN feature extractor. (c) Global information aggregator. (d) Plug in downstream tasks.

$tr_i = [e_0, e_1, ..., e_M]$ where $e_j \in [0, 127]$. Given an N-track MIDI file $\mathcal{S}$, our task is to predict the ID y^i of one single melody track, formally, $Y = \{y^i|\mathcal{S}\}$. Since a MIDI file has at most 16 sound output channels and one channel can contain several tracks, our MTI model can be seen as a supervised 16-way multirun classifier. When the melody track occupies an entire channel, the initial prediction result is the melody track ID; When the melody track shares a channel with tracks of other musical components, the model reruns a second prediction to further distinguish the melody track from the initially identified channel. Therefore, the prediction process is definitively convergent in finite time.

As shown in Figure 1, the data flow of our proposed robust MTI model is divided into several modules. First, an input MIDI file goes through the input module for preprocessing: it is quantized and serialized as a matrix with a resolution of sixteenth note (Figure 1-a1). Then the matrix is split into overlapped frames with step-wise scanning (Figure 1-a2). Second, a frame level CNN extracts the local features of a frame (Figure 1-b) and a sparse Transformer based classification module predicts the melody track ID based on the aggregated global features (Figure 1-c). Taking in a MIDI and outputting its melody track ID, the whole MTI module (Figure 1-I) can serve as a preprocessing plug-in for other melody-sensitive MIR tasks (Figure 1-II).

3.2 Input Module

Our input module converts an input MIDI file $\mathcal{S}$ into a 2D matrix $\boldsymbol{M} = [m_{ct}]_{C\times T}$, where m_{ct} denotes the pitch value in the c^{th} channel at the t^{th} time step, and T denotes the total length of the MIDI. One time step corresponds to a sixteenth-note length so that the encoding is tempo independent. If there are multiple tracks containing different pitch notes in the same channel c at time t, m_{ct} is temporarily set to the highest pitch value. The module also ensures that all input MIDI files have a full sixteen channels by padding any files with channels of zeros. This encoding provides following advantages against the piano roll representation: 1) It has a fixed dimension of channels; 2) It omits the velocity which can confuse the MTI model; 3) The tracks sharing the same channel can be temporarily fused into one representative pitch sequence and further distinguished in the rerun of the model later.

Inspired by Simonetta et al. [2], we apply step-wise scanning to split the 2D representation of a MIDI file into overlapping frames of fixed window size, w, equivalent to one bar. Each resultant frame is thus a $w \times w$ matrix $\boldsymbol{m}^{(i)}_{t-l:t+w-l}$, where $\boldsymbol{m}^{(i)}_{t-l:t+w-l}$ represents the frame centers around the t^{th} time step in the i^{th} MIDI file, and l represents the preceding l time steps.

3.3 Architecture Design

We propose a CNN + Sparse Transformer structure to learn local context information of each frame while also aggregating global information over the entire sequence. We also propose to overcome the memory bottleneck that a vanilla Transformer imposes. This enables the system to efficiently process longer music by reducing the density of self-attention connections. We adopt a hierarchical training strategy: First, we pretrain the CNN-based feature extractor by predicting the melody track ID at frame level; then, we fine-tune the whole model by predicting a single melody track ID of the input MIDI.

3.3.1 Local Context-Aware Feature Extraction

We use a CNN as our feature extractor to learn the local context information of given frames provided by the input module. The architecture for this portion of the system is shown in Figure 2. The feature extractor ϕ first goes through pretraining. Specifically, we add a temporary MLP layer with weights $\boldsymbol{W}$ and bias b to each frame to predict its fame-level melody track ID. The predicted probability for a certain frame $\boldsymbol{m}^{(i)}_{t-l:t+w-l}$ can be denoted as

$$\hat{y} = \text{softmax}(\boldsymbol{W}\phi(\boldsymbol{m}^{(i)}_{t-l:t+w-l}) + b) \tag{1}$$

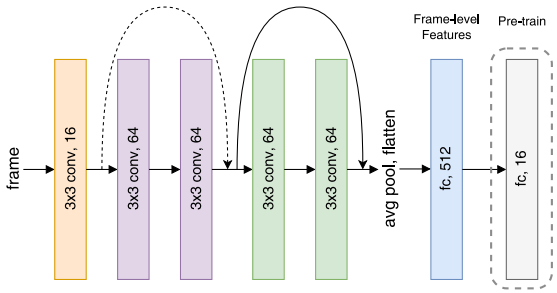

Figure 2. The architecture of our feature extractor. Shortcuts represent skipped paths. Dotted shortcut represents dimension increases. The last fully connected layer (grey) is only used in pre-training.

3.3.2 Global Classification Module

With the pre-trained feature extractor ϕ mentioned above, each MIDI file can now be transformed and concatenated into a context-aware embedding

$$\boldsymbol{M}^{(i)} = \mathop{||}_{t\in[1,T]} \phi(\boldsymbol{m}^{(i)}_{t-l:t+w-l}) \tag{2}$$

where $\boldsymbol{M}^{(i)} \in \mathbb{R}^{T\times d}$, $||$ denotes concatenation over time steps, and d denotes the dimension of feature extractor ϕ.

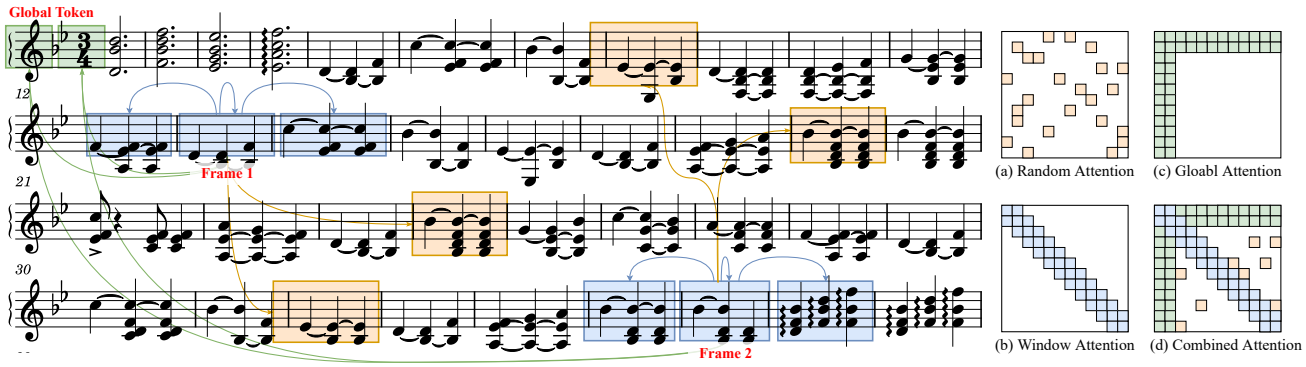

Figure 3. Left: an example of a sparse self-attention mechanism adapted in symbolic music, where frames 1 and 2 attend to three neighboring frames (blue), two random frames (orange) and a global frame (green) respectively. Right: an illustration of each sparse self-attention mechanism proposed by Big Bird, where $g = 2$, $w = 3$, $r = 2$.

We then apply and fine-tune the global feature aggregators (Sparse Transformer) upon the feature extractor by predicting a single melody track ID based on the aggregation of the frame-level features. Taking the sequence of the concatenated CNN features, the Sparse Transformer computes a sequence of embeddings with the same length and then aggregates to one single label, paying attentions to other positions in its computation. The computation of the multi-head self-attention is the same as the typical Transformer:

$$\mathcal{A}(x_i) = x_i + \phi_{attn}(\underset{h}{||}\ \delta(\frac{\mathcal{Q}_h(x_i)\mathcal{K}_h(x_i)^T}{\sqrt{d}})\mathcal{V}_h(x_i)) \quad (3)$$

where $\mathcal{Q}_h(\cdot)$, $\mathcal{K}_h(\cdot)$, $\mathcal{V}_h(\cdot)$ respectively denote the query, key and value function of x_i, $\delta(\cdot)$ denotes the scoring function, $\underset{h}{||}\cdot$ denotes concatenation over attention heads, and ϕ_{attn} denotes the projection applied after concatenation. Especially, the sparse self-attention reduces the density of self-attention connections to accommodate longer inputs.

3.3.3 Sparse Self-Attention In Symbolic Music

In a typical Transformer, the full self-attention mechanism requires a quadratic dependency on sequence length. However, the length of MIDI files is generally long; directly applying a full self-attention operation on it can lead to memory overflow. Rather than simply splitting the embedding $\boldsymbol{M}^{(i)}$ into shorter segments [29], which can cause a loss of global information, we leverage Big Bird [23], a transformer with sparse self-attention mechanism. Specifically, the following sparse self-attention mechanisms are proposed: 1) **Random Attention**, all frames attend to r random frames in the sequence, allowing the global information aggregator to have better generalization ability. 2) **Window Attention**, all frames attend to w neighboring frames in the sequence, functioning as an information gateway of a music bar. 3) **Global Attention**, g newly introduced global frames (e.g., a classification token [CLS] preceding the sequence) attend to all frames in the sequence, collecting the global information. By combining these three sparse attention mechanisms, we manage to approximate the effectiveness of a full self-attention meanwhile reducing the time and space complexity from $O(n^2)$ to $O(n)$. Figure 3 gives an example of how frames sparsely attend in symbolic music.

4. EXPERIMENTS AND RESULTS

This section contains the experiment design and the analysis of the results. First, we detail the construction of the datasets. Then we compare our proposed model with several baselines and alternative architectures so as to evaluate if our proposed MTI model can attain SOTA accuracy. Finally, we evaluate our model on three melody-sensitive downstream tasks, including melody segregation, music embedding learning, and genre classification.

4.1 Dataset

We create four different datasets, one per experiment, to train and evaluate our models. Each dataset is split into a training set and a validation set with an 8:2 ratio unless otherwise noted.

4.1.1 For MTI Model

We collect MIDI songs from three widely used MIDI datasets: LMD [30], Reddit MIDI dataset [1], and Free-MIDI [2]. We then eliminate samples with no obvious melody track, such as MIDIs of percussion instruments and chord progression patterns, and we also eliminate MIDI files where the melody changes tracks. Next, we manually annotate the melody track of the remaining songs and shuffle their melody track IDs for label distribution balance. The resultant dataset contains 11,625 samples for model training and validation (**D-MTI**). Additionally, the trained MTI model automatically annotates another 1,475 files in the Free-MIDI dataset, providing an overall dataset of 13,100 MIDI files (**D-Full**) [3] after manual checking. The proposed datasets are desirable for training and evaluating a robust MTI model because the data covers a variety of genres (17 in total), track configurations (track orders and names), as well as MIDIs with multi-track channels.

4.1.2 For Downstream Task Evaluations

To evaluate our MTI model's utility for downstream MIR tasks, we build three more datasets based on Free-MIDI: a dataset of 1,100 randomly selected MIDIs, including audio

[1] https://www.reddit.com/r/datasets/
[2] https://github.com/josephding23/Free-Midi-Library
[3] https://github.com/maxichu/MelodyTrackIdentification

renderings of the MIDIs and of their automatically identified melody tracks (denoted as **D-Audio**), a dataset of 5,000 genre-labeled MIDI files of 17 genres (**D-Genre**), and a dataset of 500 MIDI files of pop songs (**D-POP**).

4.2 Melody Track Identification

To evaluate the effectiveness, efficiency and robustness of our proposed MTI model, we select the following three baseline models: the Skyline algorithm, a Bayesian probability model with dynamic programming [28], and a 1D-CNN model with clustering [3]. The CNN-based melody segregation model [2] is not selected for comparison because it seeks to directly extract the melodic line rather than predict the melody track. We also selected three alternative architectures: a BiLSTM architecture, a CNN + MLP architecture and a CRNN architecture. We then compare our proposed CNN + Sparse Transformer (CNN-ST) architecture with all the above models.

Model	Accuracy(%)	Running Time(s)
Skyline	14.7	252.52
Bayesian	40.98	1094.15
1D-CNN	5.51	14818.89
BiLSTM	10.23	12.37
CNN-MLP	83.65	36.12
CRNN	81.60	32.74
CNN-ST	**84.40**	29.71

Table 1. Accuracy and efficiency of MTI models. The running time is the total time of infering 1,000 samples. (The frame-level accuracy of the basic CNN model is 49.72%)

As shown in Table 1, our proposed model achieves SOTA results without incurring extra computational costs. Both Skyline and the 1D-CNN model suffer sharp reductions in accuracy when dealing with samples which are not highly normative or formative. We believe that Skyline's dependency on music composition convention hinders its generalization, while the clustering phase of 1D-CNN model might be the bottleneck of the capability to accommodate complicated data sources. The Bayesian approaches obtains a lower accuracy of 40.98% on the proposed dataset than the reported 89% accuracy on a standard MIDI dataset. Its definitions of scoring algorithms targeting at only classical music could account for the accuracy drop. These issues can cause their respective algorithms to have low accuracy when processing long music with many different arrangements and genres. Worse still, the high time complexity of the 1D-CNN model can make it too costly to be incorporated into other models or applications.

As shown in Table 1, the comparison between BiLSTM and our proposed CNN-ST shows the CNN's effectiveness in capturing local musical features. The accuracy improvement over frame-level CNN indicates the ability of aggregating global information from frames of the proposed self-attention module. In the case study, our model handle the following occasions better than the baselines: 1) There are other components having a higher average pitch than the melody; 2) The music notes are dense and in large quantity; 3) There are tracks echoing the high-pitch part of the melody. Therefore, our proposed model leads in accuracy, efficiency, and robustness for the MTI task.

4.3 Downstream Tasks

We test our MTI model in three downstream tasks of different types to evaluate its benefits to the MIR community: 1) Improving melody segregation of audio music by providing more easily-obtained training samples; 2) Improving musical embedding learning by allowing more rigorous assumptions on melody; 3) Improving genre classification by emphasizing the impacts of the melody.

4.3.1 Melody Segregation

As a typical melody-as-a-target task, melody segregation requires pairs of {audio music, melody} for training. However, such data is laborious to obtain–labeling large numbers of melodic lines requires a significant amount of time and effort from trained music specialists. Training with small datasets may lead to underfitting issues, such as a recent melody segregation work whose dataset only contained 108 samples [4]. Furthermore, existing paired datasets are often collected from just a few genres, or even one genre, of music. Models trained by those datasets thus often fail to generalize to music from other genres.

This experiment aims to test whether our MTI model can contribute to the melody segregation task by both automatically labeling the melody tracks of MIDI files in order to rapidly expand the amount of audio, including audio from various genres, formats and compositional rules, which can be used to train these systems.

ID	Pretrain Data	Train Data	OA (%)
1	/	MedleyDB	37.7
2	/	D-Audio-1K	39.91
3	/	MedleyDB ∪ D-Audio-1K	**41.1**
4	D-Audio-1K	MedleyDB	**40.23**

Table 2. Accuracy of different training data settings for the melody segregation task. All results are computed on an independent 100-sample validation subset of D-Audio. OA is short for overall accuracy.

We trained four melody segregation models with the same architecture [4] but different datasets. Our control model was trained with the 108 samples of the original MedleyDB [31]. Our three other models were trained with D-Audio-1K (1,000 samples in D-Audio), a combined dataset of MedleyDB and D-Audio-1K, and D-Audio-1K (pretraining) followed by MedleyDB (fine-tuning), respectively. Validation was done with the set of the remaining 100 samples from D-Audio, denoted as D-Audio-100.

As shown in Table 2, not only does an increased amount of training data improve melody segregation accuracy but pretraining with the D-Audio-1K dataset provides superior results to using either of those datasets on their own. The

pretraining, however, does worse than the setting where all the data is used for training. This can be attributed to the bias of data distribution between the two datasets.

4.3.2 *Music Embedding Learning*

Music embedding learning is a melody-as-a-requirement task. Many music embedding learning models are trained by predicting the melody notes according to other music components. However, these models generally rely on the Skyline algorithm or track names for data preparation, which can result in errors if they do not find the melody correctly [15, 24].

We conduct an experiment with the PiRhDy embedding model [15] to evaluate how well our proposed MTI can improve music embedding learning models. We run all of PiRhDy's three subtasks for performing music embedding (token modeling, next context modeling, and accompaniment context modeling) on both the D-POP and D-Gen datasets. Before executing those subtasks, we run the Skyline and the proposed CNN-ST+ model to identify melodic lines for the tracks being analyzed.

As shown in Table 3, all three subtasks achieve higher accuracy when using melody tracks identified by our proposed model as compared to Skyline. The best improvement occurs in the subtask of token modeling on the D-Gen dataset, which indicates that our system better handles unusual genres than the existing Skyline algorithm too.

/	Skyline+ D-POP(%)	CNN-ST+ D-POP(%)	Skyline+ D-Gen(%)	CNN-ST+ D-Gen(%)
Token Modeling	60.49	**74.61**	74.77	**96.74**
Context Modeling-Next	91.43	**92.05**	91.89	**94.58**
Context Modeling-Acc	67.45	**78.74**	55.37	**56.53**

Table 3. Accuracy of models using different methods for PiRhDy embedding learning.

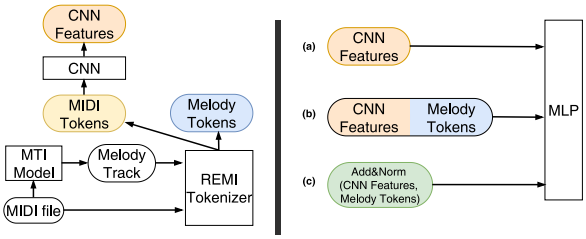

Figure 4. The three compared architectures for music genre classification with different inputs of the MLP layer. The inputs of the MLP are: (a) only the CNN features; (b) concatenation of CNN features and the melody tokens; (c) CNN features Add-Norm with the melody tokens.

4.3.3 *Genre Classification*

As a melody-as-a-dependency task, genre classification can be enhanced by explicitly emphasizing the melody over other musical components. This experiment is conducted on D-Gen. As shown in Figure 4, the full-track MIDIs and the identified melody track are first both tokenized into REMI [32] sequences with MidiTok toolkit [33]. Next, genre prediction is attempted with three different architectures. All of the architectures are CNN + MLP, and their input layers are just CNN features, CNN features appended with tokenized melody note sequences, and the CNN features Add-Norm with the tokenized melody note sequence respectively.

The results in Table 4.3.3 show that the accuracy increases when feeding the MLP layer with extra information about the melody. Therefore, highlighting the melody by either appending or blending it with the CNN features makes the music genre more distinguishable.

Inputs to MLP	Accuracy(%)
CNN features	41.51
CNN features ‖ Melody Tokens	**42.75**
Add&Norm (CNN features, Melody Tokens)	**45.76**

Table 4. Accuracy of models with different inputs to MLP layers for genre classification.

5. FUTURE WORK

We notice that emphasizing the melody track could dilute models for certain tasks where melody is not decisive, or at least is not the only decisive factor. For instance, we trained systems for key recognition [34, 35] with full MIDI files, just the melody tracks of MIDI files, and just the non-melody tracks of MIDI files. Whether using a rule-based algorithm [34] or a deep learning-based model [35], the systems trained with full MIDI files outperformed the others, and the systems trained with non-melody tracks outperformed those trained with just melody tracks. We thus estimate that accompaniments may matter more than melody for this task and are looking into ways to tweak our algorithm to account for this.

Also, the samples in our collected dataset contain only one melody track, and so for simplicity, we neglect scenarios such as multi-track melodies and melodies which switch tracks. In the future, we will develop a stronger model which can account for these scenarios even though they make the global musical structure of the song more challenging, and will also create datasets with more detailed annotations that can account for the position of the melody on a frame-by-frame basis.

6. CONCLUSION

Melody track identification is the first step towards music understanding and benefits melody-sensitive MIR tasks. This paper addresses the challenges of identifying the melody track accurately, efficiently, and robustly for any input MIDI. Our experiments show that our proposed model achieves SOTA performance and increases accuracy for many downstream tasks. We are optimistic that further research in this direction will not just enhance the ability of computers to identify melody tracks but will also improve many other aspects of MIR.

Graduate School of Informatics, Kyoto University, Japan
thalm007@umn.edu, {eita.nakamura, yoshii}@i.kyoto-u.ac.jp

ABSTRACT

Evolutionary studies have become a dominant thread in the analysis of large audio collections. Such corpora usually consist of musical pieces by various composers or bands and the studies usually focus on identifying general historical trends in harmonic content or music production techniques. In this paper we present a comparable study that examines the music of a single band whose publicly available live recordings span three decades. We first discuss the opportunities and challenges faced when working with single-artist and live-music datasets and introduce solutions for audio feature validation and outlier detection. We then investigate how individual songs vary over time and identify general performance trends using a new approach based on relative feature values, which improves accuracy for features with a large variance. Finally, we validate our findings by juxtaposing them with descriptions posted in online forums by experienced listeners of the band's large following.

1. INTRODUCTION

Music information retrieval has proven essential for the *analysis of large audio corpora*, especially ones for which traditional music analysis methods are limited. Such cases include large audio collections for which there is no appropriate symbolic transcription, such as ones containing non-western music or improvised music [1–5].

In recent years numerous studies have characterized the temporal evolution of musical characteristics in such corpora. Serra et al identified a restriction of pitch transitions, homogenization of timbral palette, and growing loudness levels in Western popular music [6]. On a similar corpus, Mauch et al discovered three stylistic revolutions between 1960 and 2010, based on topics identified via latent Dirichlet allocation of harmonic and timbral features [7]. Deruty and Pachet determined the 'loudness war' in popular music production to have peaked in 2007 [8]. Weiss et al found harmonic complexity to be gradually increasing in Jazz solos between the 1920s and the 2000s [4]. Weiss et al also confirmed common hypotheses concerning the evolution of chord transitions, intervals, and tonal complexity in Western classical music [9]. Parmer and Ahn measured information-theoretic complexity of pitch, loudness, timbre, and rhythm in a popular music dataset and identified trends over decades [10]. [1]

All of these studies look at music at a social or cultural level and use audio corpora that consist of material by various composers or musicians, as well as of different genres, subgenres, instrumentations, etc. In this paper we present an analogous study which however focuses on the *music of a single band*, the Grateful Dead, who are well-known for their ever-evolving performances. We use a dataset that consists of audio recordings of 2617 performances of 15 songs spanning three decades. Although this may be a sizable dataset for a band, we find that musical characteristics show a large variance over the relatively short timespan. For example, the tempos of the performances in the set range from 50 to 160, which over the whole time span results in a relatively sparse cloud of data points.

Previous approaches are relatively limited when dealing with such diverse data. They all consider the corpus as a whole and simply plot the evolution of audio features against time. This may work reasonably well for some musical characteristics such as tonal complexity, timbre, or loudness. However, we show how subdividing the corpus into subsets, in our case songs, and considering feature data relative to these subsets before integrating them into a whole can improve accuracy and confidence for the detection of overall trends. We identify such trends in various performance characteristics and juxtapose them with observations by experienced listeners from the band's large following. In particular, despite working with a relatively small subset of only 15 of the band's songs, we are able to identify generally perceived trends in tempo, song duration, and dynamic, spectral and harmonic content with promising accuracy.

2. DATASET

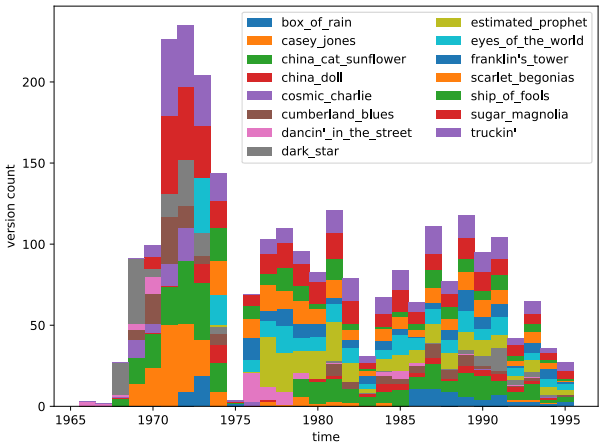
The cultural impact and decades long performance history of the Grateful Dead has led to continued interest in the band's music by both fans and scholars [14]. The band is especially known for their free and inclusive approach to music, their unwillingness to bow to the conventions of popular music, and their aspiration to provide their fans

[1] Similar trend analyses were recently done with non-audio music collections, such as with lyrics [11] or symbolic data [12, 13].

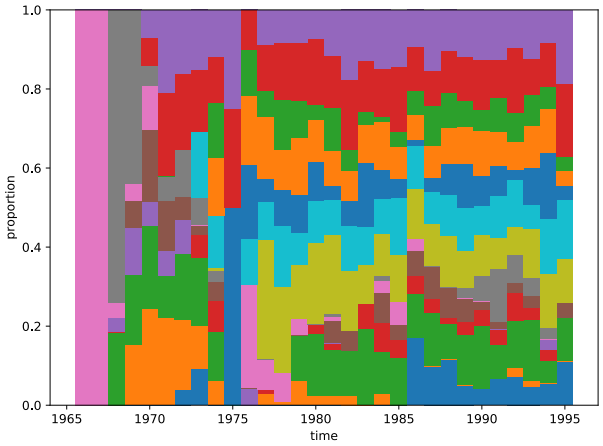
Yoshii, "Tracking the Evolution of a Band's Live Performances over Decades", in *Proc. of the 23rd Int. Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

with a new experience at every concert. The performances of their songs often vary greatly, even from day to day, and they often engage in long improvisational parts or jams. Almost all of their over 2000 concerts between 1965 and 1995 have been recorded, often multiple times, and most of these recordings are public domain and included in the Live Music Archive's (LMA) largest subcollection. [2] To musicologists, this catalog may be intimidating for these reasons [15], but this make it all the more interesting for studies using MIR methods.

We use a dataset introduced by [5] [3] which includes 2617 performed versions of a set of 15 songs from the Grateful Dead collection of the Live Music Archive. According to the authors, the songs were selected based on two criteria: a large number of versions with soundboard recordings across the whole time span, as well as a studio recording as a potential reference. Many of these recordings contain crowd noise, which may affect the quality of features, and many are out of tune due to varying tape speed during recording. The dataset comes with a script that downloads the files from the LMA and automatically resamples them based on tuning ratios determined from chroma vectors. Figure 1 (a) shows a chronological distribution of the files. We observe very low counts for the first two years which may be due to a lower number of available recordings, and 1975 when the band retired for a year. A relative distribution of songs across the years (Figure 1 (b)) shows that the first two years of the dataset only contain one song, which may be problematic for an evolutionary analysis. A more systematic generation of such a dataset may prove useful in the future, but we chose to use it here without modifications.



(a)



(b)

Figure 1: (a) Chronological distribution of the recordings for each song in the dataset. (b) Relative distribution of songs by year, order and colors correspond to (a).

3. METHOD

The fact that we have subsets of identical or similar musical pieces or recordings can be leveraged at different points in the process. First, a large number of audio features are extracted for each recording in the corpus, now tuned as described above. We then validate these features relatively for each song, which allows us to detect outliers, i.e. wrongly classified songs, as well as adjust wrongly extracted features such as double-time beats. Our statistical analysis includes two steps. We first analyze the feature distribution and evolution for each song independently, which allows us to characterize the relative evolution of normalized feature values for each song. These relative evolutions are then collated into a global evolution curve for each feature, which we validate using bootstrapping, i.e. by alternately leaving out each song.

3.1 Feature Extraction

The set of audio features used in our study were inspired by previous work on other corpuses referenced in Section 1 and extracted using madmom [4] (*beats*, from which we derived tempo), librosa [5] (*chroma* and *mfcc*, summarized to the madmom beats), as well as the essentia freesound extractor [6] (for *dynamic* and *spectral* summary features). We used standard settings for all extractors, except for with madmom's DBNBeatTrackingProcessor where we used a much higher transition lambda of 2000 rather than the suggested maximum of 300 in the documentation. This was to reduce the probability of the processor jumping between tempos within one audio file, which may have been occurring due to the many long versions (median over 10min, sometimes over 30min), as well as the amount of crowd noise.

We also calculated a few additional features, inspired by other studies. *Tonal complexity* as defined by Weiss et al as the angular deviation or spread of pitch-classes on a circular chroma vector, permuted to correspond to the circle of fifths [4,9,16]. To measure pitch content agnostic of tonality, we devised an analogous *pitch complexity* feature based

[2] https://archive.org/details/GratefulDead

[3] https://github.com/grateful-dead-live/fifteen-songs-dataset

[4] https://madmom.readthedocs.io

[5] https://librosa.org

[6] https://essentia.upf.edu/freesound_extractor.html

on the reverse-sorted normalized summarized chroma vector, which results in a right-skewed distribution, of which we took the mean. From the 36-bin harmonic pitch class profiles (HPCP) extracted by essentia, we derived a *tuning complexity* feature, which expresses the average deviation from 440Hz in both directions. [7]

3.2 Beat Correction and Outlier Detection

The extracted features allow us to address two frequently occurring problems. The first problem is that beat tracking is often inconsistent between different versions of a song, due to the large variance in tempo and the high amount of improvisation in the dataset. The second problem is that some song sets may contain incomplete fragments or recordings of other songs, due to mis-annotations in the Live Music Archive, as noted by Page et al [17].

Our *beat correction* method consists of identifying instances of beat features that should rather be double-time, half-time, or two-thirds-time. [8] We start with the original beat pairings $B^i_b = (R^i, b_{R^i})$ of recordings R^i, $i = 1 \dots K$, and their corresponding beat sequences b_{R^i}, which are simply sequences of time points, as extracted by a feature extractor. For each beat sequence b_{R^k} we create three variants, a linearly interpolated *double-time* version d_{R^k}, [9] a *half-time* version h_{R^k} which only contain every other beat, and a *two-thirds-time* version t_{R^k} which contain every third beat of d_{R^k}. We end up with four sets of K beat sequence pairings $B^i_b, B^i_d, B^i_h, B^i_t$, defined analogously to B^i_b. For each of these pairings we extract a set of features $f_1, \dots f_F$ which all depend on the beat sequence in the pairing. For each feature f with a corresponding distance function δ_f, we then create four $K * K$ distance matrices $D^{x,f}_{ij} = \delta_f(B^i_x, B^j_b)$, one for each $x \in \{b, d, h, t\}$. These matrices express how well the four types of beat pairings match with the original pairings b_{R^i}. We normalize these matrices using min-max normalizations and calculate for each pairing B^k_x its average distance from the original pairings over all features

$$\Delta^k_x = \mu_{f=f_1 \dots f_F, j=1 \dots K}(D^{x,f}_{kj})$$

Finally, we choose for each recording R^k its best pairing B^k_x with minimum Δ^k_x.

The set of features that worked well for the dataset used in this paper are chord sequence distributions, onset distributions, and tempo. We generate a chord sequence distribution from a summarized chord sequence, where for every beat interval we take the chord that occupies the longest duration. From this sequence we gather all subsequences of length L at step size 1 and count the occurrences of each possible pattern. Onset distributions are generated by calculating the position of each onset o relative to its neighboring beats $b_<, b_>$, e.g $(o - b_<)/(b_> - b_<)$ and quantizing the resulting relative onsets to a grid of G values by multiplying them by G rounding to the nearest integer. Both kinds of distributions are normalized. Tempo is simply calculated as the average distance between successive beats. For beat correction, we chose the parameters $L = 4, G = 64$.

For distance functions δ_f we used the chi-square distance $\chi^2(x, y) = \frac{1}{2} \sum_i \frac{(x_i - y_i)^2}{x_i + y_i}$ for distributions, and the analogous $\frac{(x-y)^2}{x+y}$ for two single values x, y, such as for tempo.

Next, we identify *outlier recordings* using an extension of the feature set above, by adding chord sequence distributions with $L = 2$ as well as overall beat count, i.e. the length of the beat feature vector. Similar to the beat correction method, we calculate a distance matrix $D^f_{ij} = \delta_f(R^i, R^j)$ for each feature f and normalize it. We then calculate a normalized distance $d_{f,k}$ for each feature, consisting of the difference between the average deviation of R^k from the overall average deviation $\mu(D^f)$, normalized by overall standard deviation $\sigma(D^f)$.

$$d_{f,k} = \frac{\mu_{j=1 \dots K}(D^f_{kj}) - \mu(D^f)}{\sigma(D^f)}$$

Finally, we consider recordings as outliers if they deviate by 2.5 standard deviations in at least two features ($d_{f,k} > 2.5$) or by four standard deviations in at least one ($d_{f,k} > 4$). The latter condition particularly ensures that recordings of extreme length, such as incomplete fragments or improperly segmented files that include more than one song, get excluded due to an extreme deviation of overall beat count.

We obtained the best results by applying beat correction and outlier detection *successively and iteratively*, i.e. one after another in a loop, until both the beat positions and the set of included recordings are stable. Especially for songs with less regular structure, the process only terminates after several iterations, due to the reference beat sequences b_{R^j} changing at each step. Furthermore, with iterative application we can catch cases of quadruple time etc.

When applying this method to the dataset, a total of 211 outliers were removed (around 8%), including for a case where we identified a set consisting of recordings of two songs with similar titles, possibly due to wrong annotations. Of the beat features of the remaining versions, 99 were identified as half-time, 8 as two-thirds-time, and 21 as double-time.

3.3 Statistical Analysis

We are now ready to start our diachronic analysis of the feature data, which is structured as follows. For each feature we have one data point per version of every song. Each version is associated with a specific day on which it was played. For feature f we thus have the data points $P^f = \bigcup P^{f,1} \dots P^{f,15}$ where $P^{f,i} = (p^{f,i}_{k_i})_{k_i=1 \dots K_i}$ is the sequence of data points for song i with K_i versions.

Although our dataset consists of material from only one band, we face a relatively high variation in features, due

[7] These measures are also related to the information-theoretic complexity measures used by Serra et al or Parmer and Ahn [6, 10].

[8] Two-thirds-time has proven to be useful in situations where we have a ternary meter, such as $6/8$, which might be interpreted as either binary or ternary by the beat extractor.

[9] Each successive pair of beats is interspersed with an average of the two, and an additional beat is added at the end, at an interval corresponding to last interpolated one.

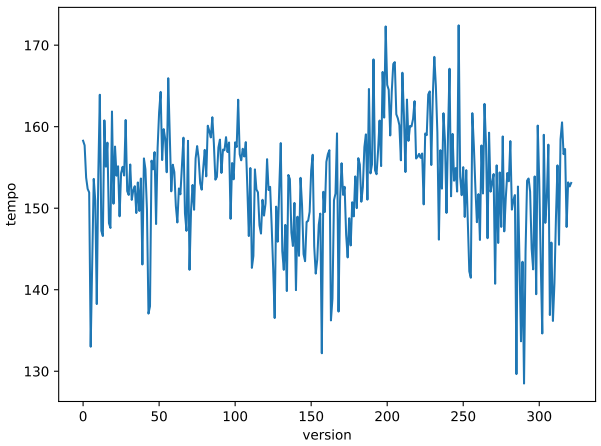


Figure 2: The chronological sequence of tempo data points of all 322 versions of *Sugar Magnolia*.

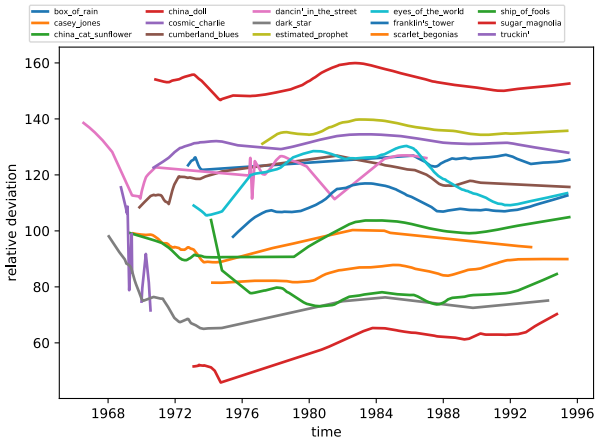

Figure 3: LOWESS plots of tempo for each individual song in the dataset.

to the constant experimentation and improvisation of the band. Figure 2 illustrates how much the tempo of the song *Sugar Magnolia* varies over time, sometimes by as much as 30% from one day to the next. We can identify a global trend in such data by creating a trend line using LOWESS [18], [10] which fits a polynomial regression line at each point, based on a local neighborhood. This neighborhood consists of a fixed proportion of all points, which we set to $f = .2$ or 20%. LOWESS works particularly well for data that is unevenly distributed along the x axis, which is the case here due to the uneven distribution of songs across time (Figure 1).

We can calculate such curves for each song individually, as shown in Figure 3. The top-most curve in this figure corresponds to the line shown in Figure 2 and we can identify two tempo peaks, one around 1973 and one around 1983. It is also apparent that the overall tempo range in the collection varies by more than a factor of 3, from around 50 to almost 160. In order to get a sense of how the tempo changes over all songs, we can create a plot for the whole set of songs, LOWESS(P^f). However, in order to make sure that the curve is not dominated by the values of a single song, we calculate a confidence interval using bootstrapping, leaving out each song once. [11] For each $j = 1 \ldots 15$ we calculate LOWESS($\bigcup_{i \neq j} P^{f,i}$), and determine at each time point the minimum and maximum value among these curves to get the confidence interval.

With absolute values, this confidence interval turns out to be quite large, leaving us unable to draw conclusions with certainty, as shown by the orange curve in Figure 4. For example, we cannot confidently say that the peak observed in 1984 is higher than the one in 1972, due to the overlapping confidence intervals. However, we can get a much better estimate of how the tempo changes by taking *relative feature values*, which we can simply calculate by

[10] As used by Moss et al in their analysis of the evolution of the distribution of pitch-class content on the line of fifths [13].

[11] An alternative method for this is bootstrap resampling, where we could ensure an equal number of points per song. However, due to limitations found in the dataset (after outlier detection one song only has 22 versions), we chose to use the present method.

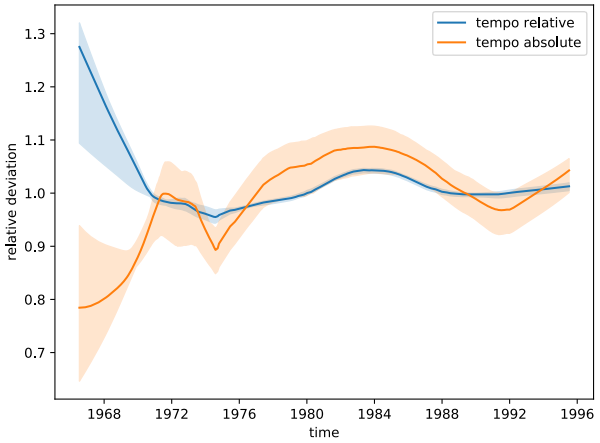

Figure 4: Bootstrapped LOWESS curves on the whole dataset for absolute and relative tempo values.

normalizing the sequences $(p_{k_i}^{f,i})$ as follows:

$$(p_{k_i}^{f,i})' = \frac{(p_{k_i}^{f,i})}{\mu(P^{f,i})}$$

In the case of tempo, each version of every song now has a relative tempo feature, which expresses how its tempo relates to all other performances of the song. The blue curve in Figure 4 is a bootstrapped LOWESS calculated on relative tempo values. We can observe a much narrower confidence interval, now enabling us to confidently claim that in 1984 the tempo was higher than any time in the 70s or 90s. We can also observe that in the beginning of the timeline the curves digress dramatically and with a much larger bootstrapping interval, which is due to the dataset containing few versions of few songs during that time, as observed in Section 2. All subsequent plots are of relative features and calculated as just described.

4. RESULTS

There has been very little musicological work on the Grateful Dead [19, 20], perhaps due to the intimidating size of

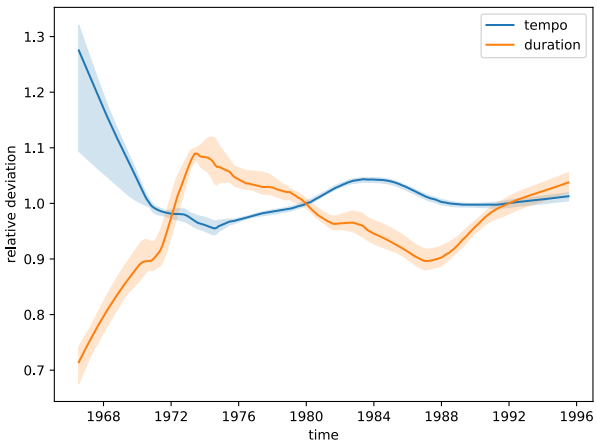

Figure 5: Bootstrapped LOWESS curves for tempo and song duration across all songs.

the band's catalog as well as the intentionally fleeting nature of the performances, as hypothesized by Tift [15]. However, when it comes to in-depth knowledge of the band's music, the best source are undoubtedly the band's fans themselves, the Deadheads. Many of them have spent decades listening to the music and debating it online, and some of them are so knowledgeable that they have an acute sense of how the music changes every single year throughout the band's history. In order to find such general yet detailed descriptions of the evolution of the band's music we searched the Grateful Dead subreddits, [12] the largest forums of their kind with a total of 174k members at the time of writing. We manually read through all pages with discussions on the differences between the band's phases and collected all general descriptions that include the musical characteristics we study, including tempo, timbre, song lengths, etc, with references to specific years. The pages were found using combinations of the search keywords *description, year, decade, 60s, 70s, 80s, 90s, progress, tempo, jam*. Some of the most detailed year by year descriptions found are by Wolfman92097, WesternEstatesHOA, MrCompletely, and an anonymous deleted user [21–24], and some people, such as maximinus-thrax have listened to, rated, and briefly described every of the band's more than 2300 shows [25, 26]. There are also many pages discussing the evolution of individual songs, such as [27]. We will now discuss our results while referring to relevant statements from the community where we can observe a consensus.

Figure 5 juxtaposes different temporal aspects of the music. We can identify an overall increase in tempo in the 1980s of more than 10%, and a subsequent decrease in the middle of the decade. In terms of duration, the differences are even more dramatic, a sharp increase in the early 70s, followed by a gradual decrease by more than 20% until the late 80s, when duration starts increasing again. Note that the early curve segments in all plots, until about 1969, can be considered biased for the reasons stated in Section 3.3. These observations coincide well with a notion in the community that, compared to the 70s, the early 80s are perceived as more energetic, faster paced, and containing fewer and less extensive jams. Wolfman92097 notes that in 1980 "the tempo [starts] to speed up a little", in 1984 "musically the tempo has really sped up", and in 1985 "the band slows the tempo a little." [22] It is striking that this increase and decrease directly corresponds to the tempo curve in Figure 5. Although a bit more abstractly, leedye similarly highlights that exact time period: "79-84 stands out to me as the disco/cocaine era ... post 84 just seems to be a little more of the slow churned vanilla as opposed to that sweet mint chocolate chip." [28] The same perception is true for individual songs. Discussing a recording of the song Eyes of the World, melwarren says "my 4 year old asked why EOTW was going so fast" and whenthattrain-rollsby replies "They played it too fast for my taste in the 80's." [29] On a different page the forum members observe how the song went back to a refreshingly new slow tempo in 1990 [27]. These observations can also be verified in Figure 3.

In terms of song duration, braney86 notes that the "late 70s was full of monster extended jams, and Jerry was absolutely on fire", while MrCompletely says that "82 through 85 is a long uneven slide down ... 87 is the comeback, shows are very different, most are tightly executed, very light on jams ... 88 starting to stretch back out a little." [23] Wolfman92097 also observes that in late 1986 "the setlists get much longer and way more experimental than they had been all year" and that in 1988 "jazz and extreme psychedelia gets added in." [22] Many deadheads' favorite years are 73/74, "the peak of their spacey, jazzy, psychedelic extended jams" according to devlinontheweb [30]. These observations again directly correspond to the plot in Figure 5. Song duration peaks in 1973, decreases throughout the late 70s and the early 80s with a turnaround point around 87/88, as perceived by MrCompletely.

Figure 6 shows plots for dynamics features. We can observe a long peak in overall loudness of the soundboard recordings, spanning the entire 1980s. With increasing loudness we see a decrease in dynamic range, which may hint at an increased use of compression in the live mix. However, when comparing with Figure 5, we can also see a striking correlation between loudness and tempo, as well as between dynamic complexity and duration. Dynamic complexity may be another indicator of the amount of improvisation in the recordings, similar to song duration. The latter two, however, seem to be somewhat independent nonetheless. We can particularly observe a bulge in dynamic complexity in the late 70s which does not occur in the duration curve, and in the 90s duration increases while dynamic complexity decreases. On the other hand increased loudness may be a direct consequence of higher tempo and energy. EvilLinux admits that "If I am alone in the car, I usually will choose the 80's. There is just more energy, more off the rails." [31] An anonymous deleted user also says that "the Dead did play some incredible

[12] https://www.reddit.com/r/gratefuldead/, https://www.reddit.com/r/grateful_dead/

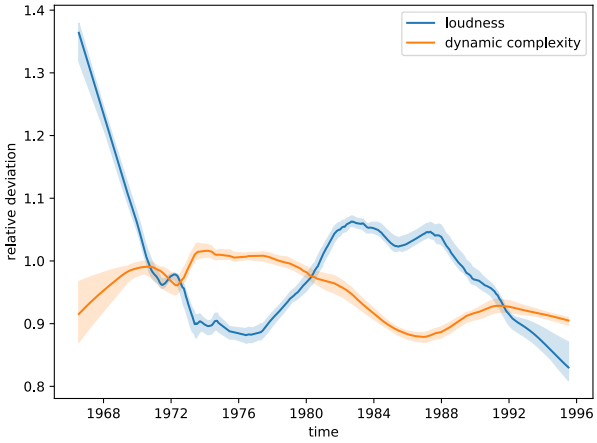

Figure 6: Bootstrapped LOWESS curves for dynamic essentia features (*loudness_ebu128.short_term.median* and *dynamic_complexity*) across all songs.

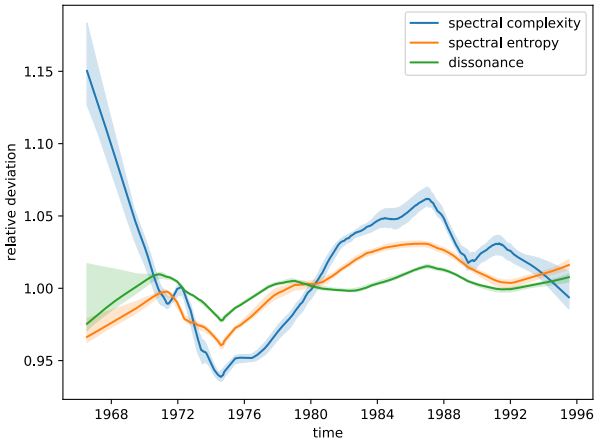

Figure 7: Bootstrapped LOWESS curves for spectral essentia features (*spectral_complexity.median*, *spectral_entropy.median* and *dissonance.median*).

shows in the early to mid-80s. They had a "fatter" sound, especially Jerry" [24].

A similar observation can be made for spectral features (Figure 7). Complexity and entropy increase for the entire duration of the 1980s, while dissonance has a shorter peak in the late 80s. Many listeners agree that the 80s have an entirely different sound, to a large part characterized by the keyboarder Brent Mydland who played with the band from 1979 to 1990 and who used a greater variety of keyboards and many synthesizers. According to BeaverMartin, Brent "really adds a whole different texture to the vocals and keys," [28] and WesternEstatesHOA says that "In 1983 the band truly takes off. The physical change of Brent's new keyboard is enough to change the band's sound alone. It has deep watery effects and adds so much depth to some of the more simple tunes." [22] Wolfman92097: "83 Garcia [guitar] is a little more distorted and Brent is using more fake keyboard sounds Phil [bass] is loud." [21]

As for tonal content, Figure 8 shows a selection of features calculated as described in Section 3.1. Tonal, pitch,

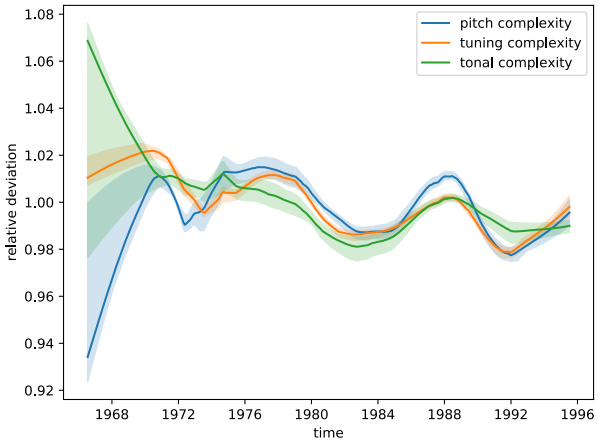

Figure 8: Bootstrapped LOWESS curves for pitch, tuning and tonal complexity features.

and tuning complexities run roughly in parallel and the period of 1980-84 is again demarcated, with a clear dip in all three features. This may again be due to the more streamlined faster performances and the lower degree of improvisation during this period. The late 1980s show parallels with the late 1970s, which may be related to the band starting to improvise more again. However, pitch and tuning complexities also seem highly correlated with dissonance (Figure 7) which may be related to timbre and the typical rich distorted and synthesizer-heavy 1980s Grateful Dead sound.

5. CONCLUSION

We have shown how evolutionary methods can not only be used for the study of general cultural trends in music, but also to investigate how the performances of a band change over time. We have also seen how we can improve the prediction accuracy of musical trends by considering the feature values relative to subsets of the data. It may be possible to apply a similar method in other situations, such as when studying the simultaneous evolution of the music of different composers, considering the music of each of them relative to their own work. We have also discovered limitations with the dataset used and suggest, in future work, to design a larger more systematic one in order to confirm our preliminary discoveries in this paper. Finally, while we have shown the potential reliability of the accounts of experienced listeners in the community, a more systematic collection and processing of online forum data may lead to more detailed results in the future.

Georgia Institute of Technology

ABSTRACT

Recent years have seen considerable advances in audio synthesis with deep generative models. However, the state-of-the-art is very difficult to quantify; different studies often use different evaluation methodologies and different metrics when reporting results, making a direct comparison to other systems difficult if not impossible. Furthermore, the perceptual relevance and meaning of the reported metrics in most cases unknown, prohibiting any conclusive insights with respect to practical usability and audio quality. This paper presents a study that investigates state-of-the-art approaches side-by-side with (i) a set of previously proposed objective metrics for audio reconstruction, and with (ii) a listening study. The results indicate that currently used objective metrics are insufficient to describe the perceptual quality of current systems.

1. INTRODUCTION

There has been growing research interest in building deep learning models that are capable of generating audio. Models such as WaveNet [1], NSynth [2], WaveGAN [3] and, most recently, DDSP [4] paved the way for data-driven Neural Audio Synthesis (NAS). Models like DDSP and NSynth have been advertised in YouTube videos prominently [5, 6], where artists make music using neural network generated audio, indicating that there is real world applicability to generative audio models.

Despite the many advances in generative modeling of sounds in the past couple of years, the evaluation of these systems lacks established methodology. Most importantly, systems are not evaluated with a consistent set of metrics. For instance, researchers have suggested the following to evaluate the output of such generative systems: the classification accuracies of neural networks trained to classify the sounds into predefined categories such as pitch and sound qualities [2,3,7,8], statistical methods [9,10], and subjective evaluation through listening studies [3, 9, 10].

This inconsistency in metrics and methodology makes a direct comparison of systems difficult at best, making it hard to understand the current state of the art and to measure the impact of new innovations in the field.

Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

In this study, we measure and compare the quality of the output of neural networks capable of producing short time-invariant samples. The goal is to evaluate state-of-the art systems comparatively with previously used evaluation metrics and to investigate the perceptual relevance of these metrics for measuring audio quality.

To pursue these goals, we trained three widely known neural networks, DDSP [4], NSynth [2], and Diffwave [9]. The evaluation results published with the introduction of these methods all imply that these models synthesize sounds at high quality. However, since different metrics are used for each system, no comparison is possible. To enable such a comparative analysis, we survey and implement a set of metrics and apply them to these systems. Furthermore, we conduct a listening study to measure the perceptual sound quality of the system outputs.

The core contributions of this paper are: (i) a review of currently used metrics for the evaluation of synthesis quality and a comparative analysis of 3 popular neural audio synthesizers, (ii) a listening study for assessing the perceptual audio quality of these synthesizers, and (iii) an investigation on the perceptual relevance of the objective metrics.

2. EVALUATION OF NAS SYSTEMS TODAY

Generative systems are notoriously difficult to evaluate [11] and new metrics are proposed frequently to understand whether generative networks are able to capture desirable characteristics required for a given task. In audio and music, the task of evaluation is difficult because (i) the ground truth is not well defined, as various outputs might be considered "correct," [12] (ii) the previously used set of objective metrics for NAS most likely misses or insufficiently models perceptual qualities of a sound [7, 13], (iii) and aesthetic preferences are, by definition, subjective. [14]

Some contemporary metrics for NAS derive from literature on evaluating Generative Adversarial Networks (GANs), where diversity of samples and modeling the distribution of data play a significant role [15]. Objective evaluation metrics typically rely on either mathematical formulations of a success measure, or —in the case of contemporary GAN literature— using a separate neural network to identify if the model is working appropriately. Accordingly, we categorize the metrics into the four groups (i) reconstruction metrics, (ii) sample diversity measures, (iii) distribution distance measures, (iv) and measures derived from subjective evaluation methods.

Reconstruction errors are computed as the difference between a given input sound S_i and a generated sound S_g.

The error is typically defined as either an ℓ_2 norm (squared error) or a ℓ_1 norm (absolute error). These differences can be computed on either the time-domain signal or a spectrogram. Typically, the MSE/MAE is computed on spectrograms, given their ubiquity as the input and generated representation for neural networks. MSE and MAE have a range between 0 and infinity, with a MSE/MAE of 0 indicating perfect reconstruction.

To give examples of practical use, Engel et al. use the multi-scale spectrogram loss, which compares spectrograms across a set of FFT sizes as a measure of reconstruction error and as a loss term for use in training [4]. This was recently used as a metric by Shan et al. to compare DDSP with their proposed Differential WaveTable Synthesis [16].

With respect to reconstruction metrics, there appears to be an ambiguity about the purpose of these metrics, as they seem to be used as both the training loss to be minimized and the evaluation metric itself. Also note that these errors are known to not have a clear perceptual meaning, as a high MSE between two sounds does not necessarily mean that such two sounds will be perceived as dissimilar (or vice versa). There is plenty of evidence in the field of (perceptual) audio coding verifying that measuring the power of the coding error is insufficient to capture the perceptual quality of the sound [17].

Sample diversity metrics: In GAN literature, a lot of emphasis is placed on the performance of the "generator" and to ensure that it is able to produce classifiable samples that capture the diversity of classes from the training dataset. The two metrics we will discuss in this section use machine learning and deep learning driven approaches to measure sample diversity.

- **Number of statistically Different Bins** (NDB/k) is a metric devised to identify mode collapse in GANs, a phenomena where a network produces a lot of outputs that look like alike, therefore lacking sample *diversity* [18]. NDB/k is computed on a Voronoi decomposition from the k-means centroids of the training samples. The clusters are computed directly in the sample space. [1] The k clusters are referred to as the "bins." To compute a score, test samples are assigned to the k clusters/bins using an $L2$ distance measure between the samples and the centroids of the clusters. A two-sample t-test on each bin identifies the statistically different bins. The final NDB score is given by counting the number of statistically different bins and dividing by the number of clusters.
  NDB/k scores are between the range of 0 and 1. According to the interpretation of the score provided by Richardson and Weiss [18], a score of 0 indicates that the network is producing a large diversity of samples that captures the training distribution well, whereas a score approaching 1 suggests that the generator has collapsed.
  This was used by Diffwave [9] and GANSynth [10] as part of their evaluation metrics.
  Richardson and Weiss [18] state in their definition of the metric that computing the distance for each pixel in an image using an $L2$ distance is perhaps not meaningful. As we have stated above, distances like $L2$ are not good at capturing perceptual qualities of sound, making this of particular concern when evaluating audio and the outputs of generative audio systems.
- **Inception scores (IS)** were proposed by Salimans et al. as a way to evaluate image generating GANs by using a classifier [15]. This classifier is used to automatically evaluate whether the output of a GAN was of reasonable quality and captured the *diversity* of samples in the dataset.
  The Inception classifier produces class label probabilities for a given input. Ideally, each input produces a high probability for one class label and our generative system is able to produce many of them. At the same time, the generator should be able to produce many such images, that can be classified uniquely into a large set of labels. If the difference between the probability distribution of predicted labels for the generated images and the marginal distribution of the labels from the generated data is small, it implies that the the generator is unable to produce a a diverse number of easily classifiable images. The mathematical formulation of IS can be found in [15]. The score itself has a lower bound of zero and an upper bound of infinity. The higher the score, the better.
  Within the context of audio, IS was used in evaluating WaveGAN [3], where an Inception network was trained on the SC09 dataset with spectrogram inputs. More recently, two inception scores have been proposed for NAS: the Pitch Inception Score (PIS) and the Instrument Inception Score (IIS) [8]. These measures tell us if generator has captured the true distribution of discrete MIDI pitch classes and the instrument classes in the NSynth dataset [2], and are thus focused on inherent sound properties that are not directly related to audio quality.
  Salimans et al. [15] stated that the Inception Score for an image generator was found to correlate well with human judgment of image quality [15]. However, no such work has been done in evaluating the perceptual meaningfulness of IS with audio.

Distribution distance metrics: Another important facet of evaluating GANs is identifying whether the distribution of data produced by the generator is close to the distribution of real data. Like the Inception score mentioned above, the metrics discussed here use neural networks. The difference here is that these metrics rely on using embeddings from a neural network.

As noted by Ananthabhotla et al. [13], matching distributions cannot guarantee a perceptually closer result.

- **Kernel Inception Distances (KID)** are scores that are generated by computing the distance between embeddings of input and generated data fed to inception networks. The distance is computed using Maximum Mean Discrepancy (MMD), a statistical

[1] in the case of images, the pixel distance

test that describes the difference between two distributions of data. They were first introduced in a paper by Binkowski et al. [19] where they used MMD to train a critic or discriminator and KID was shown as a metric to evaluate the convergence of the GAN. In order to compute KID, we compute a distribution of embeddings extracted from the Inception classifier for both the reference and generated output and compute the MMD between the distributions of reference and generated embeddings. The score is defined with a lower-bound of zero and an upper bound of infinity. This was used by Nistal et al. to compare input feature representations using GANs [7] and in a separate paper by Nistal et al. to measure the performance of an architecture they built called the VQCPC-GAN [8]. It was also used to evaluate DarkGAN [20].

- **Fréchet Audio Distance (FAD)** [21] is a metric originally developed to evaluate sound enhancement algorithms, but recently it has found use in evaluating NAS systems. The computation of the FAD relies on the VGGish embeddings for both the reference and the generated sounds. The VGGish embeddings are then fitted to multi-variate gaussians. The FAD itself is the Fréchet distance between the two distributions $\mathcal{N}_r$ and $\mathcal{N}_g$ representing the reference and generated gaussian distributions. The mathematical definition can be found in [21].
  This metric was used for evaluating Diffwave [9], Neural Waveshaping Synthesis [22], DarkGAN [20], and CRASH [23].

2.1 Subjective evaluation

Since the quality of the generated outputs is ultimately a perceptual property, listening studies have been previously used to evaluate a neural network's generated audio quality. A lot of listening studies use a popular method called "Mean Opinion Score" (MOS) [24]. Users participating in the listening study are asked to rate the sound they hear on a Likert scale between 1 and 5 across a set of questions. For example, WaveGAN asked participants to rate sounds on their "sound quality, ease of intelligibility, and speaker diversity" [3] where 1 indicates bad and 5 indicates excellent. These questions are asked for a collection of methods that the researcher seeks to evaluate.

The MOS survey strategy has been used for the evaluation of WaveGAN [3], Diffwave [9], and in neural speech generation literature [25, 26]. Kong et al. compared their results to WaveGAN using MOS and found that their network scored higher [9].

It should be noted that surveys that use MOS do not explicitly ask participants to compare the outputs against a reference and instead present participants with a single sound for every question. This means that MOS surveys give you an absolute rating for every sound, not a relative preference. The absence of reference precludes the ability to rank the methods that are being evaluated. For example, a person might like sound A and sound B in isolation and provide high ratings to both, however, it remains unclear whether the person has a relative preference for sound A or B.

A well known alternative to MOS surveys is to use a survey method called MUltiple Stimuli, Hidden Reference and Anchor (MUSHRA) [27] . It is an ITU recommendation for studies designed to evaluate differences in audio quality between audio codecs [28]. While it hasn't seen significant usage in evaluating NAS, it was recently used by Hayes et al. [22] in evaluating the performance of their Neural Waveshaping Synthesis (NeWT) model against the performance of DDSP. Their listening study results showed that their neural network outperformed DDSP on most instruments, with the exception of violins. This was shown to correlate well with the computed FAD scores for DDSP and NeWT.

3. EXPERIMENTAL SETUP

Aiming at our goal of comparing the output quality of popular generative systems and assessing the metrics commonly used for evaluation, we chose three neural networks and re-trained DiffWave and DDSP with the NSynth dataset and used the NSynth network directly. We report both objective metrics and subjective ratings of the outputs of these system.

We break our study into the three phases: (i) comparative analysis using objective metrics, (ii) comparative analysis using listening study results, and (iii) a brief investigation into the perceptual relevance of the objective metrics.

3.1 Dataset

The NSynth dataset is a publicly available dataset with approximately 300k sounds of 4 s length spanning acoustic and electronic timbres [2]. The sounds are all sampled at 16 kHz. It is comprised of 11 instrument families. There are ten unique "quality" descriptors that are attached to every sound in the dataset. The descriptors are timbral, for e.g "dark," "bright," "reverb," and "percussive." The NSynth dataset is frequently used in generative audio research and is therefore an obvious choice for this study.

The NSynth dataset's test set was used to generate all the samples that were used in both the listening study and to compute objective metrics.

3.2 Models

Model selection was based on the criteria of age, architecture, and public availability. There are a number of generative audio systems that have been published since 2017, but not all of them were available publicly or were difficult to train due to the lack of computational resources. Models selected were NSynth [2], DDSP [4], and DiffWave [9]. These models are widely known and represent different architectural designs.

NSynth [2] is a deep learning based generative audio system that uses a Variational Autoencoder architecture that learns to generate musical instrument timbres with the ability to be controllable. Its primary novelty is the fact that it can interpolate between multiple sounds and generate new timbres in the process. NSynth is the "oldest" of the

System	NDB/k (↓)	PKID(↓)	IKID(↓)	PIS(↑)	IIS(↑)	MSE(↓)	MAE (↓)	FAD (↓)
Diffwave	0.74	0.0093	0.0021	2.3814	**5.6477**	0.0291	0.1369	7.9488
DDSP	**0.20**	**0.0053**	0.0020	**3.3224**	5.3371	**0.0130**	**0.0666**	**1.1519**
NSynth	0.74	0.0101	0.0024	2.3238	4.6364	0.0329	0.1224	4.0590
Anchor	0.72	0.0123	**0.0006**	2.9356	5.3017	0.0257	0.0857	1.4952

Table 1. Table with objective results for each of the neural networks that we measured. ↓ indicates that a lower score is better and ↑ indicates that a higher score is considered better. Bold indicates best performance.

evaluated systems. The publicly available weights for the NSynth model were used for this study to generate the sounds.

DDSP [4] uses classical synthesis techniques like additive synthesis and noise filtering in the context of deep learning by treating them as differentiable blocks. It uses an encoder-decoder architecture that produces the fundamental frequency, loudness envelope and the necessary variables to control the additive synthesizer. DDSP is also known for it ability to perform "timbre-transfer," where it takes sounds produced from one instrument and outputs it on a different instrument. To train DDSP, we used publicly available code for training with the NSynth dataset and verified it worked by producing metrics similar to the metrics reported in the original paper.

Diffwave [9] is the most recent system that uses a new generative modeling technique called "Diffusion" on audio. Diffusion models start with white noise and through a fixed number of iterations, learn to generate audio. During training, the models use a forward and backward process, where the forward process takes the reference, corrupts it with white noise iteratively until the whole signal is noise. The backwards process learns how to iteratively remove the white noise to recover the reference. Diffwave was primarily evaluated on speech and produced results that seemed to outperform WaveGAN and Wavenet significantly.

DiffWave was trained with an implementation available online [2] . Since this algorithm was not originally trained with NSynth, we had to verify if our model worked properly. We trained the network for 2 million steps and evaluated the network's automatic metrics and found that the metrics aligned with the paper's reported results.

3.3 Objective metrics

To evaluate our neural networks, we used the set of metrics described above. As we discussed in Section 2, some of the objective metrics were designed with specific architectures like GANs in mind. However, since the metrics have found use in the evaluation of other types of architectures we chose to evaluate all of our networks with the same set of metrics.

The pre-trained pitch and instrument inception networks trained on the NSynth dataset from Nistal et al.'s paper on comparing audio representations [7] were used to compute neural network driven metrics such as as PKID and IIS and the "official" implementations of NDB/k [3] and FAD [4] were used. In order to compute NDB/k, we trained the K-means clustering on the NSynth dataset.

The rest of the metrics, like MSE and MAE were computed using SciKit-learn's built-in metrics [29]. We tried to include other metrics but could not select them due to high variance in scoring between implementations (such as PEAQ [17]).

To summarize, the following objective metrics are computed for the network outputs:

1. NDB/k, 2. PKID, 3. IKID, 4. PIS, 5. IIS, 6. MSE, 7. MAE, and 8. FAD.

3.4 Listening study

The listening study uses a variation of the aforementioned MUSHRA methodology. It is popularly used in evaluating "intermediate" differences in low bitrate audio codecs [28]. Given that we are measuring audio reconstruction, we believe that treating the neural network outputs similar to encoded audio is a suitable choice for evaluating audio quality differences. The rating scale used in the study is divided according to the MUSHRA specification. A score between 0 and 20 indicates that the sound is rated *bad*, 20 to 40 indicates that the sound is rated *poor*, 40 to 60 is considered *fair*, 60 to 80 is considered *good*, and 80 to 100 is considered *excellent*.

The 4096 sounds from the NSynth test set are reconstructed using the three generative systems. In addition, one anchor sound is generated for each test sample by low pass filtering the sound at a 1 kHz cutoff frequency and reducing its bit depth to 8 Bits.

Participants were recruited by emails sent to two large academic audio-focused communities. Participants were asked to use a good pair of headphones or speakers in order to participate in the survey. Prior to the listening study, the participants were asked to share their age bracket, experience with audio synthesis, and how much money they have spent on the audio equipment they used. This then led to a training phase where participants were presented with an example sound and necessary introduction to the survey.

When presenting the survey, a sound is randomly selected out of 3237 possible sounds with MIDI note numbers ranging from 22 to 84. [5] Five sliders are presented in random order, with three sliders referring to the generated audio output of the three neural networks to evaluate, and the other two sliders corresponding to the hidden reference and the anchor. The participants were asked to rate audio generated by each neural network on its audio quality

[2] https://github.com/lmntcom/diffwave

[3] https://github.com/eitanrich/gansngmms

[4] https://github.com/googleresearch/googleresearch/

[5] We used the note number range to remove sounds that were either inaudible or could potentially be uncomfortable to listen to.

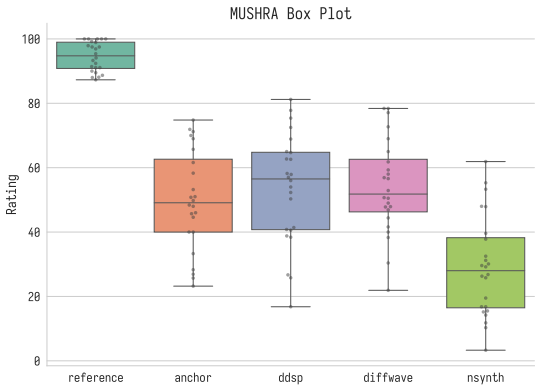

Figure 1. A boxplot of ratings from participants in the listening study. The size of the box represents the interquartile range of ratings from the listeners.

compared to the reference. This presentation is repeated ten times without collision (i.e., no two sounds are ever repeated for a participant).

To clean up the data, responses that are "incomplete" are removed entirely from data that can be used for analysis. MUSHRA analysis generally removes raters who rate the reference below a high rating threshold [30]; thus, participants who rate the reference below an average of 85 will be removed.

Statistical analysis of MUSHRA and MUSHRA-like data relies on running statistical tests such as ANOVA or Wilcoxon tests [30] to measure differences in results between the presented conditions. We will use the Wilcoxon tests for the ratings to measure statistical differences between presented conditions. The test indicates differences between the generative models. The MUSHRA results will also be broken down by demographic information collected above to measure if different demographic groupings rated the models differently.

In order to compare objective and subjective ratings, we will also compute rankings for both ratings. We are interested in knowing how frequently specific networks were considered the best and comparing it to the rankings for each metric. Rank driven correlations were used by Ycart et al. [31] in their paper validating perceptual metrics related to piano transcription.

4. RESULTS

4.1 Objective metric results

The results from the objective metrics as discussed above are shown in Table 1. Overall, these results seem to indicate that DDSP is producing higher quality samples that are more easily classifiable compared to DiffWave and NSynth.

DDSP has a 54% better PKID score over Diffwave and a 62% higher score than NSynth. This trend continues across most metrics, with the exceptions of the IIS, where Diffwave achieves a 5% higher score than DDSP, and the IKID where there is only a 4% difference between DDSP and Diffwave. The kernel distances mentioned here do not measure audio quality.

The MSE and MAE results tell us that DDSP is the "closest" to the reference sounds, with an MSE of 0.0130, a 76% and 79% improvement over Diffwave and NSynth, respectively.

DDSP significantly outperforms Diffwave and NSynth on the FrÃ©chet Audio Distance. FAD is also a category where NSynth outperforms Diffwave. This metric indicates that —according to the VGGish representation— DDSP and NSynth are generating samples that are closer to the reference than Diffwave.

Based on these metrics, we can state that DDSP outperforms Diffwave and NSynth and produces a diverse set of easily classifiable samples and produces samples that are much closer to the reference sounds.

4.2 Listening study results

Data was collected from 77 participants from our listening study. After data cleanup, a total of 24 submissions were considered trustworthy. 74% of our participants were between the age of 24 and 50, 22% of our participants between 18 and 24 and 3.7% or 1 participant over the age of 50. 37% of our participants reported that they were very familiar with music production tools and 18.5% reporting that they were extremely familiar. 29% of the participants reported that they were moderately knowledgeable about sound synthesis techniques, with an even distribution of familiarity ranging from "Not very knowledgeable" to "Extremely knowledgeable." 33% of our raters reported that they had spent over $750 on their audio equipment and 25% having spent between $250 and $500.

The overall visualization of the responses can be seen in Fig. 1. Every dot in the chart is an averaged rating from a participant. As expected, the reference scored highly with an average rating of 92. The analysis of the listening study results shows that DDSP and DiffWave scored similarly while NSynth performed considerably worse than the other networks. Both DDSP and Diffwave have average ratings around 53 while sounds generated by NSynth received an average rating of approx. 29.

The inter-rater Krippendorff α score [32] is 0.66 [6], suggesting that the subjects were largely in agreement.

The Wilcoxon test for statistical significance was applied to the data [30]. We found no statistically significant difference between DDSP/Diffwave ($p = 0.629$) and a statistically significant difference between DDSP/NSynth ($p = 8 \times 10^{-6}$) and Diffwave/NSynth ($p = 8 \times 10^{-6}$). There was a significant difference between the Reference and all the systems and the anchor ($p \leq 8 \times 10^{-6}$). There is a significant difference between Anchor/NSynth ($p = 8 \times 10^{-6}$), but no statistically significant difference between Anchor/Diffwave or Anchor/DDSP, with p-values of 0.144 and 0.4385, respectively.

Breaking down the results by the subjects' self-reported familiarity with audio synthesis technologies, we first investigate the inter-rater variation within different "expert levels."

[6] Krippendorff α ranges from -1 to 1, where -1 indicates significant disagreement between raters and 1 suggests maximal agreement

Participants who said they were the least knowledgeable had an Krippendorff α of 0.7, moderately knowledgeable raters had a Krippendorff α of 0.608 while participants who were the most knowledgeable had a Krippendorff α of 0.9. Participants who reported to be either very or extremely knowledgeable tended to rate DDSP and Diffwave lower than the overall scores (DDSP: 47, Diffwave: 43). Less knowledgeable participants tended to rate Diffwave and DDSP higher than the overall scores (DDSP: 56, Diffwave: 59). There was a statistically significant difference in how these two groups rated Diffwave ($p = 0.006$) but no statistically significant difference in how they rated DDSP, NSynth, or the reference and anchor point.

We found no statistically significant differences in ratings between the age categories or in ratings based on money spent on audio equipment.

Instrument results: To investigate whether specific instruments or instrument groups are consistently rated higher or lower than others, the listener ratings were broken down into ratings by instrument family (according to the NSynth dataset). We found no statistically significant differences in ratings between DDSP and Diffwave, but found statistically significant differences between DDSP/NSynth and Diffwave/NSynth. Additionally, there were no statistically significant differences between instrument sources and the ratings from the listeners.

The IKID metric tell us that all three networks are producing samples that are close to the reference and the IIS score tells us that Diffwave should be slightly better than DDSP and much better than NSynth. While we cannot state that this result is accurate for IKID, it is in line with the results from the IIS computation.

Comparing the listener ratings to objective metrics: In order to identify if our listening study results lined up with our objective metrics, we took the selection of sounds that were presented to participants and computed the correlation between their sample based metrics and our ratings using the Pearson correlation coefficient, which tells us how correlated two samples are from a range of -1 to 1. We have sample based results for MSE and MAE, since all the other metrics in our list rely on computing a difference across a distribution of samples. We also computed the Spearman R score and the R^2 from a linear regression between the ratings and the MSE and MAE. We found that there is no statistically significant correlation between the MSE/MAE errors and the listener ratings.

The listening responses were also ranked based on how frequently a specific network was ranked higher than the others. In the 240 responses, the listeners rated Diffwave higher than DDSP slightly more frequently (123 vs. 99). NSynth was rated the lowest most frequently (163 times). The ranking breakdown showing how frequently each of the 6 permutation of rankings between the 3 networks is shown in 2. We ran a Wilcoxon test on pairings rankings of each network by the listeners and found that the rankings were different with high statistical significance ($p < 0.05$).

When ranking the objective metrics, it is clear that DDSP is ranked the best because it has the best results in seven out of the eight metrics, with Diffwave and NSynth in second and third place. However, the rankings from our listening study tell us that the Diffwave is usually the preferred network. This tells us that the metrics are perhaps not entirely reflective of the perceptual audio quality of the networks.

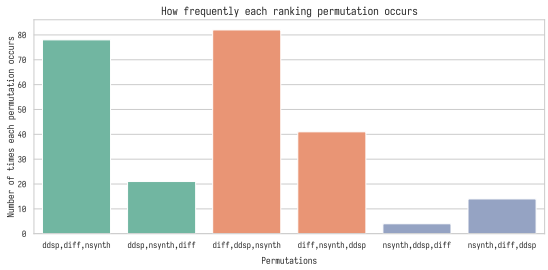

Figure 2. The plot here describes how frequently a unique permutation of rankings occurred. Diffwave is abbreivated to "diff".

5. CONCLUSION

We presented a systematic evaluation of three popular systems for neural audio synthesis, comparing them with a set of previously used objective metrics as well as a listening study. The results clearly show that (i) no previously used objective metric captures the perceptual quality of the synthesized sounds sufficiently well, (ii) any quality ranking based on these objective metrics is questionable, (iii) of the three evaluated audio generators, there is no clear listener preference between DDSP and Diffwave, but NSynth is rated lowly, and (iv) the subjects rate Nsynth worse than the 8 Bit anchor but rate DDSP and Diffwave similar to the anchor indicating that there is still considerable work to do on the quality of neural audio synthesis

These results should give pause to research in the field of neural audio synthesis. How can progress with respect to the audio quality be measured if all available metrics are unable to provide meaningful estimates of audio quality. Many of the objective metrics that we discussed in this paper were designed with the intent of measuring the performance of the sound generating component of the networks, i.e., can the generator produce (i) a diverse set of sounds, (ii) a distribution of samples that are close to the target samples in a relevant dimension, and (iii) accurate reconstructions.

Our results indicate that *measuring generator performance is insufficient to measure audio quality*. We believe that research in this space should not only include subjective results, it should also include greater efforts into critically evaluating the audio quality of network outputs with meaningful objective metrics.

In future work, we will investigate whether other objective metrics might be more meaningful than the ones evaluated here, or will start a research project on developing a more meaningful quality measure for audio synthesis.

ABSTRACT

Labeling and maintaining a commercial sound effects library is a time-consuming task exacerbated by databases that continually grow in size and undergo taxonomy updates. Moreover, sound search and taxonomy creation are complicated by non-uniform metadata, an unrelenting problem even with the introduction of a new industry standard, the Universal Category System. To address these problems and overcome dataset-dependent limitations that inhibit the successful training of deep learning models, we pursue representation learning to train generalized embeddings that can be used for a wide variety of sound effects libraries and are a taxonomy-agnostic representation of sound. We show that a task-specific but dataset-independent representation can successfully address data issues such as class imbalance, inconsistent class labels, and insufficient dataset size, outperforming established representations such as OpenL3. Detailed experimental results show the impact of metric learning approaches and different cross-dataset training methods on representational effectiveness.

1. INTRODUCTION

Sound effects libraries are collections of prerecorded audio assets curated and meant for use by sound designers and editors. In application, a user will search for sounds necessary for their project by querying the library with a computer or other commercial tools for sound search, which helps organize sounds or allow for varying modes of querying the database [1–4]. Examples of typical classes include *ambience*, *foley*, and *sci-fi*. Libraries are often used in game audio and audio post-production applications because access to raw audio assets facilitates efficiency in the creative process, accommodates lacking resources for recording equipment, and alleviates barriers to inconvenient recording locations necessary for particular sounds.

We identify two main problems with sound effects libraries in our work. First, interviews with dataset providers for this research revealed that too much time is spent labeling, re-labeling, and performing quality assurance on databases that continually grow in size and undergo taxonomy updates. One potential solution to this could be the application of machine learning and, more specifically, deep learning for automating sound classification. However, such machine learning models face several particular task-related challenges, such as (i) the size of available datasets can dramatically vary in terms of audio data and number of classes, (ii) data class distributions are often highly imbalanced, (iii) data labels are sometimes of poor quality or inconsistent, and (iv) training dedicated models on every existing sound effects library can be time-consuming.

Second, non-uniform metadata in sound effects libraries complicate the successful sound search for a user and the creation of a useful taxonomy for a vendor. The recent introduction of the Universal Category System (UCS) [1] attempts to address this problem. UCS is an industry-proposed solution to standardize taxonomies designed by and for sound designers and editors. It is designed to be complete and sufficient for sound effects library categorization. However, adopting this standard has been slow; while several sound effects libraries have already converted to this new industry standard, others continue using their own proprietary taxonomies for convenience or preference.

We address problems that arise when using a machine learning approach, training generalized embeddings that can represent any sound effects library and work on any taxonomy for sound classification. To build a powerful learned representation, we investigate two main methods for representation learning with a (i) metric-learning and (ii) cross-dataset training approach.

Our work has the following main contributions:

- the introduction of a powerful new representation for use in sound effects libraries trained on relevant, commercially available data,
- the investigation of UCS' generalizability (the industry's first approach to unifying metadata), and
- the presentation of extensive results emphasizing the positive impact of cross-dataset training, an underresearched aspect of representation learning.

The remainder is structured as follows. In Sect. 6.2, we analyze if metric learning models will learn a better-structured embedding space and produce higher classification results than a Cross-Entropy (CE) model. In Sect. 6.3, we see if a cross-dataset training scenario will outperform

all other training scenarios and discuss novel UCS-specific findings. In Sect. 6.4, we evaluate the impact of 3 different cross-dataset training methods. See Sect. 5.3.1 for data mixing methods, which explores accommodating for encoder bias with data training order, Sect. 5.3.2, which investigates accommodating for various dataset characteristics by 'Focal' dataset regularization, and Sect. 5.3.3, which experiments with using dataset-independent BatchNorm layers. We compare our best representations against OpenL3 State-of-The-Art (SoTA) deep audio embeddings in Sect. 6.5.

2. RELATED WORK

We present an in-depth literature review regarding sound effects libraries and two aspects of representation learning.

2.1 Sound Effects Libraries

While there is a plethora of work on sound event classification, there is little work that conducts extensive research for a sound effects library application. Peeters and Reiss conducted sound effects classification by focusing on the discrimination between two classes, ambience and sound effects; audio features were manually selected [5]. Audio tagging work has been done on Freesound [6], the BBC sound effects library [7], and other online collaborative sound collections [8, 9]. Some have designed features and taxonomies to improve sound classification. Moffat et al. tried to address the issue of a non-unified metadata labeling scheme with the Adobe Sound Effects Library. [2] They created a hierarchical taxonomy for sound effects based on the unsupervised learning of sonic attributes, using decision trees to assess audio and label semantic similarity [10]. Others that do not target a specific sound effects library application have experimented with psychoacoustic approaches to feature design using actions, material, and mood [3, 11–14]. Meanwhile, the rest of the work regarding sound effects libraries does not focus on classification but explores sound search, query, and retrieval. Pearce et al. investigated user search queries on Freesound [15], reducing these descriptors into timbral features to aid sound search [16]. Lafay et al. and Zhang et al. researched methods to effectively query databases without keywords or by vocal imitation [2, 4]. Yang et al. recently presented a new system for indexing sound effects libraries, evaluating their work on users [1].

2.2 Representation Learning

Representation learning aims to learn a highly discriminative embedding space that can generalize to various downstream tasks. Two examples of powerful deep audio embeddings are VGGish and OpenL3 [17–19], which have proven to be useful for many music information retrieval (MIR) and cross-modal tasks, e.g., classification, tagging, few-shot learning, and continual learning [20–23].

2.2.1 Metric Learning

A popular method for representation learning is metric learning, where methods include the Contrastive, Triplet, and Circle loss. Contrastive loss minimizes the distance between similar classes' feature vectors and maximizes the similarity between different classes' feature vectors, training on pairs of positive or negative input samples [24–26]. Triplet loss optimizes both positive and negative inputs simultaneously and adds an additional anchor input in its loss computation [27–29]. Circle loss tries to improve upon the Triplet loss, featuring more flexible optimization, more definite convergence, and tries to unify the goals of a metric learning and classification loss into one [30]. Although metric learning losses can be used in a self-supervised [25, 31–34] or un-supervised [24] manner, it is common to combine a metric learning loss with a classification loss to better fit a supervised learning problem. Khosla et al. have explored training methods to regularize and better structure the embedding space, introducing a Two-Step and Joint-Training method [26]. Furthermore, other works have explored the adoption of a contrastive approach to regression [35].

2.2.2 Cross-Dataset Training

Furthermore, training on large amounts of diverse data is a crucial aspect of representation learning [17–19]. This can be addressed with cross-dataset training; we note many similarities between cross-dataset training and multi-task learning. Though there are scattered works amongst various fields in the deep learning literature that combine multiple different datasets for training, only a few papers have explored proposing methodologies for this. Namely, most work has only been explored in the computer vision domain; there is little work in audio. Working on symbolic music generation, Dong et al. found that stratified sampling mixing alleviated the source imbalance problems that come with combining datasets of various sizes; this worked better than simply concatenating datasets for training [36]. Ranftl et al. explored a multi-task learning setup with Pareto-optimal mixing and a multi-objective loss, evaluating success in a zero-shot scenario for a monocular depth estimation task. Their multi-task learning setup and mixing strategy, which ensures that decreasing the loss on one dataset necessitates increasing the loss on another, produced results superior to a naive mixing strategy where they trained on minibatches of equally sampled datasets. They found that this method was better at leveraging the act of adding more datasets for training [37]. Wan et al. introduced a MultiReader method for a speaker verification task to support training with datasets of different keywords and languages. They regularized the datasets to address insufficient and imbalanced dataset sizes but only experimented with two heterogeneous data sources. Moreover, they do not explicitly illustrate a method of reweighing datasets, resorting to hyperparameter tuning [38]. Lastly, Wang et al. introduced a Dataset-Aware Block, which uses dataset-invariant convolutional layers and dataset-specific BatchNorm layers. They concluded that preserving heterogenous dataset characteristics improves performance [39]. To the best of our knowledge, cross-dataset training has not been explored extensively in audio-related tasks.

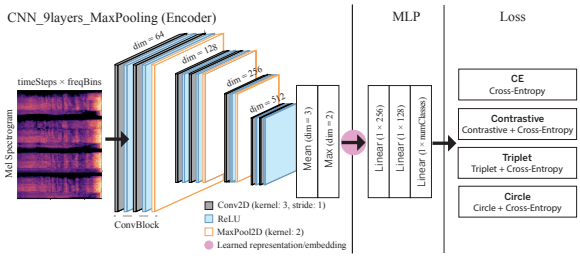

Figure 1. Network architecture: CNN9-max encoder, MLP classifier head, and loss functions.

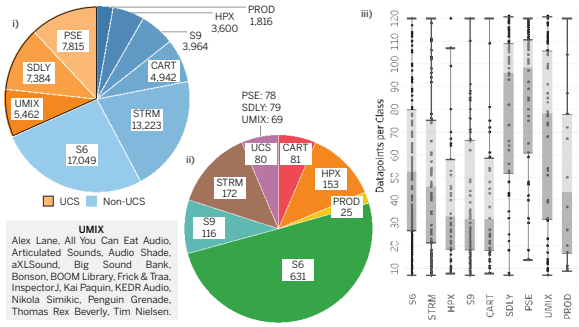

Figure 2. Imbalanced UCS & Non-UCS dataset statistics, (i) Number of audio-files per training dataset, (ii) Number of classes per taxonomy, (iii) Class distribution sorted from most to least classes among training datasets.

3. METHOD

Our best pre-trained model is freely available online. [3]

3.1 Model Architecture

Our encoder architecture adapts the Convolutional Neural Network CNN9-max architecture from a DCASE 2019 baseline system for multi-class classification and is displayed in Fig. 1 [40]. We pre-train the encoder with one Multi-Layer Perceptron (MLP) classifier head per dataset. After training, we freeze the encoder and pass the representations to a simple Nearest Neighbor classifier to train and test the learned embedding space. Models were trained with Python, PyTorch, and the PyTorch metric learning library. [4]

3.2 Input Representation

All audio files were re-sampled to 44.1 kHz, down-mixed, and normalized. Mel-spectrograms were computed with a block size of 46 ms, hop size of 23 ms, 96 Mel-Bins, and span the audible frequency range [41]. We used min-max normalization for spectrograms and z-score standardization for extracted embeddings. Spectrogram input dimensions to the network are (100, 96) and span approximately 2 s of audio. This length was determined in pilot experiments.

3.3 Training Procedure

We trained all models with a batch size of 64, the Adam optimizer, and early stopping. Model checkpoints used for inference correspond to the best validation loss. For cross-dataset training, we save the best average validation loss from all datasets. Hyper-parameters for pre-training were found via 20 trials of random search. During pre-training, 2 s frames of audio files are randomly sampled whenever a batch is retrieved. We re-shuffle the dataset per epoch. We compute embeddings with 50% overlap at inference time.

3.4 Evaluation Metrics

The macro F-1 score over classes in a dataset is our predominant metric for evaluating classification performance, as all datasets have imbalanced class distributions. We also monitor the Davies-Bouldin Index (DBI) to evaluate the quality of the embedding space structure, i.e., clustering. The DBI measures the average similarity between a cluster and its most similar cluster.

[4] kevinmusgrave.github.io/pytorch-metric-learning, last accessed May 10, 2022.

4. DATASETS & TAXONOMIES

We address our goal of training generalized embeddings by training and testing with 9 datasets and 7 taxonomies. We emphasize that we use a diverse assortment of datasets for this research and present corresponding data statistics in Fig. 2. We use 3 UCS-compliant datasets: Pro Sound Effects (*PSE*), Soundly (*SDLY*), UCS Mixed (*UMIX*), and 6 Non-UCS datasets from the Sound Ideas library: Cartoon Express (*CART*), HPX Digital (*HPX*), Production Elements (*PROD*), Series 6000 (*S6*), Series 9000 (*S9*), Soundstorm (*STRM*). For UCS-compliant datasets, we use UCSv8.1 *Category* labels as ground truth.

Preliminary experiments with UCS lead us to use experimental subsets of 150 or fewer datapoints per class. We pre-train and evaluate embeddings on the full imbalanced subsets (65k audio files) except in *Cross-Dataset* training scenarios, where we use class-balanced versions for Non-UCS data. A stratified train validation test split of 8:1:1 was conducted. For UCS-compliant datasets, the fine *CatID* labels determined stratification.

We select *PSE* as the base dataset for *UCS-Transfer* experiments because of its larger number of datapoints and classes, cleaner labels compared to Non-UCS datasets, better generalization when evaluated against other UCS datasets, and more even distribution among both levels of the UCS 2-level class hierarchy.

5. EXPERIMENTAL SETUP

We list our research questions and hypotheses below using the following experimental variables:

- *Metric learning loss functions (Fig. 1, Sect. 5.1)*,
- *Variable training scenarios (Sect. 5.2)*, and
- *Cross-dataset training methods* (Sect. 5.3).

5.1 RQ1: Impact of Metric Learning

We first ask whether metric learning loss functions that learn distances instead of absolute class labels will improve

classification results. We hypothesize that metric learning approaches will learn a more discriminative embedding space compared to CE models and that this better-structured embedding space will improve classification results.

5.1.1 Training Parameterization

We train all metric learning models with Khosla's Joint-Training scheme that optimizes a hybrid sum of a metric learning loss function and Cross-Entropy loss as it has been shown to be more effective than a Two-Step training method [26, 33, 35, 42, 43]. Fig. 1 illustrates our experiments with the joint metric learning losses (i) Contrastive, (ii) Triplet, and (iii) Circle.

The metric learning losses optimize cosine similarity. Positive and negative samples are computed from all possible pairs or triplets between samples in a batch. Accordingly, we find that our batch size is sufficient for training from initial experiments. Model training utilized online mining and the *regularface* embedding regularizer [44].

In addition to re-shuffling the dataset per epoch and randomly selecting 2 s frames, we re-sample the dataset so that it randomly selects new datapoints per class per epoch. Here, we equally sample 4 datapoints per class so that a single batch includes 16 different classes; we found minimal difference from weighted sampling.

5.2 RQ2: Impact of Cross-Dataset Training

Secondly, we ask whether cross-dataset training will improve our best Cross-Entropy and metric learning results in all training scenarios. We hypothesize that a *Cross-Dataset* training scenario will outperform all others, including *UCS-Transfer* (see definition below), improving upon both UCS & Non-UCS dataset results. Our rationale is that representations generated from *Cross-Dataset* models will have seen a more significant quantity and variety of data from different sound taxonomies, producing more generalized representations. Moreover, we hypothesize that *UCS-Transfer* will yield decent classification results as UCS is a standardized taxonomy for sound effects libraries. We denote *Cross-Dataset* models with the prefix, *X*.

5.2.1 Training Scenario Definitions

We conduct experiments with 3 training scenarios: (i) *Within-Dataset* training: Pre-train and evaluate the encoder on the same dataset, (ii) *UCS-Transfer*: Pre-train the encoder on a UCS-compliant dataset and evaluate on other datasets in a transfer learning scenario, and (iii) *Cross-Dataset* training: Pre-train the encoder on all datasets and taxonomies, evaluate the encoder on any dataset.

5.3 RQ3: Impact of Cross-Dataset Training Methods

Datasets used for training may have varying characteristics. For example, they may use taxonomies of dissimilar scopes and biases and have different dataset sizes, all of which an effective classifier must adapt to. Our final question is whether training scenarios accommodating dataset characteristics will improve classification results. We experiment with 3 methods as introduced in the following subsections, (i) Data mixing (*X-Sequential*, *X-Joint*), (ii) 'Focal' dataset regularization (*FDR*), and (iii) Dataset-independent BatchNorm layers (*BN*).

5.3.1 Data Mixing

We use two variations of data mixing. *Sequential* trains on all datapoints from a single dataset before training on the next, i.e., concatenate datasets, while *Joint* trains on datapoints from all datasets in mixed order, similar to stratified sampling in the literature [36]. We limit mixing for *Joint* so that all datapoints in a batch must correspond to the same dataset. We affirm that backpropagation is called per batch.

5.3.2 'Focal' Dataset Regularization

We regularize the datasets by 'difficulty' and reweigh them by a dataset's training convergence speed in epochs. Inspired by Focal Loss [38, 45, 46] and mining for hard pairs or triplets in metric learning [29, 47–49], easier datasets are down-weighted so that training focuses on difficult datasets.

$$\alpha_d = \frac{1 - \beta^{n_e}}{1 - \beta} \tag{1}$$

We modify the reweighting function shown in Eqn. 1 to re-balance the datasets and initialize these weights with n_e, the epoch at which a dataset's training set macro F-1 score crosses a threshold of 90% [50]. These weights may be adjusted with hyperparameter β to reduce or heighten the difference between dataset weights. a_d is the unnormalized reweighing factor per dataset, d. As previously done in the literature, we normalize α_d so that $\sum_{d=1}^{D} \alpha_d = D$, keeping the loss in roughly the same range. D represents the total number of datasets used for pre-training [45, 50].

5.3.3 Dataset-Independent BatchNorm Layers

Similar to selecting the correct classifier head per dataset when pre-training the encoder, we select a dataset's corresponding BatchNorm layers. This is equivalent to turning each ConvBlock in Fig. 1 into a Dataset-Aware Block [39].

5.4 RQ4: Comparison to SoTA

We select OpenL3 features as our reference to SoTA deep audio embeddings because L^3-Net is said to "consistently outperform VGGish and SoundNet on environmental sound classification" [18]. We use the default OpenL3 parameters as they yield the highest frame-level classification results and select the *Music* content type embeddings for comparison (6144 dimensionality, 0.1 s hop size, and 256 Mel Bins) [18]. We aggregate these features to represent 2 s of an audio file for consistency with our input representation.

6. RESULTS

All results are computed at the frame-level, i.e., aggregated over each 2 s frame extracted from audio files in the hold-out test set. Boxplot datapoints indicate results for a single dataset. Metric learning plots, Fig. 4 and 5, only show *X-Sequential* results for the *Cross-Dataset* training scenario.

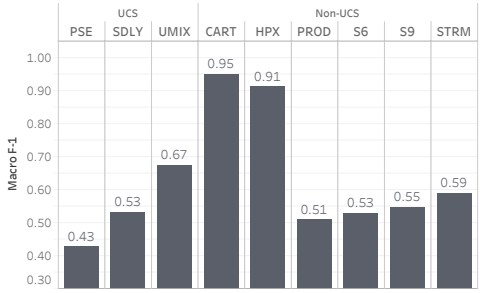

Figure 3. Baseline macro F-1 score classification results using Cross-Entropy loss, CE (*Within-Dataset*).

6.1 Baseline Results

Fig. 3 displays baseline classification results where each model is trained and tested on only one dataset, itself. Plots for the following experiments only show the change from this baseline plot.

6.2 RQ1: Impact of Metric Learning

Fig. 4 shows how metric learning models improve upon the baseline's embedding space structure to different degrees. A lower DBI indicates a better embedding space structure. Contrastive improves the space for most datasets in all training scenarios. Triplet results in a slightly higher average DBI in all but the *UCS-Transfer* training scenario. Circle performs significantly better in a *Within-Dataset* training scenario with an average DBI decrease of 0.43. However, it performs surprisingly poorly in *UCS-Transfer* & *Cross-Dataset*, suggesting that it is not ideal for generalization, a prime motivator of representation learning.

Contrary to our hypothesis, a better-structured embedding space (lower DBI) does not always improve classification results (higher macro F-1), shown in Fig. 5. We only see that metric learning models improve classification results in the *UCS-Transfer* training scenario. We specifically note that Circle significantly improves the embedding space structure compared to Contrastive in *Within-Dataset*. However, both embedding spaces still yield similar classification performance, an average of -1.75% and -1.50% from CE, respectively. We note other work by Lee et al. regarding the similarities between metric learning and classification [51].

Focusing on classification results, we identify Triplet as our 'best' metric learning loss with a slightly higher average performance than Contrastive. Triplet performs on par with CE in *Within-Dataset* and *Cross-Dataset* (less than 1% difference on average), and has an average of 4.25% improvement from CE in *UCS-Transfer*. Therefore, Contrastive and Circle loss results will be omitted in the following sections.

6.3 RQ2: Impact of Cross-Dataset Training

Results for cross-dataset training are shown in Fig. 6. Matching our hypothesis, we find that for CE models, *Cross-Dataset* outperforms *Within-Dataset* models for the majority of datasets by approximately 4-5%. We find that Triplet models also tend to improve by 1-3% except for *X-Joint-BN + Triplet*. This confirms that cross-dataset training indeed leads to better generalization across all sound taxonomies.

6.3.1 UCS Insights

We preface this section with preliminary results on UCS. We find that the UCS-compliant datasets in this study use the standardized UCS taxonomy in a non-uniform way. Without fine-tuning another classifier head, one cannot use a UCS taxonomy-trained model on other UCS-compliant datasets. This corroborates the need for generalized representations that can adapt to any taxonomy of sound.

With this said, Fig. 6 also shows that *UCS-Transfer* can achieve results considerably better than random. Although it under-performs *Within-Dataset* training by an average of 7.48% with CE models, we find that there is only an average of -1.62% difference from CE with Triplet models. Alongside, we also verify that other UCS-compliant libraries, *SDLY* and *UMIX*, can be used as base sets to achieve decent generalization in a transfer learning scenario.

We note some dataset-specific details for *UCS-Transfer + Triplet* compared to our best *Cross-Dataset* Triplet model, *X-Joint + Triplet*. Both perform similarly (around 1% worse) on Non-UCS *CART, HPX, PROD*, and *STRM* datasets. *UCS-Transfer* performs around 5-6% worse on UCS-compliant *SDLY* and *UMIX*, a substantial improvement from previous results that did not re-train a classifier head. Lastly, it performs around 7% worse on Non-UCS *S6*, likely because *S6* exhibits the highest number of classes amongst all datasets while *PSE* only has 78 classes.

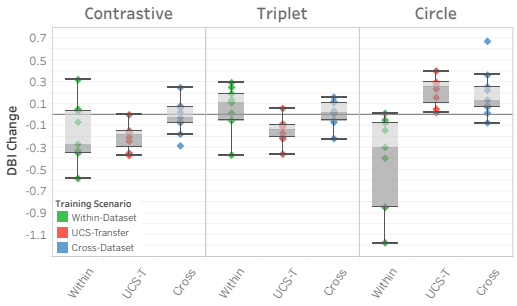

Figure 4. DBI change of metric learning models relative to CE in different training scenarios.

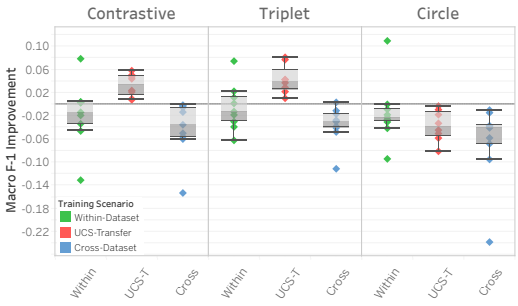

Figure 5. Macro F-1 score improvement of metric learning models relative to CE in different training scenarios.

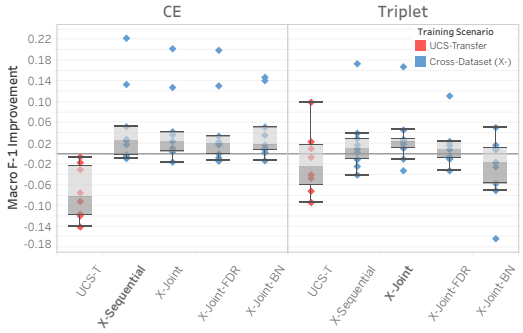

Figure 6. Macro F-1 score improvement of various training scenarios from *Within-Dataset*.

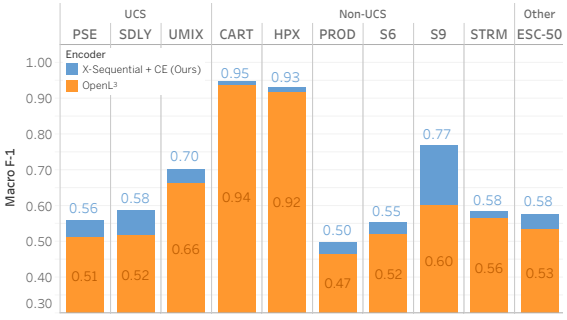

Figure 7. Our best model compared to OpenL3 audio embeddings. Blue bars illustrate the amount in which we outperform OpenL3.

6.4 RQ3: Impact of Cross-Dataset Training Methods

We experiment to see if accommodating different dataset characteristics with 3 cross-dataset training methods will further improve results. We compare all cross-dataset training methods to *X-Sequential* in our discussion.

First, sensitivity to encoder bias and training order does not severely impact results for our task. Data mixing results note an average 1% difference between *X-Sequential* and *X-Joint* in CE and Triplet.

Second, reweighing datasets as proposed in Sect. 5.3.2 does not lead to observable consistent trends. We show results that use $\beta = 0.999$. Looking at difficult datasets, the performance of *SDLY* worsens by 2.96%, while *STRM* improves by 3.27% despite having similar convergence speeds and being the second-ranked most 'difficult' datasets. We also observe an unfortunate worsening of results for faster-converging datasets, i.e., *HPX* decreases by 1.77% (Triplet), *S9* decreases by 2.32% (CE) and 6.20% (Triplet).

Third, we verify that independent BatchNorm layers do preserve dataset-specific characteristics. Unlike other work in the literature [39], we find that this may not always be beneficial as it may exacerbate dataset-specific problems. Shown in Fig. 6, we specifically note decreases in performance for Non-UCS *HPX, PROD, S6*, and *S9*, which we attribute to messier inconsistent labels and insufficient training data, apparent in Fig. 2. This decrease can be quite dramatic with *S9* dropping by 7.53% (CE) and 24.4% (Triplet). Alongside, we find that UCS-compliant *PSE* and *SDLY*, as well as Non-UCS *STRM* experience a 2-3$\%$ increase in performance, which we attribute to both the cleaner UCS taxonomy and datasets having sufficient training data.

6.5 RQ4: Comparison to SoTA

Overall, our work reveals that our best model is *X-Sequential + CE*. We compare *X-Sequential + CE* and OpenL3 in Fig. 7 and provide a commonly used benchmark dataset, ESC-50 [52], to extend the assessment of our work in a non-task-specific audio application. Unlike the rest of our datasets, we show the 5-fold cross-validation results for ESC-50 as commonly reported in the literature. Ultimately, we observe that our best model outperforms OpenL3 on all datasets. In addition, we note that our model requires fewer resources to achieve its results. While both models have a similar number of parameters (4.7M), our best model is trained on approximately 7x less data (39k audio-files vs. 296k videos) [18].

7. CONCLUSION

We introduce a new pre-trained representation for automatic sound effects library classification. Our task-specific representation outperforms OpenL3 on both UCS & Non-UCS taxonomies across diverse datasets. Moreover, we show the effectiveness of cross-dataset training with Cross-Entropy loss over metric learning for this task. Results suggest that the quality and diversity of datasets are key to pre-training robust representations, supportive of preliminary experimental results where pre-training on increasing quantities of similar data yielded improvements with diminishing returns. Our contributions include that we are the first to conduct extensive deep learning experiments on UCS, experiment on relevant data for a current problem, and investigate an under-researched aspect of representation learning with cross-dataset training in the audio domain.

We believe cross-dataset training is a prerequisite for future work. Our current research does not leverage all datasets available to us nor the abundance of taxonomies they are comprised of given that many datasets did not have sufficient labels for training. To leverage these resources, methods to effectively work with large amounts of diverse data become increasingly essential. Selecting optimal cross-dataset training methods is fundamental before introducing new techniques, such as semi-supervised or self-supervised learning to work with datasets of varying label quality [53,54]. Accordingly, we would like to (i) look into the connection between multi-task learning and cross-dataset training to understand the specific advantages and drawbacks of these approaches and (ii) conduct experiments to assess the impact of increasing the amount of training data, observing the relationship of this with more complex network architectures and other pre-training methods [55]. Finally, we hope to deepen our understanding of UCS by investigating the non-uniformity of class labels between UCS-compliant datasets in this study, looking at the interpretability and disentanglement of our representations [51], and exploring the concept of a generalized embedding from the perspective of taxonomy conversion [56].

ABSTRACT

Current approaches for explaining deep learning systems applied to musical data provide results in a low-level feature space, e.g., by highlighting potentially relevant time-frequency bins in a spectrogram or time-pitch bins in a piano roll. This can be difficult to understand, particularly for musicologists without technical knowledge. To address this issue, we focus on more human-friendly explanations based on high-level musical concepts. Our research targets trained systems (post-hoc explanations) and explores two approaches: a supervised one, where the user can define a musical concept and test if it is relevant to the system; and an unsupervised one, where musical excerpts containing relevant concepts are automatically selected and given to the user for interpretation. We demonstrate both techniques on an existing symbolic composer classification system, showcase their potential, and highlight their intrinsic limitations.

1. INTRODUCTION

The mass adoption of deep learning methods in recent years has increased interest in the field of *explainability*, [1] i.e., the study of techniques that generate a human-understandable explanation of a model's decision [1]. As deep learning models are usually not intrinsically interpretable, techniques that can be applied to trained models (i.e., *post-hoc* methods) are of great interest. The resulting explanations cannot only reveal potential issues of the system itself and the data it uses, but can also provide insights into the problem we are targeting, thus helping us to gain knowledge about it [2].

Higher-level musical tasks such as chord transcription or composer classification may require explanations that can only be understood by persons with advanced musical expertise. However, the explanation techniques for musical systems that have been proposed in recent years [3–7] are *feature-based*, i.e., the explanation is given in terms of the input features the system considers. Typical input features for musical systems, e.g., spectrograms or piano roll representations, are high-dimensional, and, since the importance of a single time frequency / pitch bin does not convey much meaningful interpretation, feature-based explanations can be hard to understand. [2] Musicologists are therefore often unable to analyse the results of trained systems, let alone contribute to the development of new learning models. This motivates research on techniques that provide explanations that are as similar as possible to those that a human music domain expert would naturally use.

Concept-based explanations offer an interesting direction. They were first explored by Kim et al. [12] and later developed in several works (e.g., by Chen et al. [13]) for image systems, which also use high-dimensional input features. Instead of producing feature-level descriptors, the explanation is based on human-understandable concepts. For example, [12] tests whether the concept of "stripes" would increase the probability that an image classifier labels an image as "zebra". Music can also be described with *musical concepts*; terms such as "diatonic sequence", "alberti bass", "difficult-to-play music", "orchestral music", "rubato", "shuffle drum beat", "funky bass line", etc. are used to describe pieces or specific elements in a piece.

In this paper, we explore two concept-based techniques to explain deep learning systems that deal with musical data: one supervised and one unsupervised. The first (see Section 4) is based on Testing with Concept Activation Vectors (TCAV) [12]: the user defines a concept by providing examples and interrogates the system to find out if the concept is relevant or not for its decision. This can be applied to any kind of neural network and, even more generally, to any system that has a hidden layer for which we can compute directional derivatives. The second technique, described in Section 5, is an adaptation of [14] and works in an unsupervised fashion, where the most relevant concepts are automatically produced and given to the user for interpretation. Each concept is presented in the form of a set of musical excerpts. This approach requires networks whose hidden layers contain only non-negative values and

Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

[2] Moreover, their truthfulness has recently been debated [8–11].

have a spatial correlation with the input data, two conditions that are satisfied by most Convolutional Neural Networks (CNNs).

Our contributions are: the first application of concept-based post-hoc approaches to musical data, in particular, we target the composer classification system of Kim et al. [15] that uses piano roll representations of piano MIDI files as input; the definition and creation of musical concept datasets; a dedicated visualisation of unsupervised concepts for symbolic music data; and, finally, the exploration of the Non-negative Tucker Decomposition (NTD) for the factorisation of hidden layers. Our code and data are available on Github. [3]

2. RELATED WORK

Recent work in the field of Music Information Retrieval (MIR) that focus on explainability for deep models consists mainly of feature-based post hoc methods (e.g., [3–5, 7]). Chowdhury et al. introduce pre-defined "mid-level features" that could be considered concepts as intermediate targets in a two-level prediction model [16]. Related to this, approaches that consider instrinsic as opposed to post-hoc methods gain increasing attention in the audio domain as well (e.g., [17–19]). However, no prior studies have examined post-hoc concept-based explainability techniques on systems that work with musical data. To provide a technical context for our work, we focus on related approaches that work on audio or image data.

A recent approach [20] applies concept-based techniques to multimodal data (video, audio, and text) to explain an emotion classifier for video sequences of human conversations. For the audio signal, they only test the concept of "voice pitch", i.e., the averaged fundamental frequency of the speaker's voice. In another related study, Parekh et al. [21] learn a codebook of sounds (e.g., alarm sound) from input audio through Non-negative Matrix Factorisation (NMF), which is then used to obtain hidden network layer representations that indicate time activations of these pre-learnt components. This has some similarities with our unsupervised approach, as we also make use of non-negative factorisation techniques to disentangle concepts. However, while [21] performs the factorisation on the input and propagates the results to a hidden layer, we factorise the hidden layer activations and project the results back to the input data. The approach of [21] is promising if we assume that the underlying reason for a system decision can be extracted directly from the input with unsupervised separation approaches. However, since this might not always be the case, we factorise the layer activations to exploit the non-linear feature extraction a network does internally to obtain more meaningful explanations.

Our work uses techniques and results originally proposed for the image domain. The work of Kim et al. [12] provides the basis for the supervised explanation, although the creation of concept data sets is more challenging for music. We base the unsupervised explanation on the work of Zhang et al. [14], but propose a dedicated visualisation of piece excerpts and test different solutions for the tensor factorisation step by employing the NTD.

3. EXPERIMENTAL SETUP

This section details the type of data and the system that we use to demonstrate our explainability techniques.

Data: We use MIDI representations of piano performances from the MAESTRO v2.0.0 dataset [22]. As proposed by Kim et al. [15], we pre-select data by composers with at least 16 pieces and remove files with more than one composer (e.g., Schubert/Liszt, "Der Mueller und der Bach"), so that pieces of 13 different composers remain (see Table 1). We randomly split the resulting 667 pieces in a training (462 pieces) and validation (205 pieces) set. For each piece, we sample 90 excerpts of 20 seconds randomly across time and different performances of the same piece (if available).

Composer Classifier: In this work, we investigate the composer classification system proposed by Kim et al. [15]. For more recent systems, the code was not available [23] or we were unable to reproduce their results [24]. During preprocessing, we transform MIDI excerpts into piano roll representations with a 50 ms time step, i.e., a matrix 88×400, which is used as input to a ResNet-50 [25]. Kim et al. [15] use an additional channel with onset information, which we omit because it does not improve the performance of our system. As proposed by [15], we train the network with Stochastic Gradient Descent with momentum (factor 0.9), L2 weight regularisation (factor 0.0001), and cross-entropy loss function. The initial learning rate is set to 0.01, and scheduled with cosine annealing [26]. Our attempt to retrain the system results in a F1 score of 0.93 compared to 0.83 in the original work [15]. The accuracy of our system is 0.93. The difference in performance could be attributed to a problem during preprocessing in the original code, which reduced the resolution of the piano roll.

4. SUPERVISED CONCEPT-BASED EXPLANATIONS

In this section, we use TCAV [12] to build a supervised concept-based explainer. We manually define musical concepts and interrogate a music classifier to find out how much a concept influences the results of the classifier.

4.1 Musical Concepts

Musical concepts describe the characteristics of a certain group of notes and are identified by musicologists with a specific name or with a small sentence (e.g., "staccato", "rubato", "melody with jumps", etc.). To define a musical concept in a way that can be used within our system, we construct *concept datasets*, i.e., sets of pieces that have one specific musical concept in common. In this paper, we build three different concept datasets, each consisting of 30 musical excerpts of ~25 seconds. Ideally, the bigger and more diverse the concept datasets is, the lower is the probability that it will also represent other unwanted concepts.

The first dataset describes the *"alberti bass"*: an accompaniment pattern first used during the classical period, where notes of chords are horizontally distributed in the left hand part [27]. For this dataset a semi-professional pianist composed ~25 second excerpts that contain this pattern, while trying to vary as much as possible other musical elements (e.g., key, tempo, content of the right hand).

The second concept is *"difficult-to-play music"*. A dataset of difficult musical excerpts was collected using the ranking produced by the musical score publisher G. Henle. [4] Excerpts were sampled from difficult pieces available in the MAESTRO dataset among different composers to avoid introducing biases toward some of them.

The third concept is *"contrapuntal texture"*, which denotes piano pieces composed of multiple monophonic voices that behave as separate instruments. This style is mostly present in pieces by some Baroque composers (e.g., Bach, Telemann, Händel, Buxtehude). For this dataset, we sampled Bach fugue performances, ensuring that they were not used during training the targeted composer classifier.

In addition to these three concept datasets, in this paper we use a collection of 10 different *random datasets*, which are built by randomly sampling 20 second excerpts from the MAESTRO dataset.

4.2 CAVs and Conceptual Sensitivity

A *Concept Activation Vector (CAV)* [12] $\mathbf{v}_l^k$ represents a concept k in the output space of a neural network layer l. To compute it, we need the corresponding concept dataset (containing e.g., pieces with alberti bass) and a random dataset [12]. For a specific network layer l, we compute the layer activations (i.e., the output of the layer) for every piano roll $\mathbf{x}$ in the concept dataset, as well as the random dataset (see Figure 1). These activations can be seen as points in a $(H \times W \times C)$-dimensional space, where H, W, C are the horizontal, vertical, and channel size in the layer activations tensor. We train a binary linear classifier (e.g., Support Vector Machine (SVM) or logistic regression) that separates the layer activations of the concept pieces from those of the random pieces. The vector of coefficients of this binary classifier, i.e., the vector orthogonal to the classification boundary, is the CAV $\mathbf{v}_l^k$ [12].

To measure whether a concept k is relevant for a piece being classified as a certain composer o, we use the *conceptual sensitivity* $S_{k,o,l}$ of the system [12], i.e., the directional derivative of the prediction in the direction of the CAV,

$$S_{k,o,l} = \nabla g_{l,o}(f_l(\mathbf{x})) \cdot \mathbf{v}_l^k. \quad (1)$$

Here, $g_{l,o}$ transforms the activation vector $f_l(\mathbf{x})$ to the logit for the output class o, that is, it represents the remaining computations after a layer l up to the output of the system. Intuitively, S is a scalar that measures how much the output logits change if we perturb the layer activations in the direction of the CAV. Positive values mean that a concept k encourages the classification of $\mathbf{x}$ as class o.

[4] https://www.henle.de/us/about-us/levels-of-difficulty-piano/

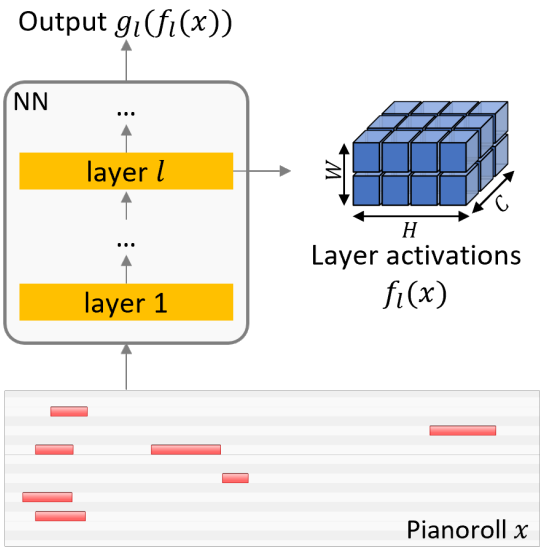

Figure 1. Layer l activations for one piece excerpt. H, W and C are the horizontal, vertical, and channel size. The function encoded by the neural network is represented in two parts: f_l from the NN input to the layer output, and g_l from the layer output to the NN output.

The conceptual sensitivity is a local explanation, i.e., it explains how a system behaves for a specific input. We produce a global explanation, the TCAV score, that no longer depends on a specific input, by taking multiple pieces that belong to one class and computing the ratio of pieces for which S is positive [12].

4.3 Experiments and Results

To investigate TCAV, we first compute a CAV for every one of our proposed concepts "alberti bass", "difficult-to-play music", and "contrapuntal texture". [5] As a linear classifier that separates the activations of the concept samples from those of the random samples, we use a linear SVM. This approach requires inputs of the same dimension, so we crop or pad all concepts to 20 seconds length (also used during training). Cropping is done by selecting the middle 20 seconds of a MIDI performance; padding adds silence until the appropriate length is reached.

In the next step, we examine the conceptual sensitivities of all the validation data and compute the TCAV score for all pieces by the same composer, i.e., the relative amount of positive conceptual sensitivities over the pieces. We again need to ensure inputs have the same length as our concepts, so we split every piece into non-overlapping 20 second segments and use all of these for subsequent computations. Although we can compute the TCAV score for any layer of the composer classifier, for brevity we show results of the penultimate layer subsequently, expecting this layer to encode the highest level features, similar to the image domain [28]. To compute TCAV scores, we perform ten runs with ten random datasets [12], and run a two-sided t-test and a Bonferroni correction for all concepts and composers

[5] Using https://captum.ai/api/concept.html

	Bach	*Scarlatti*	*Haydn*	*Mozart*	*Beethoven*	*Schubert*	*Chopin*	*Schumann*	*Liszt*	*Brahms*	*Debussy*	*Scriabin*	*Rachmn.*
alberti bass	+		+	+	+		-		-	+	-	-	-
diff.-to-play music	-		-	-				+	+			+	+
contrapuntal texture	+			+		-	-		-		-		

Table 1. Summary of TCAV scores for three concepts and the penultimate layer of a composer classifier. "+" indicate a positive influence of a concept on the classification of a composer, "-" negative influence. Empty cells show results that fail significance testing, i.e., the concept does not consistently en-/decourage the classification of a certain composer.

to validate our experiments. We use a significance threshold of $\alpha = 0.05/13$ (correcting for 13 hypothesis tests).

In our experiments, the SVM differentiating between concepts and random data has an accuracy greater than 0.9 for all concepts (in most cases, even 1). This means that the activations of the penultimate layer for the concept and the random samples are linearly separable, i.e., the CAV we produce represents the concept it is targeting. The TCAV score results are summarised in Table 1. All cells with "+" or "-" show results that pass our statistical significance test, and the remaining (empty) cells show results that fail. The symbol "+" means that a particular concept appears important for the classification of the corresponding composer (i.e., average TCAV score > 0.5); "-" that a concept discourages the classification of an input as a certain composer (i.e., average TCAV score < 0.5).

Table 1 shows both results that we would expect (e.g., alberti bass being relevant for Mozart, contrapuntal texture for Bach), and a few results which seem counter-intuitive (e.g., the model relying on alberti bass for Bach or Brahms – although one can find examples of such structures also in their works). It is possible that our model mixes the proposed concepts with other confounding ones, e.g., all pieces in the Alberti Bass dataset have also a quite simple harmonic structure. In general, there is no proof that the model *understands* our proposed concepts similarly to how a human listener would, yet we can make some interesting observations. Remarkably, even an extremely abstract concept such as "difficult-to-play music" might be grasped by our model: Liszt, Scriabin, Rachmaninoff are clear candidates for this attribute. The same applies to the "contrapuntal texture". Cases with negative impact ("-") should probably be interpreted with care: the fact that the classifier did not consider these concepts relevant for the classification does not necessarily mean that they are not present in the pieces. This could apply in particular to the subtle concept of contrapuntal texture. Also interesting is the case of Scarlatti, who is very much an outsider in classical music, style-wise ("a freakish if not downright incorrect composer" [29]) and could not be associated with any of our concepts.

5. UNSUPERVISED CONCEPT-BASED EXPLANATIONS

The supervised approach requires the user to pre-define concepts. This is very time-consuming, and the user could have to try a potentially infinite number of concepts if the network works differently than expected. In this section, we discuss an unsupervised approach instead: we build an explainer that identifies the relevant concepts and presents pieces where this concept is maximally activated (and some where the concept is not present). The musical expertise of the user is then used to translate these example pieces into a musical concept (with or without a name).

For the unsupervised approach described below, we introduce two limitations on the target neural network: we assume it to be convolutional and to use a non-negative activation function [30] (e.g., ReLU).

5.1 Tensor Factorisation for CAV Extraction

Consider a set of layer activations $\mathcal{X} = \{f_l(\mathbf{x}_1), \cdots, f_l(\mathbf{x}_N)\}$ generated from multiple pieces $\mathbf{x}_1, \ldots, \mathbf{x}_N$. Layer activations that are close together (in terms of Euclidean distance) correspond to perceptually similar inputs [31] and therefore might describe similar concepts within the inputs. We could cluster similar activations and consider the pieces that generate these activations as examples of the same concept [32].

This works best if only one concept is present in a piece excerpt. However, we expect an excerpt to contain a number of different musical concepts, e.g., an alberti bass and a legato melody, both following a certain chord progression. Since these concepts can be shared across the same notes, we need a way to disentangle their effects on the layer activations. Due to the restriction on the type of activations (only non-negative) that we introduced in this section, we can use the NTD for this objective (see Section 5.3).

5.2 Channel CAVs

Given layer activations $f_l(\mathbf{x})$, let us consider their *channel-mode tubes* [33], i.e., the vectors obtained by fixing an index h and w for the horizontal and vertical dimension (see left-hand side of Figure 2). In the case of CNNs, we can consider each of these vectors as a different representation of the same piece with a different receptive field [34]. As proposed in [14], we can analyse channel-mode tubes $\in \mathbb{R}^C$ instead of full layer activations $\in \mathbb{R}^{H \times W \times C}$. This increases the

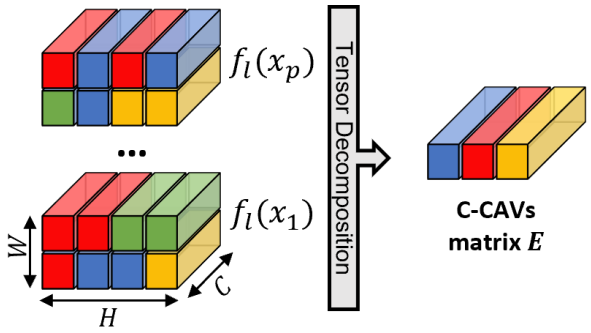

Figure 2. Left: Channel-mode tubes that result from fixing indices of activations in the W and H dimension of the activation space. Right: C-CAVs extraction from the layer activations of multiple pieces. Each channel tube is decomposed as a weighted sum of C' C-CAVs.

amount of data and reduces the dimension of each data point by a factor of $H \times W$, therefore, we expect that the tensor decomposition that we will run on these data will achieve better results. Since every channel-mode tube represents a piece, we can compute CAVs in this restricted channel space $\mathbb{R}^C$, and refer to them as *Channel-CAVs* (or C-CAVs). We can again compute the conceptual sensitivities for such C-CAVs, as explained in Section 4.2.

We compute C-CAVs by starting from a dataset of pieces (segmented in 20-second excerpts) of the composers we want to explain (any number of composers can be considered). We input each excerpt into the trained system and produce activations for a certain layer l (see Figure 1). The set of all activations can be seen as a tensor $\mathcal{X} \in \mathbb{R}^{N \times H \times W \times C}$, where N is the number of piece excerpts and H, W and C are the frequency, time, and channel size of the layer activation tensor. We then apply a NTD to $\mathcal{X}$ to obtain a set of C-CAVs.

Moving to a channel-based formulation also permits us to highlight in which part of a piece a certain concept is present: since layer activations have a spatial correlation with input data [35] we can project the position h, w of each C-CAV onto the input piano roll. This creates a *concept presence* heatmap showing the presence of a C-CAV [14] on a piano roll, which can be visualised to improve the user's understanding of the concept. Averaging the values in this heatmap gives a number that expresses how much a concept is activated in a certain excerpt and allows a ranking of the pieces according to their average concept presence.

5.3 Non-negative Tucker Decomposition

The NTD is a technique to decompose a tensor (e.g., $\mathcal{X}$) into a so-called non-negative *core* tensor $\mathcal{T}$, and multiple *factor* matrices $\mathbf{A} \in \mathbb{R}^{N \times N'}$, $\mathbf{B} \in \mathbb{R}^{H \times H'}$, $\mathbf{D} \in \mathbb{R}^{W \times W'}$ and $\mathbf{E} \in \mathbb{R}^{C \times C'}$ (one for every dimension) [33], such that

$$\mathcal{X} \approx \sum_{n=1}^{N'} \sum_{h=1}^{H'} \sum_{w=1}^{W'} \sum_{c=1}^{C'} t_{nhwc} \mathbf{a}_n \circ \mathbf{b}_h \circ \mathbf{d}_w \circ \mathbf{e}_c \quad (2)$$

Here, the core tensor $\mathcal{T}$ is in $\mathbb{R}^{N' \times H' \times W' \times C'}$, and one of its scalar elements is denoted by t_{nhwc}. The symbol "$\circ$" denotes the vector outer product of the column vectors of the (four) factor matrices $\mathbf{a}_n, \mathbf{b}_h, \mathbf{d}_w, \mathbf{e}_c$. The number of columns of the factor matrices (i.e., the NTD ranks), N', H', W' and C' are hyper-parameters that can be chosen by the user; if we set them to $N' = N$, $H' = H$, etc., an exact reproduction of the original tensor $\mathcal{X}$ is possible [33]. However, we mostly want to set them at lower values (i.e., $N' << N$, $H' << H$, etc.) to decrease the size of the matrices.

Equation 2 tells us that every channel-mode tube in $\mathcal{X}$ can be reconstructed as a weighted sum of the columns of matrix $\mathbf{E}$. As previously mentioned, each channel-mode tube represents a piece (in activation space), and each piece contains a sum of multiple concepts as C-CAVs. Then the C-CAVs we are looking for are disentangled as columns in $\mathbf{E}$ (see Figure 2), and their number is specified by rank C'.

The NTD also allows us to reconstruct an approximation of the original tensor (i.e., the original layer activations), and compute the output of the composer classifier by feeding it back into the network. We can then compute the ratio of the predictions that remain unchanged after the NTD step (i.e., the *fidelity*) [14] to evaluate its impact on the composer classifier. For more details on NTD, we refer to [33]; in this paper, we use the implementation provided in [36], with the Hierarchical non-negative Alternating Least Squares algorithm to update the factor matrices and the Fast Iterative Shrinkage-Thresholding Algorithm to update the core.

5.4 Experiments and Results

We compute the unsupervised explanations for the penultimate layer of our composer classification system and test multiple NTD ranks. As in [14], we present each concept to the user through the five piece excerpts with the highest average concept presence. The presentation of piece excerpts is more challenging for musical data than for images. Although symbolic performances can be visualised with piano rolls, some musical elements (e.g., harmonic elements) may be hard to understand in this format. We opt for a mixed audio-image visualisation where each excerpt is represented both with a piano roll (with a colour scale for velocity information) and with a listenable MIDI file. We create interactive piano roll visualisations (using Plotly [37]) in which the user can zoom in and out to explore different resolution levels. The concept presence heatmap is displayed as a semi-transparent mask over the piano roll. A heatmap with a fixed threshold, as proposed in [14], is hard to interpret for our data, so the user is presented with a slider that adapts the heatmap threshold (see Figure 3). We also provide "contrastive examples" for each concept, i.e., the 5 excerpts where the average concept presence is minimal. Although our explainer could find relevant concepts starting from a dataset that includes any number of composers, we focus on the results with only two composers. According to psychological studies [2], explanations are easier to understand when they involve only a small amount of information and when they target contrast cases [1], i.e., understanding why a composer is selected instead of another is easier than

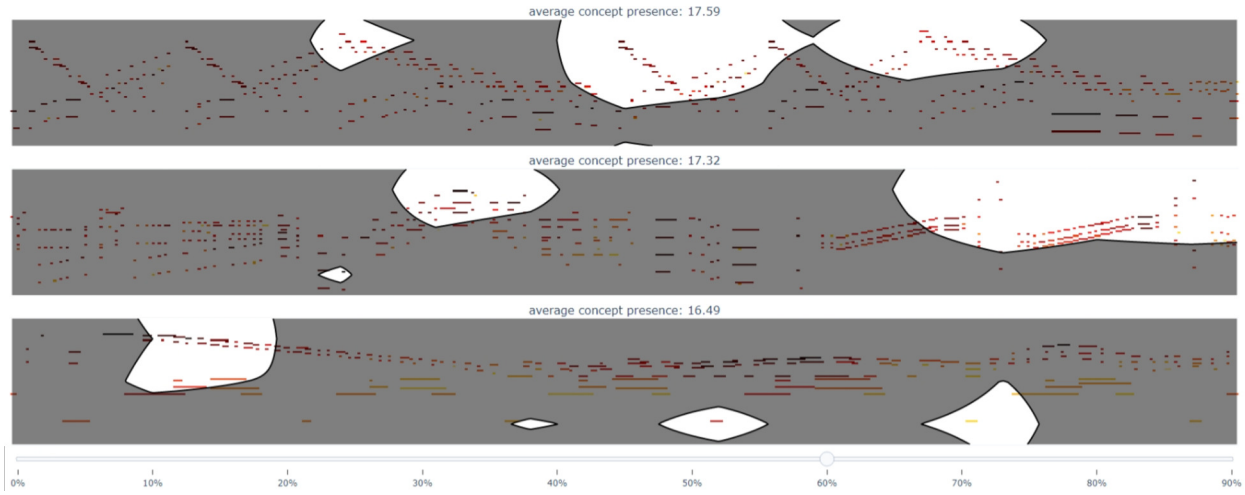

Figure 3. Visualisation of one concept (out of 4 produced by 4d NTD) through the masked piano rolls of the three dataset excerpts with the highest average concept presence. The concept heatmap threshold is set to 60%. This concept has positive conceptual sensitivity for Chopin and negative for Bach, therefore it is useful to distinguish between the two composers.

understanding why a composer is selected in general. For this reason, we also focus on C-CAVs with opposing conceptual sensitivities, i.e., negative for one class and positive for the other. We experimented with three different non-negative factorisation approaches: NTD applied to the 4d matrix (as explained in Section 5.3), NTD on a 3d matrix with concatenated horizontal and vertical dimensions, and NMF on a 2d matrix (as proposed by [14]) with concatenated horizontal, vertical, and piece dimension.

We found that the target classifier, when only two composers are considered, can be approximated with maximum fidelity by using only 3 to 5 C-CAVs, depending on the composers considered. For a fixed number of C-CAVs, we found no clear advantage for one of the three factorisation techniques with respect to the fidelity score. NTD allows for a much higher compression of $\mathcal{X}$, up to 15 times smaller, preserving the same fidelity; but it is also much slower to compute. From a manual analysis, we see that our unsupervised explainer finds, for each opposing concept, examples of typical composing styles that are useful for discriminating between two composers.

Figure 3 shows an example of what our model considers a typical Chopin-style pattern that is not present in Bach's music. In musical terms, it might be named "fast upward or downward movements (in the upper register) in parallel or broken thirds/sixths/octaves". Since our approach is based on non-negative factorisation techniques, some of their typical problems are also present in our results. For example, our system could produce one C-CAV that comprises what musical experts would typically interpret as two different concepts, or vice versa, produce two C-CAVs, both referring to the same concept. The former might have happened with the four small, seemingly unrelated blobs in the lower registers in the last two piano rolls of Figure 3. Furthermore, it is difficult to assign musically meaningful concept names to some C-CAVs, especially those with low average concept presence.

6. CONCLUSION AND FUTURE WORK

In this paper, we explored a supervised and an unsupervised approach with the aim of producing explanations of deep musical classifiers interpretable by musicologists. In the supervised approach, we define high-level musical concepts (e.g., alberti bass) by building concept datasets and interrogate a classifier to find the relevance of a concept for the classifier decisions. This approach is useful when the user wants to test a specific concept. However, the process of creating a concept dataset can be time-consuming, requires high-level music expertise, and it could be necessary to try many different concepts before finding a relevant one. A solution to these problems is the unsupervised approach, which selects the relevant concepts by itself. Each concept is presented as a set of piece excerpts where the concept is maximally present. The user can listen to those excerpts and visualise them in a piano roll representation with a heatmap highlighting the concept position.

Future work on the supervised explainer will integrate recent promising results on model non-linearity and stricter hypothesis testing [38]. The unsupervised part will benefit from a formal user-based evaluation by musicologists to see which number of C-CAVs produce the most interpretable musical concepts and if there is agreement on their naming. Sparsity constraints applied to the core tensor and matrices in the NTD may attenuate the non-negative factorisation problems. While both supervised and unsupervised approaches work on piece excerpts of fixed length, an extension to variable length pieces could enable the study of concepts that span a longer time frame (e.g., piece structure). Moreover, our two approaches could be applied to explain audio classifiers, although this would complicate the visualisation of the concept heatmap for the unsupervised explainer, and could make the creation of concept datasets more challenging. Finally, dedicated user interfaces enabling to define concepts and visualise results would be helpful for musicologists.

ABSTRACT

Lyrics-based genre recognition aims to automatically determine the genre of a given song based on its lyrics. Previous approaches for this task have commonly used textual features extracted from the entirety of a song's lyrics, neglecting the inherent structure of lyrics consisting of, for instance, verses and choruses. Therefore, we pose the hypothesis that features extracted from different parts of the lyrics can have significantly different predictive power. To test this hypothesis, we perform a series of experiments to determine whether models trained on features taken from verses and choruses perform differently for genre recognition. Our experiments indeed confirm our hypothesis, showing that generally, using features extracted from verses leads to higher performance than features extracted from choruses. Digging deeper, we found that this is especially true for *pop* and *rap* songs. *Rock* songs show the opposite effect, with features extracted from choruses performing better than those taken from verses.

1. INTRODUCTION AND RELATED WORK

In music information retrieval, genre recognition (also known as genre prediction or genre classification) is the task of automatically classifying the genre of a given song by assigning it to one or more predefined genres. This has a variety of applications, including the organization of music collections into easily recognizable categories, or using genre information as a feature in recommender systems. Over the years, many approaches have been developed for this task, most of which focus on audio-based genre recognition, i.e., using information extracted from the song's audio signal [1]. Less, but still substantial, work has also been done on lyrics-based approaches, which use features extracted from a song's lyrics (e.g. [2–5]). Lastly, hybrid approaches combining both audio and lyrics information have also been proposed (e.g., [6,7]), and it has been shown that audio and lyrics features are complementary and that using both together can lead to increased model performance. The approaches making use of lyrics information cover a wide range of feature types as well as underlying machine learning models.

For instance, Neumayer and Rauber [6] explored using lyrics features in conjunction with low-level audio features to detect the genre of songs. For the lyrics, they extracted feature vectors using the popular bag-of-words model and weighted the words using *tf-idf* weighting. They then performed classification via support vector machines. Mayer et al. [2] relied only on lyrics and extracted *tf-idf* weighted bag-of-words features, rhyme, and part-of-speech features as well as general statistical text descriptors for their approach. These features were then used to perform genre recognition using different machine learning models. Ying et al. [3] used information of the parts-of-speech used in a song's lyrics to recognize both genre and mood of a song. They used these features to train and evaluate three different machine learning models, namely support vector machines, k-nearest neighbor, and naive Bayes.

What these, and most other, lyrics-based approaches have in common is that they treat a song's lyrics as a uniform document, extracting features from the entirety of the song's lyrics. However, in reality, song lyrics have a structure. They consist of different parts, which can be divided into categories such as *intro*, *verse*, *chorus*, *bridge*, or *outro*. Leveraging such structural information, Tsaptsinos [4] proposed using a hierarchical neural network model using an attention mechanism. To the best of our knowledge, this is the only work that directly seeks to exploit song structure for genre recognition, making use of the hierarchical structure of song lyrics (words forming lines, lines forming segments, and segments, in turn, forming the song). Their results show that their model, which due to its attention mechanism can automatically learn on which parts of a song it should focus, outperforms existing approaches that extract and use features uniformly across the whole song. This shows that the location of features within a song plays an important role in genre recognition. However, their model applies attention at the word, line, and segment level only, and does not incorporate higher structural elements like *verse* or *chorus*. Fell

Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

and Sporleder [5] used a variety of textual features for three distinct music classification tasks, including genre recognition. The features they employed include features describing information about a song's structure, like the number of repeated segments in a song and whether the song contains a chorus. Their results for genre recognition suggest that including such features can increase genre recognition performance, and therefore that song structure plays a role in determining a song's genre.

Inspired by those results, we formulate the following hypothesis: The structure of a song's lyrics plays a substantial role in genre recognition, and extracting features from different parts of the lyrics can lead to a significantly different performance of genre recognition models. To this end, we make the following contributions: (1) We construct a dataset of lyrics that contains the required information about lyrics' structure; (2) We perform a series of experiments, covering both feature sets as well as machine learning algorithms used in the past for genre recognition, and show that there indeed exists a significant difference in predictive performance between features extract from the verses of a song as opposed to the same features extracted from the choruses; and (3) We examine how that difference in performance depends on the concrete machine learning algorithm and feature set used, as well as on the genre.

The remainder of this paper is structured as follows. Section 2 explains how we created the dataset required for our experiments. In Section 3, we provide a detailed overview of our experiments. Following that, we discuss our results in Section 4 and finally provide a summary and outlook to future work in Section 5.

2. DATASET

To investigate the impact on classification performance of features from different structural elements of lyrics, we require a dataset that contains both lyrics data with structure information (i.e., information on which structural part of the song— verse, chorus, etc.—any particular line in the lyrics belong to) as well as genre tags. Since no such dataset is publicly available, we describe the creation of such a dataset in the following and subsequently, provide a statistical description of its contents.

2.1 Dataset Creation

We used the popular LFM-2b dataset [8] to obtain an initial list of songs. Using this list of songs, we then obtained lyrics data from *genius.com*. We chose this source because it not only provides lyrics for a large number of songs, but it also has an active community of users who annotate lyrics with structure information. In addition to lyrics, they also provide tags for many of the songs in their database. We use the primary tag as given by *genius.com* as our genre tag, and then filtered the list of songs such that only songs with one of the top five most occurring genre tags — *pop*, *rock*, *country*, *rap*, and *r&b* — remained. These steps provided us with an initial dataset of 2,135,504 songs with both genre and lyrics information.

Property	Value
Number of songs	295,416
Number of artists	39,357
Number of tokens in all choruses	193,696,032
Number of tokens in all verses	195,567,571
Average number of choruses per song	3.46
Average number of verses per song	2.37

Table 1: Summary statistics of our dataset.

We then performed a series of cleaning and transformation steps on this initial dataset. First, we expanded repeating parts of the lyrics that were given in short form; i.e., lyrics on *genius.com* frequently use annotations like *[x2]* to indicate that a given part (paragraph or line) in the lyrics should be repeated. We removed those repeating annotations and duplicated the corresponding parts in the lyrics text accordingly. Following that, we removed all other annotations that do not correspond to structural parts of the lyrics; for instance, instrument annotations or singer information. In the next step, we used `langdetect` version `1.0.9` as well as `polyglot` version `16.7.4` to remove all songs with non-English lyrics from the dataset. Finally, since the dataset at that point contained duplicates—i.e., songs with identical lyrics—we removed those. These duplicates exist because LFM-2b sometimes contains multiple versions of the same song, like covers by a different artist or versions recorded during live events. To decide which song among a given set of duplicates to keep, we used the number of listening events according to LFM-2b and kept the copy with the highest listening count. We chose this approach since the copy with the highest listening count is also most likely to have the most complete set of genre tags.

Following these cleaning and transformation steps, we split the lyrics of each song into its constituent structure parts. For this, we used the structure annotations provided by *genius.com*. These annotations specify which part of the song the subsequent text belongs to, with that part extending until the next structure annotation or until the end of the song. They often also give some additional information, like who sings the given part or which number the part has in the song. Examples of such annotations include *[Chorus]* or *[Verse 1: Austin Brown]*. For our splitting, we considered the following set of structural annotations: *verse*, *chorus*, *intro*, *outro*, *bridge*, *hook*, *refrain*, *interlude*, and *drop*. We also combined *chorus* and *refrain* and mapped both of those annotations to *chorus*. For our subsequent experiments, we considered only the *verse* and *chorus* parts of the songs in the dataset, but we retained the other parts for potential future work.

Subsequently, we removed all songs that did not consist of at least two parts. This gave us an intermediate dataset consisting of 416,945 songs. Finally, since our experiments focus on *verse* and *chorus*, we created a final dataset containing only those songs which have at least one verse and at least one chorus, yielding a total of 295,416 songs.

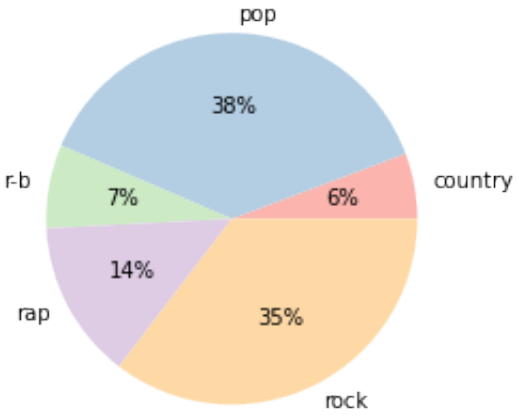

Figure 1: Genre distribution for primary genre.

2.2 Dataset Statistics

The final dataset consists of 295,416 songs created by 39,357 different artists. A summary of the dataset contents is given in Table 1. The total number of tokens (i.e., unigrams) contained in the choruses and verses for all songs is 193,696,032 and 195,567,571, respectively. This means that the amount of textual content for both chorus and verse is mostly balanced, ensuring that any difference in performance we may observe between using only chorus or verse does not stem from imbalanced training data. The distribution of primary genre labels in the dataset is given in Figure 1.

3. EXPERIMENTAL SETUP

The goal of this work is to determine whether there exists a difference in the predictive power between features extracted from different structural parts of a song's lyrics. For this, we carried out a series of experiments using different sets of textual features and different classification algorithms, each trained and evaluated once on only the *verse* and once only on the *chorus* parts of the songs in our dataset.

As explained in Section 2, we limited our final dataset to only songs which contain both at least one *chorus* and one *verse* part. This was done because, to get comparable results, we need to perform all our experiments on the same set of songs. As *chorus* and *verse* are the most common parts of a song, limiting our experiments to these two parts ensures that we have a dataset of sufficient size left to train and evaluate our models.

3.1 Feature Sets

Our experiments were performed using ten different sets of textual features commonly used in the literature (e.g., [2, 5–7, 9]). Those features together capture a wide variety of information about the lyrics, including content, grammatical structure, sound structure as well as complexity. Before using them in our experiments, we standardized them by scaling them to unit variance. We describe the feature sets used in the following:

- **Bag-of-words**: Classic bag-of-words features, counting the occurrences of word sequences of a given length, also known as n-grams, in the lyrics. In our experiments, we use unigrams, bigrams, trigrams, as well as (1,3)-grams, which is a combination of all word sequences of lengths one to three. To limit memory consumption of the resulting feature vectors, we only used the top 20,000 most common sequences appearing in the data. We also only consider sequences that appeared in at most 80% of all songs. This was done to filter out very common terms like function words. Such bag-of-words features have been frequently used in lyrics-based music classification, including for genre recognition, before (e.g. [2, 5–7, 9]).

- **Rhyme features**: A set of nine features describing the rhymes and alliterations present in the lyrics. The rhyme features (numbers of couplets, clerihews, alternating rhymes, and nested rhymes, percentage of rhymes in the text, and the number of unique rhyme words) were originally used by Mayer et al. [2] for lyrics-based genre recognition. Since alliterations play an important role in rap lyrics [10], we additionally added features describing alliterations (numbers of alliterations of length two, three, and four or longer).

- **Readability features**: A set of 13 readability metrics: Flesch reading easy, SMOG index, Flesch-Kincaid grade, automated readability index, Coleman-Liau index, Dale-Chall readability score, Linsear Write score, Gunning Fog index, Fernandez-Huerta score, Szigriszt-Pazos score, Gutierrez-Polini score, Crawford score, and the number of difficult words (i.e., words that are not on the Dale-Chall list of easy words). Readability features have been used for genre classification on normal texts, e.g. by Falkenjack et al. [11]. We included them in our experiments since we expect that they also carry useful information for lyrics.

- **Lexical features**: A set of 32 general lexical features, including token count, character count, repeated token ratio, number of unique tokens per line, average token length, average number of tokens per line, line count, unique line count, blank line count, blank line ratio, repeated line ratio, counts for specific symbols (exclamation mark, question mark, colon, etc.), count of digits, ratio of punctuation to the whole text, stop word count, stop word ratio, and hapax/dis/tris legomenon ratios. Different combinations of such lexical features have frequently been used for genre recognition (e.g., [2, 7, 9]).

- **Lexical diversity features**: A set of five lexical diversity metrics: measure of textual lexical diversity (MTLD), Herdan's C, Summer's S, Dugast's U and Maas' a.

- **Part-of-speech features**: A set of five features measuring the frequency of specific parts-of-speech within the lyrics: pronoun, adjective, adverb, noun, and verb frequency. Features describing the distribution of specific parts-of-speech within lyrics have been used for genre recognition for example by Mayer et al. [2], Mayer and Rauber [7], and Fell and Sporleder [5].

- **Morphological features**: A set of six features describing morphological properties of the lyrics: past tense ratio, -ing form ratio, comparative and superlative ratios for adjectives, and comparative and superlative ratios for adverbs. The ratio of verbs in past tense has been used for genre recognition before by Fell and Sporleder [5]. Since this was shown to be a valuable feature, we added the other five features to capture additional information about the morphological properties of a song's lyrics.

Since our goal is to determine potential differences between *verse* and *chorus* for individual feature types, we did not include a combination of all features in our experiments. It has already been shown before that different textual features carry orthogonal information, and combining them leads to increased performance [9].

3.2 Classification Algorithms

We repeat our experiments with different classification models to ensure that any difference in performance we measure between features extracted from different parts of a song is not only due to a specific property of any of the classification algorithms. Concretely, we chose the following algorithms: random forests, support vector machines, and feed-forward neural networks. All of these models are widely used in the machine learning community and have been shown to work well on many different tasks, including specifically genre recognition (e.g. [2–6, 9]).

For all three algorithms, we used the implementations provided by scikit-learn [1] version `1.0.2`. For support vector machines, we chose scikit-learn's `LinearSVC`, which uses LIBLINEAR [12], and followed the recommendation in the sklearn documentation to set `dual=False`, since in our case the number of training samples is significantly higher than the number of features. All other parameters for the used algorithms were left at their default values (100 estimators and Gini impurity for `RandomForstClassifier` and one hidden layer with 100 neurons and ReLU activation for `MLPClassifier`). Note that we did not perform a grid search to find the best hyperparameters, since our goal is only the determine the difference between features extracted from verses and choruses, not to get the best possible performance from the models.

[1] `https://scikit-learn.org/`

4. RESULTS AND DISCUSSION

We investigated every combination of song part (chorus or verse), feature set, and machine learning algorithm. Training and evaluation were done using 5-fold cross-validation. For the cross-validation, the data was shuffled before splitting it into folds. Feature extraction was done completely separately for the different song parts. For models trained and evaluated on the songs' verses, feature extraction only considered text located within the verses of the songs in the dataset, and equivalently for models trained and evaluated on the songs' choruses.

For evaluation, we chose the F_1 score to quantify the performance of each model. Since our dataset is imbalanced in terms of genres, we will focus our discussion on the macro-averaged F_1 scores, so as to not over-weigh the importance of the most common genres. However, for the sake of full transparency, we also report the micro-averaged F_1 scores for each model. Since the goal of our experiments is to determine whether there exists a performance difference between models trained on choruses and verses, we also performed statistical significance tests whenever our results indicated that the model trained on choruses performed better than the corresponding model trained on verses, or vice versa. For this, we employed a one-sided t-test ($p = .01$) on the scores of the individual cross-validation folds of both models, using the alternative hypothesis that the better overall score was indeed greater than the lower score.

We provide the results obtained in Table 2. We first take a look at the general performance of the models and feature sets. As is expected, we observe a substantial variance in performance for different machine learning models and features. The overall best performance in terms of the macro-averaged F_1 score is achieved by the support vector machine model trained on (1,3)-gram features extracted from the songs' verses, with an F_1 score of 0.5108. The best performance of the random forest and neural network model, respectively, was 0.4296 and 0.5082, both also for (1,3)-gram features trained on verses. The ten feature sets also exhibit substantial variability in performance across different machine learning models. This is especially true for part-of-speech features as well as morphological features. These two feature sets show a significantly lower performance when used with a support vector machine as opposed to random forests or neural networks. Looking at the higher score, obtained for the models trained and evaluated on the songs' verses, part-of-speech features achieved a score of 0.1872 against 0.2970 and 0.2888, and morphological features achieved a score of 0.1694 against 0.3154 and 0.2914.

Next, we examine the difference in performance between models trained and evaluated on choruses and verses, respectively. The results draw a clear picture: models trained and evaluated on verses consistently outperform the equivalent models trained and evaluated on choruses. We observe a difference in performance for every single combination of machine learning algorithm and feature set, at least in terms of the macro-averaged F_1 score. The

Table 2: Summary of the results of our experiments. For all numbers, leading zeros were omitted for space reasons. *Diff.* is the change in F_1 score between verse and chorus. Numbers in parentheses are the standard deviation between the five cross-validation folds. Bold numbers indicate the highest and underlined numbers to lowest amount of change for each combination of feature set and machine learning algorithm. † indicates that the difference in performance is statistically significant.

micro-averaged F_1 scores show almost the same picture, with one notable exception: morphological features used with a support vector machine achieved the same score for *chorus* and *verse*. The exact difference in performance again varies depending on the machine learning algorithm and feature set. The biggest absolute difference in terms of macro-averaged scores is seen with support vector machines using readability features. Trained and evaluated on choruses, this model achieves an F_1 score of 0.2244, as opposed to a score of 0.3552 for verses. This constitutes an absolute change in score of 0.1308. The biggest relative difference is also shown by support vector machines, but for lexical diversity features. For this model, the score for verses is 0.3188 as opposed to 0.1946 for choruses, for a change of 0.1242, which is a relative change of 63.82%. The lowest difference in terms of macro-averaged F_1 scores is observed for morphological features used with support vector machines. The difference between *chorus* and *verse* for this model is 0.0056, which is also the lowest relative difference of 3.42%. For micro-averaged F_1 scores, the lowest change is 0, as mentioned before, also for morphological features using support vector machines.

To get a better sense of how the difference in performance depends on the used machine learning algorithm or feature set, we computed the average difference in macro-averaged F_1 scores between *chorus* and *verse* along both of these dimensions. The results for this are given in Table 3. We can observe from these that the performance difference

Table 4: Performance differences for the feature sets *readability* and *lexical* for individual genres in terms of F_1 scores. The values in the table are computed as the differences between chorus and verse, with positive numbers indicating that models trained on verses performed better, and negative numbers indicating that models trained on choruses performed better. † indicates that the difference in performance is statistically significant. Abbreviations: RF = random forest, SVM = support vector machine, NN = neural network.

does not seem to vary much with the machine learning algorithm. The biggest difference here is obtained by neural networks, with an average of 0.0826, while the smallest change is seen for random forests, with an average of 0.0708. In contrast, performance differences between feature sets are more substantial. The biggest average score difference there is produced by *readability*, with an average of 0.1117, while the smallest difference is seen for *lexical*, with an average of 0.0521.

Those results confirm our initial hypothesis: The predictive performance of genre recognition models is indeed significantly different depending on which parts of a song we extract the features from. Concretely, results show that features extracted from the verses of songs perform significantly better than those extracted from the choruses. As mentioned in Section 2, the amount of textual content in choruses and verses is almost identical for our dataset. We can therefore rule out that this difference is caused by different amounts of training data for the model. We also conducted our experiments with various machine learning algorithms and feature sets, showing that the changes in performance are also not due to any particular properties of specific features or algorithms. We can therefore conclude that these differences are caused by a more fundamental difference in information content between choruses and verses.

Finally, we aimed to investigate how this observed difference in performance depends on the concrete genre. To this end, we took the feature sets with the biggest and smallest difference — *readability* and *lexical* — and computed per-genre F_1 scores for them, again for the same three machine learning algorithms. We then, as before, computed the difference in performance between verse and chorus. These per-genre differences are given in Table 4. In this table, positive numbers indicate that the model trained on verses performed better, while negative numbers indicate that the models trained on choruses performed better.

Looking at these results, we can see a varied picture of the different genres. For *country*, we observe that the differences change between positive and negative, which indicates no clear tendency for whether verses or chorus perform better for this genre. The differences for countries are also not statistically significant, with one exception (random forests using *lexical* features). For *r&b*, there is also no clear tendency, with differences likewise varying between positive and negative. For *pop*, we consistently see better performance when using verse features, ranging from 0.011 to 0.0367, with five of the six observed differences being statistically significant. *Rap* is the genre for which we observe by far the largest difference in performance. Features extracted from verses clearly outperform those extracted from choruses for this genre, with differences between 0.295 and 0.6587, all of which are significant. Finally, for *rock*, we find the opposite behavior, with features extracted from choruses outperforming those extracted from verses. The statistically significant differences here range from -0.0154 to -0.0412.

5. CONCLUSION AND OUTLOOK

Building on earlier results that the structure of lyrics may play a role in genre recognition, we formulated the hypothesis that features extracted from different structural parts of a song lead to significant differences in predictive performance for genre recognition models. Through a series of experiments, we confirmed this hypothesis and showed that, depending on genre, features extracted from songs' verses can perform better than those extracted from choruses. Looking closer at how performance varies with the concrete genre, we found that this is especially true for the genres *pop* and *rap*. *Rock*, on the other hand, exhibits the opposite behavior, with classifiers using features extracted from choruses achieving better accuracy than those using features extracted from verses.

In future work, we will investigate whether we can find similar differences for other lyrics-based MIR tasks, like mood recognition or popularity prediction. Additionally, the observed differences might be used to construct better features or classification models which exploit the structure of song lyrics. Finally, we plan to incorporate audio-based features extracted from verses and choruses, respectively, and investigate whether those show similar behavior and whether they can complement lyrics-based features in a multi-modal classification setup.

ABSTRACT

Automatic speech recognition (ASR) has progressed significantly in recent years due to the emergence of large-scale datasets and the self-supervised learning (SSL) paradigm. However, as its counterpart problem in the singing domain, the development of automatic lyric transcription (ALT) suffers from limited data and degraded intelligibility of sung lyrics. To fill in the performance gap between ALT and ASR, we attempt to exploit the similarities between speech and singing. In this work, we propose a transfer-learning-based ALT solution that takes advantage of these similarities by adapting wav2vec 2.0, an SSL ASR model, to the singing domain. We maximize the effectiveness of transfer learning by exploring the influence of different transfer starting points. We further enhance the performance by extending the original CTC model to a hybrid CTC/attention model. Our method surpasses previous approaches by a large margin on various ALT benchmark datasets. Further experiments show that, with even a tiny proportion of training data, our method still achieves competitive performance.

1. INTRODUCTION

Automatic lyric transcription (ALT) systems allow for lyrics to be obtained from large musical datasets without requiring laborious manual transcription. These lyrics can then be used for many music information retrieval (MIR) tasks, including query by singing [1], audio indexing [2], etc. Besides, because lyric alignment systems are typically built upon ALT models [3, 4], a strong-performing ALT model can lay a solid foundation for better audio-to-text alignment performance. Consequently, ALT is becoming an increasingly active topic in the recent MIR community.

One option for improving ALT performance is to incorporate knowledge obtained from studies involving the transcription of speech. Indeed, ALT is usually treated as a separate problem from automatic speech recognition (ASR), e.g., [3,5–8], eschewing large-scale speech datasets and well-developed ASR systems. However, the absence of large-scale singing datasets has impeded the construction of high-performing ALT models. While there are distinctions between sung and spoken language, e.g., sung language being less intelligible and hence harder to recognize [5, 9], they share many similarities, such as having the same vocabularies and being produced by similar physical mechanisms. Therefore, we believe it is worth investigating whether we can use knowledge and datasets from the speech domain to compensate for the inadequacy of singing datasets and bolster the performance of ALT systems.

Transfer learning methods have been found to effectively alleviate the requirement for a large amount of training data for some low-resource tasks [10,11]. For example, speech recognition for non-native speakers [12], and machine translation for low-resource languages [13]. In such scenarios, transfer learning helps mitigate the problem of insufficient data by adapting data and knowledge from related high-resource tasks or domains.

In recent years, self-supervised learning (SSL) has become a new paradigm in ASR research. Several SSL methods can perform excellently with access to only a few hours or even a few minutes of labeled data [14–16]. Among them, wav2vec 2.0 [16] has been shown to be a particularly promising model for transfer learning [12]. wav2vec 2.0 is an effective few-shot learner that only requires a small amount of data from the target domain or problem to achieve impressive results [17, 18]. This property makes wav2vec 2.0 a promising candidate to help ALT systems overcome the issue of limited training data by transferring speech representation knowledge to the singing domain.

The contributions of this paper contain four aspects:

- We propose an ALT solution that takes advantage of the similarities between spoken and singing voices. This is achieved by performing transfer learning using wav2vec 2.0 on singing data after pretraining and finetuning on speech data.
- We maximize the effectiveness of transfer learning by exploring the influence of different transfer starting points. We show that both pretraining and finetuning on speech data contribute to the high performance of our ALT system.
- We further enhance the system's performance by

Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

extending the original connectionist temporal classification (CTC) model to a hybrid CTC/attention model for better convergence and more accurate decoding.

- Our method surpasses previous ones on various benchmark ALT datasets, including DSing [5], DALI [19, 20], Jamendo [21], Hansen [22], and Mauch [23], by about 25% relative WER reduction on average. We further show that with less than one-tenth of labeled singing data, our method can still achieve state-of-the-art results on the test split of DSing, demonstrating its effectiveness in low-resource ALT setups.

2. RELATED WORK

2.1 Automatic Lyric Transcription

Recent progress in lyric transcription has been mainly driven by three factors. First, the construction and curation of datasets containing aligned audio and lyrics, including DAMP Sing! 300x30x2 [5, 24] and DALI [19, 20], lay the foundation for data-driven ALT models. Second, the design of ALT acoustic models benefits from architectures of automatic speech recognition (ASR) models and can be further improved by adopting singing domain knowledge as inductive bias. Representative work includes TDNN-F with its variants [3,5–7] and vanilla/convolution-augmented Transformers [8, 25, 26]. Additionally, [27] proposed to leverage the complementary information of additional modalities (video and wearable IMU sensors) for ALT systems. Third, through data augmentation methods such as adjusting speech data to make it more "song-like" [28] or synthesizing singing voice from speech voice [25,26], more training data can be created for ALT models, thus alleviating the data sparsity problem.

2.2 Self-supervised speech representation learning

The success of deep learning methods is highly related to the power of the learned representations. Although supervised learning still dominates the speech representation learning field, it has several drawbacks. For example, substantial amounts of labeled data are required to train supervised learning ASR models [15, 16]. Moreover, representations obtained through supervised learning tend to be biased to specific problems, thus are difficult to extend to other applications [29].

To mitigate the above problems, a series of self-supervised learning (SSL) frameworks for speech representation learning have emerged, e.g., Autoregressive Predictive Coding (APC) [30], Contrastive Predictive Coding (CPC) [15], and Masked Predictive Coding (MPC) [14, 31, 32]. Moreover, wav2vec 2.0 takes advantage of both CPC and MPC to conduct self-supervised learning and has become the new paradigm for the ASR task [16]. wav2vec 2.0 has been also widely adopted as the feature extractor for other speech-related applications, e.g. speech emotion recognition [33, 34], keyword spotting [35], speaker verification and language identification [36], demonstrating that speech representations learned from wav2vec 2.0 are robust and transferable for downstream tasks.

3. METHODOLOGY

In this section, we firstly recap the structure of wav2vec 2.0 [16]. Then we elaborate on the three training stages of the proposed methods, including pretraining on speech data, finetuning on speech data, and transferring to the singing domain.

3.1 Structure of wav2vec 2.0

As shown in Fig. 1, wav2vec 2.0 is built with a CNN-based feature encoder, a Transformer-based context network, and a quantization module. For raw audio inputs $\boldsymbol{x}$ with a sampling rate of 16 kHz, the feature encoder accepts $\boldsymbol{x}$ and obtains the latent speech representations $\boldsymbol{z}$. The feature encoder has seven blocks, each of which includes a 1D temporal convolution with 512 channels followed by layer normalization [37] and GELU activation [38]. Consequently, $\boldsymbol{z} \in \mathcal{R}^{T\times 1024}$ are 2D representations with a frequency of 49 Hz. To exploit the temporal relationship among different frames of latent representations, $\boldsymbol{z}$ are further fed into the context network, which is parameterized by 12 Transformer blocks [39]. Each block has a multi-head attention module with 16 attention heads and a Feed-Forward Network (FFN) with 4,096 hidden dimensions. Resulting context representations $\boldsymbol{c} \in \mathcal{R}^{T\times 1024}$ are the features extracted from the audio signal and used for downstream tasks.

In addition to being fed into the context network, $\boldsymbol{z}$ are also accepted by a quantization module, which learns quantized speech representations $\boldsymbol{q}$, thus facilitating the self-supervised training.

3.2 Stage I: Pretraining on speech data

wav2vec 2.0 is pretrained through an SSL method [16] on large-scale unlabeled speech data, as displayed in Fig. 1(a). Before latent representations $\boldsymbol{z}$ are fed into the context network, several consecutive frame sequences are randomly masked. The masked frames are replaced by a trainable vector. wav2vec 2.0 is trained by optimizing the combination of contrastive loss and diversity loss $\mathcal{L}_m + \alpha\mathcal{L}_d$ (α refers to a balancing hyper-parameter). The contrastive objective is defined as:

$$\mathcal{L}_m = -\log \frac{\exp(sim(\boldsymbol{c}_t, \boldsymbol{q}_t)/\kappa)}{\sum_{\widetilde{\boldsymbol{q}}\sim \boldsymbol{Q}_t} \exp(sim(\boldsymbol{c}_t, \widetilde{\boldsymbol{q}}_t)/\kappa)} \quad (1)$$

where $\boldsymbol{c}_t$ is t-th frame of context representations, $\boldsymbol{Q}_t$ represents all possible quantized representations, the temperature value κ is set as 0.1 and sim refers to the cosine similarity. The diversity loss $\mathcal{L}_d$ is designed to encourage the usage of all entries in codebooks. We refer readers to [16] for more details.

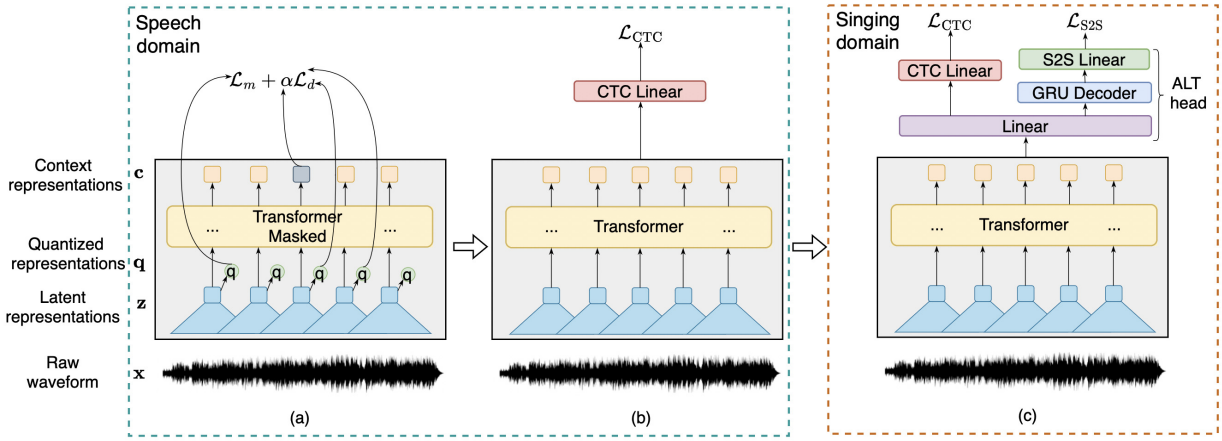

Figure 1. An overview of our training framework. (a) Stage I: Pretraining on speech data. (b) Stage II: Finetuning on speech data. (c) Stage III: Transferring on singing data.

3.3 Stage II: Finetuning on speech data

The process of finetuning requires labeled speech data. As shown in Fig. 1(b), the quantization module in wav2vec 2.0 is disabled since it is only used in Stage I, and a linear layer (CTC linear) is added on top of the Transformer. The whole model is trained by optimizing the connectionist temporal classification (CTC) loss $\mathcal{L}_{\text{CTC}}$ [40]. Suppose the ground-truth transcription is $\boldsymbol{w}^*$, which is a sequence of character tokens. The CTC loss is defined as:

$$\mathcal{L}_{\text{CTC}} = -\log \sum_{\boldsymbol{\pi} \in \mathcal{B}^{-1}(\boldsymbol{w}^*)} \prod_{t=1}^{T} p(\boldsymbol{\pi}_t | \boldsymbol{f}_t) \tag{2}$$

where $\boldsymbol{f}_t$ refers to $\boldsymbol{c}_t$ in this stage, T is the number of frames, $\mathcal{B}$ is a function to map an alignment sequence $\boldsymbol{\pi}_{1:T}$ to $\boldsymbol{w}^*_{1:N}$ (where N represents the number of character tokens) by removing duplicate characters and blanks while its inverse function $\mathcal{B}^{-1}(\boldsymbol{w}^*)$ refers to all the CTC paths mapped from $\boldsymbol{w}^*$. For speech data, there are 31 tokens for character targets, including 26 letters, the quotation mark, a word boundary token, $< bos >$, $< eos >$, and CTC blank token. The probability $p(\boldsymbol{\pi}_t | \boldsymbol{f}_t)$ is computed by the CTC linear layer followed by a softmax operation. Besides the supervised CTC loss, pseudo-labeling is also adopted during finetuning. Please refer to [16, 41] for more details.

3.4 Stage III: Transferring on singing data

3.4.1 From CTC to CTC/attention

To transfer the trained wav2vec 2.0 from the speech domain to the singing domain, we retain the weights of the feature encoder and the context network after Stages I and II. Furthermore, inspired by [42], we extend the original CTC system into a hybrid CTC/attention system through the addition of an ALT head on top of wav2vec 2.0 instead of a single CTC linear layer (Fig. 1(c)).

The context representations $\boldsymbol{c}$ are first fed into a linear layer followed by a leaky ReLU activation layer to obtain the features $\boldsymbol{f}$. Then $\boldsymbol{f}$ are sent to two network branches. One branch is a CTC linear layer, which aims to compute $p(\boldsymbol{\pi}_t | \boldsymbol{f}_t)$ as explained in sec. 3.2.2. Another branch is an attention-based GRU decoder [43] followed by a sequence-to-sequence (S2S) linear layer. The GRU decoder has a single layer with a hidden dimension of 1,024 and utilizes location-aware attention [43] with attention dimension 256. The decoder and S2S linear layer autoregressively compute the probability $p(\boldsymbol{w}_n | \boldsymbol{w}_{<n}, \boldsymbol{f}_{1:T})$, $n = 1, 2, ..., N$.

3.4.2 Training and Evaluation

During Stage III, wav2vec 2.0 and the ALT head are trained through the combination of CTC loss [40] and S2S loss [44]:

$$\mathcal{L}_w = \lambda_a \mathcal{L}_{\text{CTC}} + (1 - \lambda_a)\mathcal{L}_{\text{S2S}} \tag{3}$$

$$\mathcal{L}_{\text{S2S}} = -\log \prod_{n=1}^{N} p(\boldsymbol{w}^*_n | \boldsymbol{w}^*_{<n}, \boldsymbol{f}_{1:T}) \tag{4}$$

where λ_a is a hyper-parameter to balance the CTC loss term and S2S loss term. To overcome catastrophic forgetting, we adopt a smaller learning rate for wav2vec 2.0 compared to the ALT head.

To evaluate the performance of the trained model, the most likely lyrics are predicted using beam search:

$$\begin{aligned} \boldsymbol{w}' = \arg\max_{\boldsymbol{w}} \lambda_b \log \sum_{\boldsymbol{\pi} \in \mathcal{B}^{-1}(\boldsymbol{w})} \prod_{t=1}^{T} p(\boldsymbol{\pi}_t | \boldsymbol{f}_t) \\ + (1 - \lambda_b) \log \prod_{s=1}^{S} p(\boldsymbol{w}_s | \boldsymbol{w}_{<s}, \boldsymbol{f}_{1:T}) \\ + \lambda_c \log p_{LM}(\boldsymbol{w}) \end{aligned} \tag{5}$$

where λ_b and λ_c are two hyper-parameters in the decoding process. The language model is implemented by a 3-layer LSTM. The characters are firstly projected to embeddings and then fed into the LSTM with a hidden dimension of 2,048 to obtain RNN features. Finally, the RNN features are accepted by a 3-layer MLP with a hidden dimension of 1,024 to output the probability $p_{LM}(\boldsymbol{w})$.

4. EXPERIMENTS

4.1 Datasets and preprocessing

We use various accessible mainstream lyric transcription datasets for our experiments, including DALI [19, 20], Hansen [22], Mauch [23], Jamendo [21], and a curated version of DAMP Sing! 300x30x2 [24] called DSing [5]. The train/development/test splits in our experiments are defined as follows. For the DSing dataset, we use the same split configuration as in [5]. Specifically, there are three different sizes of training sets (DSing1, DSing3, DSing30), as well as a development set DSing$^{\text{dev}}$ and a test set DSing$^{\text{test}}$. As for the DALI dataset, we divide all publicly available audio in DALI v2 [20] into training and development subsets (DALI$^{\text{train}}$ and DALI$^{\text{dev}}$ respectively). [1] We use DALI$^{\text{test}}$ [7], a subset of DALI v1 [19], as a test set for experiments involving DALI. The full Hansen, Mauch, and Jamendo datasets are used as additional out-of-domain test sets. In the training and development splits of the DALI dataset, songs that overlapped with any of our test sets are removed for more objective testing.

The speech data used to pretrain and finetune the wav2vec 2.0 is initially monophonic. Therefore, we expect wav2vec 2.0 to extract better representation features for singing data if monophonic audios are given as the inputs. Thus, we extract vocal parts from all of the polyphonic recordings in DALI, Mauch, and Jamendo datasets using Demucs v3 *mdx_extra* [45], which is the state-of-the-art source separation model that achieved the first rank at the 2021 Sony Music DemiXing Challenge (MDX). This ensures that we are consistent with the input requirements of wav2vec 2.0 and minimize the interference of musical accompaniment. We adopt utterance-level input for both training and testing. To facilitate the experiments, we perform utterance-level segmentation on all audios according to their annotations. Utterances with obvious faulty annotations are removed (e.g., utterances labeled as several words but have shorter than 0.1 s duration). The statistics of all datasets after utterance-level segmentation are listed in Table 1. The "total duration" column refers to the sum of durations of all utterances in the datasets, excluding the instrumental-only parts between utterances, hence resulting in shorter durations than [7]. We notice that the average utterance duration of DSing is longer than DALI (6.52 s vs. 2.47 s). Finally, lyric texts in training sets are normalized by converting all letters to upper case, converting digits to words, discarding out-of-vocabulary characters, discarding meaningless lines (e.g., "**guitar solo**"), and removing redundant space.

4.2 Experiment setup

Our experiments are conducted through SpeechBrain toolkit [46] [2]. Before transferring on singing data, the wav2vec 2.0 has been pretrained on LibriVox (LV-60K) and finetuned on LibriSpeech (LS-960) [3] [16]. Then we randomly initialize the ALT head. During Stage III, we downsample all audios to 16 kHz and convert them to mono-channel by averaging the two channels of stereo audio signals. Then the singing data is augmented through SpecAugment [47]. wav2vec 2.0 and ALT head are trained using Adam optimizer [48]. The initial learning rates of ALT head and wav2vec 2.0 are 3×10^{-4} and 1×10^{-5} respectively. Learning rates are scheduled using the Newbob technique, with annealing factors of 0.8 and 0.9 respectively. The batch size is set as 4, and hyper-parameter λ_a is set as 0.2 during the experiments. We conduct our experiments on 4 RTX A5000 GPUs. Utterances whose duration is longer than 28 seconds are filtered out during training to prevent the out-of-memory issue. This filtering is not performed during the evaluation for a fair comparison with other existing methods.

We firstly utilize DSing30 to train the whole model for 10 epochs. We evaluate the performance of our model on DSing$^{\text{dev}}$ after each epoch. Finally, the best model is selected to be evaluated on the test split DSing$^{\text{test}}$. Word error rate (WER) is adopted as the evaluation metric. During the evaluation, WERs are averaged over all utterances in a test set. The RNNLM is trained for 20 epochs using an Adam optimizer [48] on texts of DSing30 split and validated on the DSing$^{\text{dev}}$ split after each epoch. The learning rate is 1×10^{-3} and the batch size is 20. During the decoding, the beam size is 512, and the hyper-parameters λ_b and λ_c are 0.4 and 0.5, respectively. The trained model is evaluated on the DSing$^{\text{test}}$ set.

For other test splits, we adopt both DSing$^{\text{train}}$ and DALI$^{\text{train}}$ to train the whole model. Since these two datasets are collected from different domains, we adopt a consecutive training strategy instead of training together in order to reduce the difficulty of training. Specifically, we continue training the whole model on DALI$^{\text{train}}$ split for 4 epochs. The weights of learnable parameters are initialized using the model trained on DSing30. After training, we evaluate the model on DALI$^{\text{test}}$ as well as the Hansen, Mauch, and Jamendo datasets. The configuration

[1] At the time of this research, some audios are not retrievable through their YouTube links in the public-available metadata. Although audios containing the same titles and artist names can be found online, we cannot guarantee they perfectly match the annotations for the original audio versions in DALI. Discarding invalid audio is only performed for the training and the development sets.

Method	DSing^{dev}	DSing^{test}	DALI^{test}	Jamendo	Hansen	Mauch
TDNN-F [5]	23.33	19.60	67.12	76.37	77.59	76.98
CTDNN-SA [6]	17.70	14.96	76.72	66.96	78.53	78.50
Genre-informed AM [3]	-	56.90	-	50.64	39.00	40.43
MSTRE-Net [7]	-	15.38	42.11	34.94	36.78	37.33
DE2 - segmented [4]	-	-	-	44.52	49.92	-
Ours	**12.34**	**12.99**	**30.85**	**33.13**	**18.71**	**28.48**

Table 2. WERs (%) of various ALT systems on different singing datasets. "-" refers to "non-applicable". We use **bold face** to highlight the best results, and underline to mark the second-best results. Note that the results of [5–7] on DALI^{test}, Jamendo, Hansen, and Mauch datasets are obtained without utterance segmentation.

of RNNLM is the same as above, except that we utilize texts of both DSing30 and DALI^{train} to train the model. To decode the lyrics, we set the beam size as 512 and the hyper-parameters λ_b and λ_c as 0.3 and 0.2, respectively.

5. RESULTS

In this section, we firstly compare our method with state-of-the-art ALT systems on multiple benchmark datasets. Then we conduct extensive ablation studies to show the benefits of our design choices on the DSing dataset, which has more accurate manual annotations on its development and test splits. Finally, we show that our method is still effective with a limited amount of singing data.

5.1 Comparison with the state-of-the-art

We compare the performance of the proposed method with previous approaches, as shown in Table 2. Our method outperforms all previously published results on all the evaluation datasets. Our method achieves 5.36%, 1.97%, 11.26%, 1.81%, 18.07%, 8.85% absolute WER reduction on the DSing^{dev}, DSing^{test}, DALI^{test}, Jamendo, Hansen, and Mauch datasets, compared with the best results among all the previous state-of-the-art approaches respectively. Especially, on DALI^{test}, Hansen, and Mauch datasets, our method significantly exceeds MSTRE-Net [7] by an average of 12.73% absolute WER.

5.2 Effects of pretraining & finetuning on speech data

As shown in Fig. 1, wav2vec 2.0 is pretrained and finetuned on speech data before transferring to singing data. The feature representation knowledge learned from speech data is the key to the success of our method. To validate this statement, we conduct ablation studies by comparing the proposed method to two alternative configurations. The first alternative configuration is that we randomly initialize the weights of wav2vec 2.0 and ALT head and then train the whole model on the DSing dataset as per the experiment setup in section 4.2. Note that the first alternative has no transfer learning from the speech domain (without both Stages I and II). The second alternative configuration is that we only perform pretraining on speech data [4] without Stage II before transferring the wav2vec 2.0 to the singing domain.

Figure 2. Comparison of different training configurations. "w/o PT & FT" refers to without Stages I and II. "w/o FT" refers to without Stage II. (Left) Training loss of all configurations for the first 10 epochs; (Right) validation loss of all configurations for the first 10 epochs.

Method	DSing^{dev}	DSing^{test}
Ours	**12.34**	**12.99**
- Finetuning	12.64 (+ 0.30)	14.58 (+ 2.59)
- Pretraining	35.61 (+24.27)	39.13 (+26.14)

Table 3. WERs (%) of different training configurations on DSing dataset.

We evaluate the above training configurations on the DSing dataset. First, we show the curves of training loss and validation loss (loss of the development set) during the training for the first 10 epochs in Fig. 2. The losses are computed through Eq. 3. We observe that without Stages I and II, the training loss and validation loss are much higher than in the other two training configurations. In addition, its convergence is much slower. When we enable Stage I but disable Stage II, the behavior of the training loss is similar to the proposed configuration, except that the training loss is higher at the beginning. However, the validation loss in this setup is higher than that of the proposed configuration.

We continue training both alternatives until convergence and display the resultant performances in Table 3. We note that without Stage II, the performance drops by 0.30% higher WER on DSing^{dev} and 2.59% higher WER on DSing^{test}. Furthermore, without Stages I and II, the performance degrades severely as WERs on DSing^{dev} and

[4] https://huggingface.co/facebook/wav2vec2-large-lv60

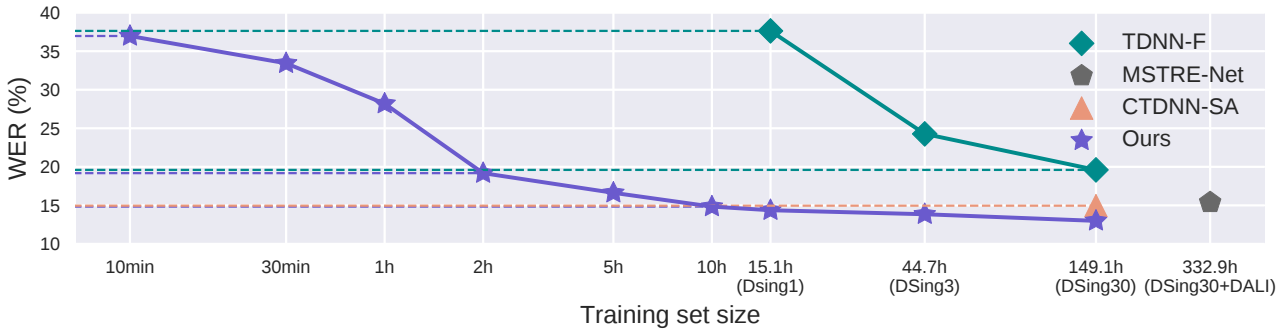

Figure 3. Transcription performance comparison when using different training set sizes, testing on the DSing$^{\text{test}}$ dataset.

Method	DSing$^{\text{dev}}$	DSing$^{\text{test}}$
CTC	19.86	20.99
+ S2S	15.63 (-4.23)	16.95 (-4.04)
+ LM	**12.34** (-7.52)	**12.99** (-8.00)

Table 4. WERs (%) of CTC model and hybrid CTC/attention model on DSing dataset.

DSing$^{\text{test}}$ increase by 24.27% and 26.14% respectively, compared to the proposed configuration. The results are consistent with our observations in Fig. 2. Therefore, we conclude that pretraining on speech data plays a significant role in transferring wav2vec 2.0 to the singing domain. Although finetuning on speech data is less crucial than pretraining, it also contributes to empirical performance gains.

5.3 Effects of extending CTC to CTC/attention model

To validate the effectiveness of changing from CTC to CTC/attention (as in Fig. 1), we compare the performance of our hybrid CTC/attention model with its CTC version, as shown in Table 4. We set $\lambda_b = 1$ in Eq. 5 to disable the branch of the GRU decoder and the S2S linear during the decoding. When $\lambda_c = 0$, the RNNLM is disabled.

We observe that the hybrid CTC/attention model achieves better performance by 4.23% and 4.04% WER on DSing$^{\text{dev}}$ and DSing$^{\text{test}}$ respectively than its CTC counterpart, which demonstrates the superiority of our ALT head design. Furthermore, we evaluate the benefits brought by the language model and find that the final model leads to 3.29% and 3.96% further absolute WER improvements compared to the hybrid CTC/attention model.

5.4 Effectiveness of transfer learning in low-resource scenarios

To explore the effectiveness of our transfer learning method in reducing the amount of required training data, we conduct an ablation study with different training set sizes. We first train our model on DSing30, DSing3, and DSing1, respectively, to observe the performance differences. Then, we further reduce the training set size to a minimum of 10 minutes to create more demanding low-resource setups. We report the WERs achieved on DSing$^{\text{test}}$ as the performance measure. When training on 10-minute and 30-minute datasets, the GRU decoder converges too slowly; hence, WERs are computed according to the CTC outputs.

As shown in Fig. 3, our method achieves 14.84% WER with only 10 hours (about 6.7% size of DSing30) of labeled singing data, which surpasses the state-of-the-art results of 14.96% WER achieved by CTDNN-SA [6] trained on DSing30. It also has better performance with only 2 hours of training data (about 1.3% size of DSing30) than TDNN-F [5] trained on DSing30 (19.18% vs. 19.60% WER). Further, with only 10 minutes of data (1.1% size of DSing1), our method achieves better results than TDNN-F trained on DSing1 (36.97% vs. 37.63% WER). These results demonstrate the feasibility of achieving competitive results with much less training data by adopting the representation knowledge from the speech domain.

6. CONCLUSION

We have introduced a transfer learning approach for the automatic lyric transcription (ALT) task by utilizing the representation knowledge learned by self-supervised learning models on speech data. By performing parameter transfer on wav2vec 2.0 towards the singing domain and extending the original CTC model to a hybrid CTC/attention version, we achieved significant improvement compared to previous state-of-the-art methods on various singing datasets. We demonstrated that both pretraining and finetuning on speech data contribute to the final ALT performance and that pretraining brings more performance gains than finetuning on speech data. Additionally, our method still showed competitive performance using only a tiny proportion of training data, indicating its potential in low-resource scenarios.

7. ACKNOWLEDGEMENT

We would like to thank anonymous reviewers for their valuable suggestions. We also appreciate the help from Emir Demirel, Gabriel Meseguer-Brocal, Jens Kofod Hansen, Chitralekha Gupta for providing datasets. This project is funded in part by a grant (R-252-000-B78-114) from Singapore Ministry of Education.

A NOVEL DATASET AND DEEP LEARNING BENCHMARK FOR CLASSICAL MUSIC FORM RECOGNITION AND ANALYSIS

Daniel Szelogowski **Lopamudra Mukherjee** **Benjamin Whitcomb**

ABSTRACT

Automated computational analysis schemes for Western classical music analysis based on form and hierarchical structure have not received much attention in the literature so far. One reason, of course, is the paucity of labeled datasets — which, if available, could be used to train machine learning approaches. Dataset curation cannot be crowdsourced; one needs trained musicians to devote sizable effort to carry out such annotations. Further, such an analysis is not simple for beginners; obtaining labeled data that can capture the nuances of a musician's reasoning acquired over years of practice is fraught with challenges. To this end, we provide a system for computational analysis of classical music, both for machine learning and music researchers. First, we introduce a labeled dataset containing 200 classical music pieces annotated by form and phrases. Then, by leveraging this dataset, we show that deep learning-based methods can be used to learn Form Classification as well as Phrase Analysis and Classification, for which few (if any) results have been reported yet. Taken together, we provide the community with a unique dataset as well as a toolkit needed to analyze classical music structure, which can be used or extended to drive applications in both commercial and educational settings.

1. INTRODUCTION

Musical form analysis is the process of analyzing classical music pieces based on structure, themes, harmonies, and the relationship between them. This includes the large form (i.e., the musical "template" defining the piece's overall structure) and the hierarchical breakdown of themes, phrases, and often other substructures, including cadences. It has applications in various areas of music, such as music education, music analysis, forensic musicology, and so on, which we will discuss shortly. Typically, this task is carried out by music theorists benefiting from formalizations that have evolved over the centuries. However, form analysis is considered challenging, both for human analysts and signal processing algorithms. For humans, it takes years of training to learn to *understand* (not just read) classical music well enough to classify its structure. On the other hand, developing an ML-based approach is hindered by the difficulty of formulating this in a way that can be successfully learned as a computational task. Indeed, the curation of labeled datasets, a central ingredient in the success of supervised machine learning models, is prohibitive in terms of both time and money. First, it would require highly skilled musicians as annotators. Second, the dataset size is open-ended. With little guidance from the literature, it is also not obvious what sample sizes may be meaningful to get a basic model operational. Thus, budgeting is risky, even for a feasibility study, with assured cost overruns.

Motivation: The above challenges notwithstanding, let us consider the potential value for some key applications, *if* such a resource were publicly available.

Audio Thumbnail and Fingerprint Generation: Such a system can enable audio thumbnail/fingerprint generation for classical music where the user can quickly grasp the key sections without listening to the entire piece. This can be beneficial in marketing a piece of music as a product in a streaming service or web store (iTunes, Amazon Music) to draw in revenue for content creators [1–3].

Copyright Detection and Forensic Musicology: Such a system can also facilitate Forensic Musicology, which compares numerous pieces for similar or exact replications of musical phrases, motives, or other structures [1, 4].

Data Mining for Anthologies: Such a system can drive the production of musical form/analysis-based anthologies, alongside other fields of musicology where significant computational research is still in its early stages [5–7].

Music Education and Pedagogy: So far, music education and evaluation are purely human-guided. The availability of such a tool can facilitate the development of music practice and analysis software, such as dividing a piece by themes for rehearsal, assignment generation, or a grading system for human-analyzed scores. During a transitional time where many educational formats are moving to a hybrid setup, these developments will be a net win [8, 9].

Other potential applications also include Audio classification and Generalized Audio Structure Analysis.

Limitations of existing methods: In spite of the clearly defined need, existing structural analysis methods have been investigated almost exclusively in the context of popular music and for such tasks as segmentation of a piece into intro, verse, chorus, bridge, and outro [10]. These ideas cannot be directly applied to classical music: the for-

Whitcomb, "A Novel Dataset and Deep Learning Benchmark for Classical Music Form Recognition and Analysis", in *Proc. of the 23rd Int. Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

Figure 1. Example of phrase labeling from analysis of Bourrée from J.S. Bach's BWV 996 on a human-annotated score, where the relation between phrases and their respective part can be seen hierarchically. On an analyzed score, it is standard that only the first instance of a structure is labeled, although it may continue far beyond the initial instance.

mal structure in classical music is much more complicated and includes multiple forms which do not appear in popular music. Further, beyond form classification, one can also classify a musical piece into *phrases*, which typically correspond to smaller units within the piece. While classical music form analysis shares some similarities to poetic form at the *part/section* level(s) ($A\prime$ or stanza), which can be likened to popular music form (i.e., Verse-Chorus), the phrase-level analysis is drastically different due to the hierarchy of musical structures involved and a vast number of possible labels. In addition, classical music forms apply to the majority of pieces of classical music (given the large variety of large form structures). This means the form structure should be applicable to the audio (or the sheet music) by itself without the need for the segmentation of lyrical structure since a large majority of classical pieces are entirely instrumental or only partially lyrical.

Limitations of available datasets: The closest related dataset available, the Structural Analysis of Large Amounts of Music Information database, or SALAMI [11], lacks standardized conventions for the purpose of allowing for genre flexibility. It uses live recordings for time-relational analysis rather than basing timestamps on the sheet music or the score. This is not very useful for classical music since different conductors and performers often take drastically different tempi (which may be adjustable, but we seek the best overall system performance for this benchmark) and may omit or add repeats, therefore the audio cannot be compared to the sheet music directly. Hence, the use of this dataset for our goals is unfeasible.

Our Contributions: This paper provides a starting point for automated analysis of classical music forms and phrases. First, we introduce a new dataset, the **Standardized Musical Form and Structure Analysis (SMFSA) Database**, [1] consisting of 200 manually classified MIDIs, which use common analytical conventions and have categorical divisions by large musical forms. To demonstrate the use of the dataset, we also develop a deep learning-based framework to perform full form analysis, including form classification, segmentation, and part/phrase labeling. Together, this provides a comprehensive system for automated analysis of classical music, which is not otherwise available. This work provides the starting point for further development of computational techniques devoted to classical music as well as stimulating the development of numerous end-user applications.

[1] The database, research [12], and all code for this project can be found in [13]. The dataset was compiled from open sources, including [14–18].

2. RELATED WORK

While there are methods to perform genre classification, musical segmentation, and single-label segment classification in popular music, none have focused on the analytical process used by classical musicians specifically. These systems typically focus on popular music tasks including Verse-Chorus classification/segmentation [19] and genre classification [20], as well as segmenting a piece by phrases [21] — albeit without classifying. Next, we discuss a few related methods in chronological order.

Hörnel and Menzel [22] presented a melody and harmony generator using Feedforward Neural Networks to analyze musical and structural data in order to learn the characteristics of the writing style of a composer. However, their models were unable to learn higher-level musical structures occurring at multiple time scales simultaneously or recognize the melodic versus harmonic context of notes and intervals. Ponde de León and Iñesta [23] provided a framework for automatic musical style recognition of digital scores (MIDI) through the classification of rhythmic, harmonic, and melodic descriptors using k-Nearest Neighbors (k-NN), Bayesian classification, and Self-Organizing Maps (SOMs). Ullrich et. al. [24] discussed the importance of boundary recognition in structural music analysis using Convolutional Neural Networks (CNNs). Their model was trained on annotated Mel-scaled log-magnitude Spectrograms (MLS) [24] (from SALAMI) to peak-pick the onset boundaries of a given piece. Grill and Schlüter [25] further improved this model by assigning labels to digital audio using the MLS, Self-Similarity Lag Matrices (SSLMs), and human-annotated data (again from SALAMI). O'Brien [26] proposed an extension to the CNN architecture in [24] using the matrices derived from the Non-negative Matrix Factorization of a piece of music and identifying boundaries using segment association. O'Brien also noted that two major issues with their model were the lack of model memory in the CNN (i.e., the lack of LSTM or Recurrent cells) and the architecture had to be expanded to allow for a larger dataset [26]. De Berardinis et. al. [27] discussed the challenges of automatic musical structure detection and the issue of most current algorithms only being able to produce flat segmentations that cannot be applied to reveal the hierarchical structure of the piece. As such, they presented a new system for this task using multi-resolution community detection and graph theory to perform boundary detection and structural grouping, yielding a structural hierarchy. They noted that the method might also be used for structure visualization and finer-level musical structure analysis using tree representations to reflect additional structural relationships, and that CNNs will continue to lack improvement without recurrent layers or unsupervised methods.

3. METHODS

Next, we describe the key components of our model, starting with the dataset collection, the network architecture of the form analyzer, as well as a peak-picking scheme needed as input for the phrase analyzer.

3.1 Data Collection

We constructed a dataset — the **SMFSA Database** — consisting of 200 pieces of classical music in MIDI format [2] (for ease of score conversion, error correction, and signal processing). For each piece, we have an accompanying text document containing the form classification and part/phrase labels with their respective timestamps (obtained from the sheet music analysis performed by a human annotator), [3] written in a format similar to the SALAMI dataset. To represent the audio signals, the Mel Spectrogram was first generated by resampling the audio with a sample rate of 44.1 kHz, then computing the Short-Time Fourier Transform (STFT) over the entire signal with a hop length of 6144 (0.139 seconds per frame, see [28]) and 8192 samples per frame (a window size of 0.209 seconds per frame multiplied by the sampling rate). Further, to extract meaningful representations from the raw data, we obtain the 2D Self-Similarity Matrix (SSM) [25] of the Mel Spectrogram, constructed from various attributes and similarity metrics as well as the duration of the piece to create the set of features. The final tabulated dataset contains the mean and variance arrays for the following features: Mel Spectrogram SSM, Mel-Frequency Cepstral Coefficient (MFCC) Spectrogram SSLMs (Euclidean and Cosine distances), Chromagram SSLMs (Euclidean and Cosine distances) [24], as well as 15 other features. Since only 200 data samples may not be enough for many training tasks, we extend our dataset to 1200 by augmenting the dataset using speed shifting, pitch shifting, time shifting, and noise injection [12, pp. 41-46]. The features were extracted similarly for the augmented dataset as well.

3.2 Form Analyzer Architecture

Our goal is to identify a piece of classical music as one of the following 12 forms: Arch, Bar, Binary, Minuet & Trio, Ritornello, Rondo, Sonata (-allegro), Ternary, Theme & Variation, Through Composed, Unary/Strophic, and Unique. Note that not all of the forms are equally distributed in the dataset (reflecting real-world musical pieces) and this leads to a class-imbalanced multi-class classification problem (see Supplement Figure 3 for the relative proportion of each form in the dataset). To address this problem, we adopt a framework that implements an ensemble of decision trees using a neural network, which has been shown to work well for class-imbalanced multi-class datasets [29, 30]. We note that other alternatives such as focal loss [31] or imposing fairness in terms of model performance across each pair of classes can also be used [32].

In our implementation, we use the TreeGrad approach by [33], which implements Gradient Boosted Decision Trees as Neural Networks and has been shown to have a small computational footprint. TreeGrad is an extension of Deep Neural Decision Forests (DNDF), which treats the node split structure of a decision tree as a neural network architecture search problem. Similar to DNDF, they have three layers: a *decision node* layer, a *routing* layer, and a *prediction* layer [34]. The decision layer consists of decision stumps, each of which computes the probability of routing the data node x to (left/positive or right/negative) child nodes for a node n and is formulated as (shown here only for the positive route) $d_n^+(x;\theta_+) = \sigma(\theta_+^{\mathrm{T}} x + b)$, where θ_+ are the learnable parameters and σ is a temperature-controlled softmax function. These routing probabilities (both positive and negative) of all nodes are then concatenated to yield $D(x;\tilde{\theta})$, which is the output of the first layer. The parameter vector in $\tilde{\theta}$ forms the linear decision boundary that results in how each node is routed. This is followed by the routing layer, which computes the probability that each node uses to route a data point to a particular leaf. For this step, we use a binary preconstructed matrix Q of size $l \times 2n$, where l is the number of leaves, and n is the number of internal nodes. This allows for enumerating the relationship between nodes and leaves. This layer computes μ_l which indicates the probability of reaching a leaf l and can be written as

$$\begin{aligned}\mu_l(x|\theta) &= \textstyle\prod_{j=1}^{n}(D(x;\tilde{\theta}_j) \odot Q_l + (1 - Q_l)) \qquad (1)\\ &= \exp(Q_l^{\mathrm{T}} \log(D(x;\tilde{\theta}))\end{aligned}$$

where Q_l is the l-th row of Q and $\odot$ is the Hadamard Product [33]. We then pass it through a softmax activation function to produce the output of the second layer. The final output layer is the leaf layer which is a fully connected layer. The activation function used here is $\exp(x)$. See Figure 2 for an illustration of the network architecture.

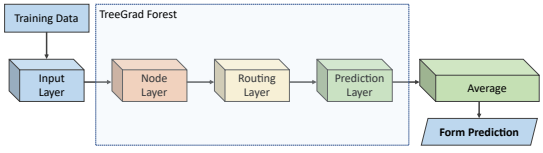

Figure 2. Architecture diagram of Form Analyzer

3.3 Phrase Analyzer Architecture

Recall that phrase analysis is a significantly more challenging task than form. To be able to learn phrase analysis similar to a musician, the model must be able to differentiate between musical events that can be labeled as having only the part label (*CODA*, *Episode 1*, *Middle Entry*, etc.), or only the phrase label (a, $a\prime$, b, *transition*, *melodic (variation)*, etc.) or both part and phrase labels. This presents several problems – the first deals with making the subtle distinction of when to assign both labels or just one, as well as choosing a suitable metric that captures the similarities correctly. Moreover, labels for varied phrases are also extremely difficult to grade, as a phrase (or part) may be repeated with a different harmonic goal (phrase a to a'

[2] While VSTs may differ across sequencing software, the Form Analyzer and Peak-Picking algorithm are intended to be instrument-neutral methods. As such, the timbral difference is negligible — including running the algorithm on different rendered sequences of the same pieces; we only seek to discover how the pitches are distributed structurally and temporally.

[3] We simply follow the human annotations from the original analyzed sheet music and copy these exactly at the time of their occurrence (in seconds, i.e., Part B with phrase d occurring at 15.27 seconds would be written as "15.270 B, d"), of course omitting the implicit labels as well.

or Parts A and A'). Variations of a can be either the same variation a' or a new variation a'' or a''' (these varied repetitions sometimes continue beyond 3, such as a^4 and so on). Since scoring such variations can be different based on the annotator, for experimentation on our dataset, we simply reduced the label set to remove prime marks and retain the phrase/part letter(s). Likewise, large and/or hybrid forms (such as Sonata-allegro form) in our dataset which have their own unique labels are simplified (during experimentation) to the letter label set with parts A, B, A'.

The task of Phrase Analysis requires labels to be provided with the form of the piece as well as the knowledge of where the musical phrase starts — a problem potentially solved using Onset or Peak Detection [25]. To do this, we implement a simple algorithm for peak-picking based on existing literature which is described next. The timestamps of the peaks, along with the output of the Form Analyzer (which is added as a feature), are provided as input to the Phrase Analyzer, where labels are classified sequentially (shown in Figure 4). We describe its components next.

3.3.1 *Onset Detection – Peak-Picking for Phrase Events*

To find the timestamps (in seconds) of the musical phrases, we use a reduced version of the peak-picking algorithm described in [35]. This algorithm computes the Mel Spectrogram and Self-Similarity Lag Matrix (SSLM) Chromagram (a group of pitch class distributions over time) to perform the onset detection. The Chromagram SSLM is computed using the Mel Spectrogram, which is clustered by pitch-class using k-Nearest Neighbors. The audio frames captured by the Short-Time Fourier Transform (STFT) are represented as a computed vector of peaks, which is returned as an array of timestamps. The choice of this scheme was based on preference for ideas that are common in the community, and we verified that it was comparable to other CNN architectures [36] and also greatly reduced system design time, given that training was not needed (since the approach was unsupervised).

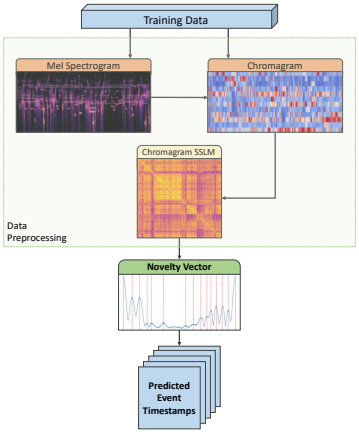

Figure 3. Schematic diagram of Peak-Picking algorithm

3.3.2 *Bidirectional LSTMs for Phrase Classification*

Using the onset detection method, the musical piece is essentially segmented into smaller phrases (i.e., the musical content between timestamps t and $t+1$ is denoted as feature vector x_t). Therefore, we think of a piece X as a collection of phrases $\{x_1, ..., x_T\}$, which occur in sequence. The task is to tag each phrase with a label for the phrase and/or the part. In all, we use 9 phrases, 9 parts, and 5 variations (phrase labels used for Theme & Variation pieces) for the labeling; specific names of these are provided in the Supplement. Clearly, the specific labeling associated with a phrase is dependent on what came before it, as well as what comes after. Therefore, we propose to use Bidirectional LSTMs to capture the dependence in such sequence data and replicate segment-segment similarity analysis.

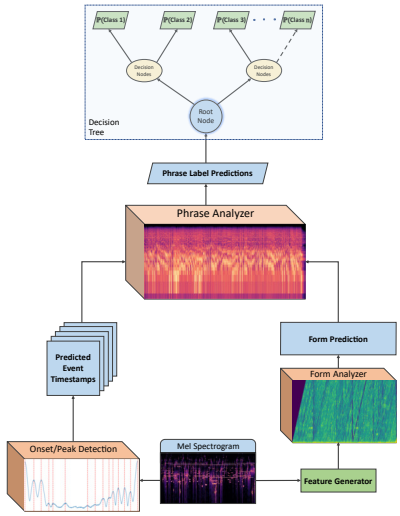

Figure 4. Architecture diagram of Phrase Analyzer

We now discuss the network architecture. X is passed as input to a Bidirectional Long Short-Term Memory (LSTM) [37] network. LSTM networks can capture long-term dependencies in temporal data and have been successfully used for a number of time series classification problems. LSTM (similar to Recurrent Neural Networks (RNNs) [38]) contains loops in its architecture that allow it to memorize previous states such that the network can effectively process temporal data. A typical LSTM layer consists of a set of recurrently connected blocks, known as memory blocks. Each block contains one or more recurrently connected memory cell (c^t) and three multiplicative units - the input (i^t), output (o^t), and forget gates (f^t) which regulate the extent to which data is propagated through the LSTM unit. The operations inside an LSTM block can be formulated using:

$$\begin{aligned} f_t &= \rho(W_f x_t + U_f h_{t-1} + b_f) \\ i_t &= \rho(W_i x_t + U_i h_{t-1} + b_i) \\ o_t &= \rho(W_o x_t + U_o h_{t-1} + b_o) \\ \hat{c}_t &= \phi(W_c x_t + U_c h_{t-1} + b_f) \\ c_t &= f_t \circ c_{t-1} + i_t \circ \hat{c}_t \\ h_t &= o_t \circ \phi(c_t) \end{aligned} \tag{2}$$

Here ρ and ϕ are activation functions, $\circ$ denotes the element-wise product operation, x_t is the input vector, W and U are weights, and h_t is the hidden state vector — also known as the output vector of the LSTM unit. Because of the dependence on both past and future phrases, we use a Bidirectional LSTM (Bi-LSTM), which includes both a forward and backward layer of LSTMs. Both the forward and backward layer outputs are calculated by using the standard LSTM update equations (2). Then, Bi-LSTM

connects the two hidden layers to the same output layer. More details about Bi-LSTMs can be found in [39, 40].

To perform the final classification, the Bi-LSTM is connected to a Decision Tree to provide the label(s) for each timestamp. To accomplish this, we used the feature vector output from the (Time Distributed) Dense layer as the training set for the tree, which is fit along with the original set of labels. Once the tree is combined with the Bi-LSTM, it can be used to provide the final prediction for new timestamps. Using this approach also helped greatly decrease the training time of the Phrase Analyzer model and reduced the overfitting that the LSTM would suffer from by itself.

4. EXPERIMENTS

We evaluate each component of our system individually as well as a whole for the Phrase Analyzer, which utilizes all the components. For all the experiments, we utilize the entire augmented dataset, where 85% of the data was used for training, and the rest is used for testing.

4.1 Form Analyzer Evaluation

Setup: The Form Analyzer model takes in the features as described in Section 3.1 (the duration and Mel Spectrogram SSM) and outputs the predicted classification, which is compared against the "ground truth" label in the dataset. To turn the Mel Spectrogram SSM into a usable feature vector, we calculate the mean of the SSM to obtain a 1D array, which the model receives with the duration appended. Note that we can use the Form Analyzer architecture as a standalone model to identify the form of the musical piece. This can be useful to search a musical database by forms or for a musicologist to understand when and why a composer may choose a particular form over another. On the other hand, it can also be used to provide input to the Phrase Analyzer. Therefore, we evaluate its efficacy independently to evaluate its performance compared to other methods. The augmented dataset was split into 85% training and 15% testing for cross-validation, [4] and the analysis model was evaluated using the classification accuracy in addition to other metrics such as Precision, Recall, and F1 scores.

Parameters: The TreeGrad model was tuned to 31 leaves per tree, an unbound max depth, 100 estimators (trees in the forest) with refit splits enabled, and the learning parameters include $\alpha = 0.1$ and a batch size of 32.

Results: The final Form Analyzer model achieved a classification accuracy of 83.9% — a surprisingly good performance given the subjective nature of the form classification, as many of the "inaccurate" classifications may be subjectively true based on personal bias. We compared our model with a number of other classification methods — 2D CNN [41], 2D CNN Ensemble [42], 1D CNN [43], Autokeras [44], Neural-SVM [45], XBNet [46], DJINN [47], and an implementation of Neural Decision Trees [48]. In the plot in Figure 5 (left), our model outperforms other methods significantly. The next closest approach is the decision tree method, illustrating that the decision tree-based approaches indeed works better for this data. Note that the model can be further fine-tuned by using a different boosting method. Furthermore, our method reported a Precision value of 85%, whereas both Recall and F-Score were 84%.

In addition to numerical accuracy, we wanted to study the mistakes in our method and how others performed in identifying the forms, and whether some specific forms were commonly misclassified as others. For this, we compared the confusion matrices from each approach. To compare the confusion matrices numerically, we compute the confusion entropy [49] for each — this is shown in Figure 5 (center and right). Confusion entropy is computed by exploiting the class distribution information of misclassifications of all classes as other classes (off-diagonal elements of the confusion matrices) and is an appropriate measure for this purpose. The results show overall, our method has the lowest entropy. The confusion entropy for each class (Figure 5 (right)) shows which classes were harder to classify. Here we found that our method has an entropy of $.24$ even for the worst-performing class. In addition, by quantitative analysis, a common theme we found is that most models tended to confuse forms that are typically similar in length (binary/unary, theme & variation/sonata, etc.) or hybrid/compound forms and their derived form (e.g., sonata/binary) even though for our model, such misclassifications are minimal.

4.2 Peak-Picking Algorithm Evaluation

Results: While the onset detection algorithm was not evaluated by a formal metric, it was tested against the training data, and the output timestamps were found to be nearly identical or had a low enough difference to be subjectively true (similar to the bias of a human analyst). The output of the algorithm was compared to numerous hand-labeled pieces from the dataset, and the difference was found to be negligible for most pieces (around $\approx \pm 5.269$ seconds on average), with the greatest absolute time difference being $\approx \pm 14.823$ seconds for pieces much greater than 6 minutes in duration. This metric was based on the approach found in [25]. The algorithm was also found to be comparable to other machine learning approaches such as SOMs [23] and CNNs [24]. Our result was based on a comparison between the "ground truth" and predicted timestamps in the validation dataset by index pairs rather than by the pair of closest timestamps since the algorithm may report more or fewer events than our own analysis.

4.3 Phrase Analyzer Evaluation

This model is much more difficult to evaluate using a classification evaluation metric due to numerous factors that vary from conventional machine learning classification models. First, the model gets the timestamps from the Peak-Picking algorithm, which is difficult to compare to human-annotated scores (our "ground truth") due to integrative disagreement (i.e., a group of analysts would need to collectively agree on a ground truth as their analyses will likely vary). The labels are also often highly subjective and vary by the judgment of the annotator. In addition, some of the labels are implicit (for example, Part A continues until timestamp n but is only labeled at the first occurrence).

[4] The dataset is sorted alphabetically by form per augmentation; other permutations typically performed the same or worse.

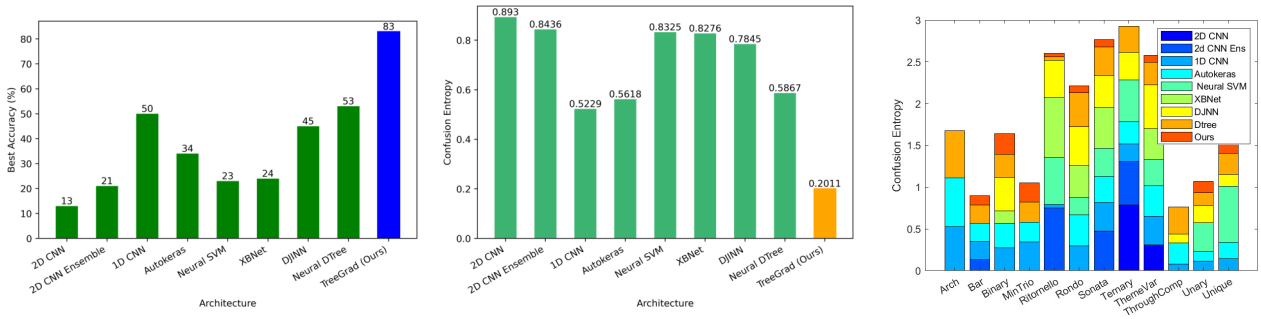

Figure 5. Form Analyzer Architecture Comparison with other methods (left), Confusion Entropy calculated for each method (center), and the class-wise Confusion Entropy for each method (right)

Therefore, we decided not to use a $0/1$ accuracy metric but a more realistic one based on how a music theory expert would grade the labeling of other musicians (such as in a music theory class) based on a rubric. Such rubric-based grading is commonly used in case of challenging problems such as automated essay and clinical note grading [50, 51].

Setup: We design a rubric as follows: we score each labeling in $[0, 1]$ giving a score of 1 if the part and/or phrase match perfectly, but also have a variety of other values in $[0, 1)$ for partially correct labeling. These partial score scenarios cover a range of possibilities, such as if either the part or phrase but not both has been guessed correctly, the degree of similarity of the predicted phrase to the actual phrase, and accounting for the fact that time stamping may be off by a few seconds. These partial scores are ordered from high to low depending on the extent and multiplicity of the issues mentioned above. The rubric is presented in the Supplement, and the code to do this grading on the output of the system will be provided with the dataset [13].

Parameters: The LSTM-Tree model has 4 LSTM units with a dropout rate of 0.2, a batch size of 10, sigmoid activation, and the learning parameters use the binary cross-entropy loss function, Adam optimizer, and 5 epochs.

Results: We evaluated the phrase analyzer using other state-of-the-art methods such as 1D CNN, RNN, and Feed-forward Neural Network and used the same rubric to come up with a weighted assessment score of the predicted phrases. We found that our LSTM-Tree architecture outperformed other NN architectures — our model reported a weighted score of 79.16%, whereas the best of the comparable methods reported a score of 77.75% (see Supplement Figure 1 for a plot related to this). A qualitative evaluation of the results reveals our LSTM-Decision Tree method produced labels that are more consistent with a human analyst (who is prone to some errors) even on one attempt, whereas for some of the other methods, the labelings are more random and less interpretable. These results show that the LSTM-Decision Trees not only substantially increased accuracy quantitatively for the Phrase Analyzer but also gave reasonably realistic phrase labels.

5. DISCUSSION

Here we briefly discuss some possible extensions and improvements to the dataset as well as methods presented in the paper. On the dataset front, we hope to expand the number of pieces as well as add additional annotators. The current dataset also features class imbalance; anthologies of classical music classified by form are lacking, [5] though our system could be employed to assist in the compilation of such a database. A more sophisticated system may also greatly benefit from restructuring the analysis labels in the database to the standards specified in [54]. On the method front, an obvious area of improvement is the Peak-Picking algorithm, which can be replaced by a deep learning approach such as CNN or LSTM so that the whole network can be considered as one large deep learning system and parameter weights learned jointly. The Phrase Analyzer model can also benefit from the inclusion of Curriculum Learning or a Human-in-the-Loop type of approach, much like that of a traditional Form and Analysis class — though a Sequence-to-Sequence or Autoencoder model may also be useful in developing a faster/more accurate system.

6. CONCLUSION AND FUTURE WORK

In this paper, we introduce a new dataset, the **SMFSA Database**, accompanied by deep learning benchmark methods to analyze classical music forms and phrases. To the best of our knowledge, this is the most comprehensive study of a computational approach used toward classical music structure analysis. While the current system is specific to classical music, it could be extended to classify numerous additional forms (e.g., through transfer learning or an extended architecture), such as those found in popular music, ethnomusicology, and more complex hybrid forms. Another difficult task lacking substantial research is Optical Music Recognition (OMR) — our methods could potentially be extended to perform both visual music analysis and the classification/segmentation on the score directly (i.e., in the style of a human analyst). The system may also be extendable for use in Forensic Musicology and Copyright Detection systems, using the output analysis from the system to compare multiple pieces of music for potentially similar or exact replications of musical phrases.

[5] Green's book on Form Analysis [52] was found to be the most useful and accurate resource resembling such an anthology, whereas other resources were presented as anthologies for analysis rather than classified works. As such, our dataset was built primarily on the pieces (and musical forms) selected in this book (including some from [53] as well) to serve as a common ground for analysis.

ABSTRACT

Audio Fingerprinting (AFP) is a well-studied problem in music information retrieval for various use-cases e.g. content-based copy detection, DJ-set monitoring, and music excerpt identification. However, AFP for continuous broadcast monitoring (e.g. for TV & Radio), where music is often in the background, has not received much attention despite its importance to the music industry. In this paper (1) we present BAF, the first public dataset for music monitoring in broadcast. It contains 74 hours of production music from Epidemic Sound and 57 hours of TV audio recordings. Furthermore, BAF provides cross-annotations with exact matching timestamps between Epidemic tracks and TV recordings. Approximately, 80% of the total annotated time is background music. (2) We benchmark BAF with public state-of-the-art AFP systems, together with our proposed baseline *PeakFP*: a simple, non-scalable AFP algorithm based on spectral peak matching. In this benchmark, none of the algorithms obtain a F1-score above 47%, pointing out that further research is needed to reach the AFP performance levels in other studied use cases. The dataset, baseline, and benchmark framework are open and available for research.

1. INTRODUCTION

Audio Fingerprinting (AFP) is the information retrieval task of identifying audio recordings in a given database of reference songs. The task is based on extracting content-based signatures that summarize an audio recording (*extraction*) [1], storing them in a database or in hash tables (*indexing*), and efficiently linking short snippets of unlabeled audio to the same content in the database (*matching*).

AFP has been successfully applied to different tasks such as query by example [2], advertisement tracking [3], integrity verification [4], and data deduplication [5]. A relevant AFP application is broadcast monitoring for its crucial role in royalties distribution. In 2021, US$ 2.9 billion were distributed among rights holders [6], representing 11.5% of the global recorded music industry revenues.

A great AFP system for broadcast monitoring must provide exact start and end timestamps within long audio recordings. It also must be robust against common distortions in broadcasting like music being in the background and with low SNR. To the best of our knowledge, the literature has not addressed the AFP use case of broadcasting monitoring with a heavy presence of background music. In this scenario, music may have a very low Signal-to-Noise ratio (SNR) that makes it difficult to identify [7]. Moreover, music may be masked by a large variety of non-musical sounds, such as speech, applause, laughter, urban and nature sounds, etc. [8].

To promote research in AFP for broadcast monitoring we propose BAF: a Broadcast Audio Fingerprinting dataset with TV recordings in which production music is played. The references are part of Epidemic Sound's private catalog [9], a collection of music for content creators (production music). BAF reflects a challenging (but realistic) scenario [7] for broadcast AFP systems: low sample rate monaural audio, background music of variable SNR, a large variety of contexts, long queries with true negative sections, and matches of multiple durations. More details about the dataset can be found in Section §3.

In order to show the challenges that BAF presents, in Section §4 we present a benchmark with 4 of the available AFP algorithms: Audfprint [10], Panako [11, 12], Olaf [13], and NeuralFP [14]. These are open-source implementations that represent different approaches to AFP. In addition, we propose an open implementation of a simple baseline based on spectral peak matching and the evaluation framework used in the benchmark.

2. RELATED DATASETS

In this section, we present public datasets that have been used in the AFP literature. We also gather information about the contents of private datasets and depict them in Table 1. We include information about the queries, references, and the goal of the dataset or publication. We have found in the literature 21 datasets that have been used for

Table 1. Private (top ↑) and public (bottom ↓) datasets that have been used for AFP. For each dataset information about the queries, references and the goal of the original work is given. Synthetic (✓) queries have been created by applying transformations to reference audios. We also indicate if the queries are excerpts and the number of original audio pieces that have been transformed, not meaning the total number of queries after the transformation.

AFP. Even though the nature of the data varies from each dataset, most of them rely on the same principle: a private collection of tracks that constitute a reference set and a query set formed by applying transformations to some of the references. This is a good way to test the limits of the robustness to degradations like pitch-shifting or time-scaling. Still, it does not target the characteristics of realistic broadcast monitoring, where the music is in the background, masked by speech and a wide variety of sounds and noises (See Section §3.3.1 for a detailed analysis).

As Table 1 reflects, only 6 out of the 21 datasets are public, mainly due to the difficulty of legally publishing copyrighted music. In other cases, data remains private to protect intellectual property, as with private companies. To that extent, private datasets hinder reproducibility and slow-down scientific progress in AFP research. Of all private datasets, only the ones built by Fenet et al. [20] reflect the use case of broadcast monitoring: they use real radio broadcasted emissions as queries and a reference set of 459 songs. Moreover, only Fenet's [20], Sonnleitner et al., [24] and Walter and Gould [25] used unknown audios as queries. All other works used a version of the reference songs often modified with some degradation: echo, pitch and/or tempo alteration, reverb, etc. Besides these private datasets, there are some other public datasets that have been used in AFP works, even though none of them fits the broadcast monitoring task.

MagnaTagATune [29] is a public dataset created for Music Tagging. Each audio clip has associated a vector of binary annotations of 188 tags that describe the music piece. The dataset was used for AFP by Ramona and Peeters [30] in which they followed the experimental protocol of Haitsma and Kalker [15] applying a series of distortions like Amplitude dynamic compression, MP3 encoding, time-shifting, or equalization to 500 music clips from MagnaTagATune.

NIST-TRECVID [31, 32]. One of the tasks the TREC Video Retrieval Evaluation (TRECVID) proposed until 2011 was Content-Based Copy Detection (CCD) [36]. Various works [33–35] used the dataset provided with the task to evaluate AFP algorithms. The length of queries varies from 3 to 180 seconds and compromises multiple transformed fragments from 201 unique audio recordings.

Mixotic [24] was created by Sonnleitner et al. to test the robustness of QuadFP, Panako, and Audfprint in real DJ mixes. It was generated from free, CC-licensed DJ mixes that were published on mixotic netlabel.

Panako [11], **QuadFP** [23, 37] and **NeuralFP** [14] present public datasets that were curated to test their algorithms. Since these datasets are reproducible we list them as public AFP datasets, but in the case of Panako and QuadFP they share a script that downloads tracks from Jamendo instead of the audio files. It can happen that some audio works are not available anymore thus impeding the reconstruction of the dataset. NeuralFP shares the audio files since they come from the FMA dataset [38]. It was trained on 10k FMA songs and tested on a larger set of 100k songs ($\approx$ 8,000 hours).

3. BAF DATASET

This section describes the characteristics of BAF: Broadcast Audio Fingerprinting dataset. It is the only available dataset designed for broadcast monitoring. BAF contains TV recordings, reference tracks, and annotations done by 6 different annotators that cross-annotated matching queries and references. It is a self-contained dataset available upon user's access request. Open for non-commercial, research-only, with no adaptations or derivative works allowed and proper attribution. It must not be used for music generation or music synthesis research. Towards addressing ethical and sustainability concerns, we distribute a datasheet using the format proposed by Gebru et al. [39] with practical and detailed information about the dataset. Audio files, annotations, and the dataset datasheet are hosted in Zenodo [1] while the baseline code and evaluation scripts are in Github [2].

3.1 Methodology

The reference set contains 2,000 production music tracks (74 hours of audio) obtained directly from the Epidemic Sound [9] private catalog, described in Section 3.3.2. The queries are initially derived from TV stream monitoring on 478 TV channels from 43 countries, for a 2.5 months period at stereo maximum quality. We extract the audio with FFMPEG and we split the large audio files into 1-minute length queries.

As an automatic pre-annotation stage, we match queries with references relying on a proprietary stereo matching algorithm developed by BMAT. The algorithm is non-scalable and it relies on spectral peaks matching using stereo signals. It has been tailored to avoid false negatives, disregarding the presence of false positives and low computational efficiency. We then select all query segments that have at least one pre-annotation match. In addition, we discard queries matching more than 3 unique references since most of them contain false positives, which would be manually deleted during the later annotation process. Then, we shuffle all queries and select 3,425 of them, corresponding to 57 hours of TV broadcast audio from 203 TV channels across 23 countries. Finally, we convert all audios to publishing format: 8kHz mono, WAV `pcm_s16le`, a common specification in AFP [2, 14, 15, 34].

3.2 Annotation criteria

BAF has been annotated by six different annotators in a controlled environment. We built an in-house annotation web app in Django, secured by user credentials, in order to facilitate the annotation to remote users. The app displays all segments resulting from the automatic pre-annotation stage. Annotators were instructed to listen to the query and reference pairs, filter out false positives, and adjust the start and end times of the true positives with deciseconds precision. Queries with slight alterations with respect to the reference have also been annotated as true positives, such as versions with some missing stem (e.g. instrumental vs vocal), or 'edit' versions.

We ensured that each segment was annotated by three different annotators (sets of annotators created by random combination). We then created the cross-annotations with 3 different levels of agreement: *single, majority, unanimity*. These cross-annotations are the result of splitting annotations into segments and merging overlapping segments, assigning a tag depending on how many annotators marked a match in that time interval (1, 2, and all 3, respectively). Out of the 57 hours of queries, over 37 hours were marked as true positive by at least 1 annotator.

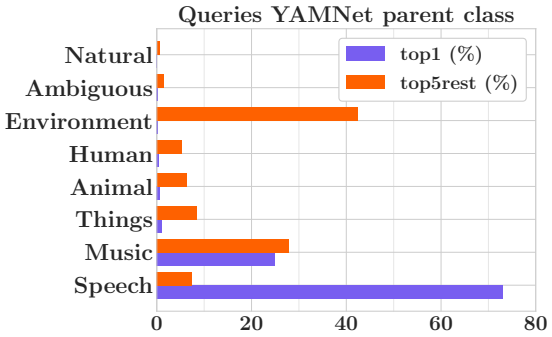

Figure 1. YAMNet classification of BAF queries. YAMNet uses a sliding window of length 0.96s and stride of 0.48s to generate one prediction for each step. Percentages are relative to each top classification.

3.3 Analysis

3.3.1 Queries

We have used the YAMNet sound event classifier [40] to study the most common sounds of BAF queries. YAMNet is a pretrained deep network that predicts 521 audio event classes based on the AudioSet-YouTube corpus [41]. Audioset ontology follows a tree structure so all classes are gathered under 7 different parent classes [42], from that, we extract *Speech* from *Human* as a separate class to better evaluate its presence. Figure 1 reflects that YAMNet's most predominant class is *Speech*, with 73% of the output predictions while only nearly 25% of them correspond to *Music*. Regarding the *top5rest* classes, *Environment* and *Music* are the most predominant, which means that noises and background music are common in the broadcast.

To obtain the YAMNet distributions we first run YAMNet for all queries and then select the outputs corresponding to the annotated segments. After that, we average the scores using a moving average window of length 2 to soften noisy scores. Lastly, we extract the top1 and top5 distributions and translate all labels to the corresponding parent class, following Audioset ontology. For each window, we remove from the top5 the parent class that matches that window's top1 parent class so with this, only the classes that are detected in the background remain. We name this distribution top5rest.

[1] `https://doi.org/10.5281/zenodo.6868083`
[2] `https://github.com/guillemcortes/baf-dataset`

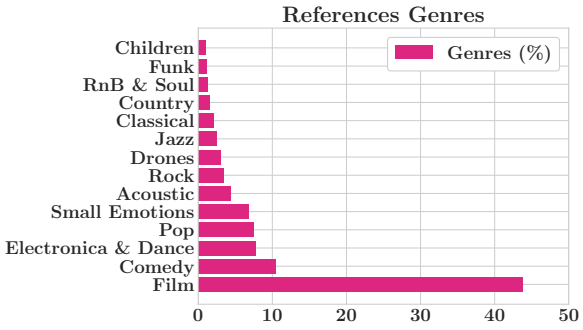

Figure 2. BAF references music genres. Only genres representing more than 1% are listed, the remainder represents 3% of the dataset.

In addition YAMNet predictions we used the MIREX 2019 Music Detection winner model [43, 44] to analyze BAF queries. The system is based on computing the Relative Music Loudness distribution [45] and classifies as *Foreground Music* only 18.07% of the total cross-annotated segments with the tag *unanimity* (segments all annotators agreed that there's music). Verifying the high presence of background music.

3.3.2 References

The BAF reference set is a selection of production music tracks from Epidemic Sound's private catalog of 35,000+ human-annotated tracks. In order to give valuable insights about instrumentalization, BPM, or genre, we have analyzed the tags and found that 7% of the selected tracks contain vocal elements like singing, while the remaining 93% are instrument-only versions. Figure 2 shows how the majority of the references are categorized as *Film music*, and cover styles/moods like Suspense, Drama, Build, Pulses, Small Emotions, or Solo Piano. Common keywords or tags found in this set of tracks include: comedic, piano, strings, driving, tension, corporate, guitar, and documentary. The references BPMs follow a Normal Distribution $\mathcal{N}(\mu, \sigma^2)$ with mean $\mu = 109$ and standard deviation $\sigma = 33$.

3.3.3 Matches / Annotations

Table 2 shows that 90.41% of the total annotated time (133,846 seconds) has been agreed by unanimity. Most of the differences between annotators come from divergences in start and end matching timestamps partially due to the difficulty to tell when a song starts or ends in a stream, especially with background music.

Additionally, to evaluate the reliability of annotators' agreement we compute the Fleiss' Kappa [46] indicator, a statistical measure of inter-rater reliability. It needs fixed-length elements to categorize them so we computed the Fleiss' Kappa indicator using 0.05 seconds length annotations. We obtained a factor of 0.9364 that can be interpreted as an almost perfect agreement [47].

3.4 Limitations

The size of the reference set is not large enough to mimic real production environments, where recordings are expected to be analyzed against tens of millions of tracks [25]. For future work, in order to study thoroughly the impact of False Positives (FP), a set of additional *noise* tracks should be added to the reference set. For this, public datasets mentioned in Section §2 could be used.

4. BENCHMARK

We benchmark the following available AFP algorithms: Audfprint [10], Panako [11, 12], Olaf [13], and NeuralFP [14] to study the performance of AFP in the broadcast monitoring use case. Additionally, we also propose a simple baseline that gives context to the results.

Audfprint is based on Shazam's algorithm [2]. It uses the locations of pairs of spectrogram peaks (local maxima points) as robust features for matching. **Panako** extends Shazam fingerprint by saving triplets of local maxima points in Constant-Q non-stationary Gabor transform. It uses time ratios to form a time-scale invariant fingerprint component. These components are hashed alongside a coarse value of the frequency position of the triplet, making it robust to time-scale and pitch modifications. **Olaf** is a lightweight AFP algorithm able to run in embedded systems. In the benchmarked version, it uses absolute exact frequencies and timestamps in the hash (like Shazam [2]) of triplets of peaks (like Panako [11]). It is not robust to pitch shifting or time distortions. **NeuralFP** is based on deep neural networks and created for high-specific audio retrieval using contrastive learning. It creates pairs of data applying distortions to short audio snippets so each batch of training data consists of randomly selected original samples and their augmented replicas. Then, it maximizes the inner product between pairs.

All algorithms except NeuralFP ran as they are published. NeuralFP, though, required changes in the indexing and matching modules to match the broadcast monitoring use case. The indexer now stores indexes on disk rather than on a memory map, and the matcher integrates the Maximum Inner Product Search used by the authors into PeakFP matcher pipeline, to be able to give start and end times of each match. The implementation [3] has been

[3] https://github.com/guillemcortes/neural-audio-fp

Class	%
single	3.69%
majority	5.90%
unanimity	90.41%

Table 2. Annotators agreement in percentage of annotation time length. *single* correspond to intervals where only 1 of the 3 annotators marked a match. In *majority* 2/3 annotators agreed while in *unanimity* there's full agreement.

validated by NeuralFP authors. Towards a fair comparison between systems, all algorithms return top1 matches. Audfprint and Olaf use the default configurations, Panako parameters are adjusted for 8kHz input signal and NeuralFP needs extra parameters for the custom matcher pipeline. Additionally, we study the impact of fingerprint density by increasing Audfprint (x2) and Panako (x1.5) peak density and also test two additional NeuralFP models *spcm1510* and *spc3000* that were trained with different levels of speech intensity [-15, 10] dB and [0, 10] dB, respectively. All configuration parameters used in this publication have been discussed with the authors of each respective algorithm and are available in the publication git repository.

Apart from the algorithms mentioned above, there are some others that we would have liked to benchmark, but no official public implementation of them was found. That is Fenet's et al. CQT approach [20], Google's Now Playing [26] lightweight, neural network-based, continuous monitoring system, and also Son's et al. FFMAP-based algorithm [27,48]. For QuadFP [23,49] and Waveprint [17] we tried to run third-party implementations but without success. We also plan to include Chromaprint [50], a public AFP implementation based on Ke et al. computer vision approach for music identification [51], and other algorithms to the benchmark.

4.1 Baseline: PeakFP

Available AFP systems aim at obtaining the best algorithm in terms of robustness, scalability, efficiency, etc. However, many existing systems are distributed as closed software packages or embedded into complicated frameworks which are difficult to adapt. Also, the literature lacks a simple and easy-to-use baseline that may be used as a starting point in AFP research. We address these issues by introducing PeakFP, a simple, open, non-data-driven, non-scalable, AFP algorithm based on spectral peak matching that it has been designed to be as simple as possible and not optimized for scalability, but at the same time, useful for detecting background music. While algorithms commonly use pairs or triplets of spectral peaks, PeakFP uses single-peak matching because pairs of spectral peaks are more prone to break when the SNR of the music signal is low due to music peaks being masked by other sounds. As a consequence, PeakFP is ineffective in front of pitch-shifting or time-scaling distortions.

PeakFP is divided into three modules: extractor, indexer, and matcher. They are designed to work independently following a simple pipeline we detail below. Note that the code of our implementation is available online (see Section 3). The extraction process involves finding peaks in a monaural audio magnitude spectrogram using a 2D max filter. Then, all the peaks (time-frequency tuples) are sorted by the time frame index and saved in a serialized binary file. The reference signature files are used to generate an inverted index on the peak frequency values. For a given frequency, the index contains the list of all occurrences of that frequency in every reference. The hash space comprises all the possible frequency values. This small hash space translates to a high quantity of hash matches that yield a high number of comparisons in the matching step. The matcher splits the peaks of the query recordings using a sliding temporal window defined by window length and hop size. Then, for all windows, it counts the common peaks for a specific query-reference time alignment similarly to Shazam [2]. After that, all matches go through a postprocessing stage in order to consolidate and resolve overlapping matches.

Figure 3. Proposed metric Match ratio. It defines the ratio between the number of identifications with respect to the number of annotations in the groundtruth.

4.2 Evaluation Metrics

A variety of metrics are used in the AFP literature for benchmarking and comparing algorithms, most of them based on classifying predictions into false positives/negatives or true labels [52], and using metrics derived from information retrieval such as True Positive Rate [11] Precision, Recall, and Specificity [2,23]. Other papers use Top-1 Hit Rate [14] or TRECVID's proposed evaluation metric Normalized Detection Cost Rate (NDCR) [33–35].

In broadcast monitoring, it is typically required to provide exact start and end matching timestamps for each reference identification. For this reason, we propose to use the percentage of identified seconds alongside to match classification into Precision, Recall, and F1-score.

Some algorithms are prone to give short overly-split matches, while others tend to generate longer matches that include gaps without annotations. Towards quantifying this we introduce a new metric *Match Ratio*, defined in equation 1 and depicted in Figure 3, that represents the ratio between the total correct identified segments (TP matches), and the total unique annotations identified, groundtruth (GT) segments.

$$\text{Match Ratio} = \frac{\#\text{ TP segments ID}}{\#\text{ TP segments GT}} \tag{1}$$

A Match Ratio value bigger than 1 means that some of the identifications belong to the same annotation. Conversely, a value lower than 1 indicates that the algorithm generates a single identification for a segment in which there is more than one unique identification according to the groundtruth. The value for an algorithm that perfectly matches the annotations is 1.

Algorithm	Match Ratio	# matches		seconds identified		
		Precision	GT Recall	Precision	Recall	F1-score
PeakFP (baseline)	1.64	.96	**.72**	.96	**.32**	**.47**
Panako2.0	1.85	**.98**	.21	**.98**	.06	.12
Panako2.0 (x1.5)	2.12	.70	.41	.69	.15	.25
Olaf	1.95	**.98**	.14	**.98**	.06	.11
NeuralFP	1.39	.22	.23	.37	.10	.15
NeuralFP-spcm1510	1.56	.23	.45	.38	.22	.28
NeuralFP-spc3000	1.40	.69	.31	.83	.13	.22
Audfprint	N/A*	.76	.05	.86	.02	.04
Audfprint (x2)	N/A*	.71	.10	.81	.04	.08

Table 3. Benchmark results on *unanimity* annotations. *Audfprint reports 1 match per query by default.

4.3 Results

Table 3 summarizes the performance of all benchmarked algorithms on *unanimity* annotations. All systems increase their Precision when considering the identified seconds because the False Positives identifications are shorter than the True Positives. At the same time, Recall decreases because the identifications are partial and do not cover the full annotation groundtruth. Hence the importance of studying also the performance in terms of identified seconds.

All algorithms except Audfprint obtain a Match Ratio > 1. This is caused because algorithms tend to detect small excerpts of the music (parts where the music SNR is higher) resulting in more than one identification per annotation. Audfprint only returns one identification per query by default, so its Match Ratio will always be 1 with this configuration. This also means that if a query has more than one annotation, Audfprint can't identify all of them.

The good Precision results (PeakFP, Panako, Olaf obtain over 0.96) should be analyzed taking into account that BAF is not challenging to False Positives since the reference set is limited to 2,000 references. The low Recall values show that there are a lot of identifications missed (False Negatives), manifesting that algorithms do not work well with background music or broadcast distortions. Increasing fingerprint density improves the F1-score in seconds identified: it helps to boost the Recall in both Panako (x1.5) and Audfprint (x2) but at expense of Precision.

Additionally, to frame the computational cost of each algorithm, we have benchmarked their extraction, indexing, and matching times as well as index size. Table 4 shows that Olaf is the fastest benchmarked system. On the other hand, PeakFP is the slowest even though the extraction process is quick due to its simplicity, but the reduced hash space yields a high collision of hashes that slows down the matching. NeuralFP extraction process takes a lot of time compared to others, mainly due to the deep neural network model complexity. This process can be sped up by running it on a GPU, where deep learning models operate more efficiently. For both Panako and Audfprint, the matching step takes x2.5 times longer than the extraction.

Algorithm	Extraction & Indexing	Matching	Index size
Olaf	53m	3h 30m	349 MB
Panako 2.0	2h 17m	5h 24m	273 MB
NeuralFP	49h 34m	9h 30m	37 MB
Audfprint	9h 50m	23h 01m	19 MB
PeakFP	50m	98h 39m	160 MB

Table 4. Computational cost benchmark.

Regarding the index sizes, Audfprint and NeuralFP generate the smallest indexes (19MB and 37 MB) to represent a set of 2,000 references (74 hours of audio). Olaf generates the biggest index with almost 350 MB, 18 times the size of the Audfprint index. Olaf would take around 1.75 TB for an industrial database of 10 million references while Audfprint would take 95 GB.

Experiments have been run in a reproduceable, isolated environment. All audios have been loaded on the RAM disk and ran on a 98GB RAM server with two 16-cores CPUs at 2.60GHz. We have executed each algorithm with multiprocessing (when it was possible) and cleared the cache before each run. The results in Table 4 are normalized to one single thread.

5. CONCLUSIONS AND FUTURE WORK

We present a new dataset for broadcast monitoring with 57 hours of TV broadcast recordings, 74 hours of production music, and over 37 hours of human cross-annotations. All audios are monaural sampled at 8kHz and more than 80% of the annotated music is in the background. The Benchmark of state-of-the-art public algorithms shows that AFP for broadcast monitoring with a high presence of background music is yet to be solved. For this task, in addition to other metrics used in the literature, we propose using the Match Ratio and analyzing Precision, Recall, and F1-score, especially in terms of seconds identified. We also provide a simple AFP baseline named PeakFP.

In future experiments, we plan to add noise tracks to the references set to study the evolution of False Positives and the scalability of each algorithm. We will get more insight into their behavior for different levels of background music, and we will benchmark more AFP algorithms.

6. ACKNOWLEDGEMENTS

The authors would like to thank Carl Thomé for making this collaboration possible. This research is part of *NextCore – New generation of music monitoring technology (RTC2019-007248-7)*, funded by the Spanish Ministerio de Ciencia e Innovación and the Agencia Estatal de Investigación. Also, has received support from Industrial Doctorates plan of the Secretaria d'universitats i Recerca, Departament d'Empresa i Coneixement de la Generalitat de Catalunya, grant agreement No. DI46-2020.

CADENCE DETECTION IN SYMBOLIC CLASSICAL MUSIC USING GRAPH NEURAL NETWORKS

ABSTRACT

Cadences are complex structures that have been driving music from the beginning of contrapuntal polyphony until today. Detecting such structures is vital for numerous MIR tasks such as musicological analysis, key detection, or music segmentation. However, automatic cadence detection remains challenging mainly because it involves a combination of high-level musical elements like harmony, voice leading, and rhythm. In this work, we present a graph representation of symbolic scores as an intermediate means to solve the cadence detection task. We approach cadence detection as an imbalanced node classification problem using a Graph Convolutional Network. We obtain results that are roughly on par with the state of the art, and we present a model capable of making predictions at multiple levels of granularity, from individual notes to beats, thanks to the fine-grained, note-by-note representation. Moreover, our experiments suggest that graph convolution can learn non-local features that assist in cadence detection, freeing us from the need of having to devise specialized features that encode non-local context. We argue that this general approach to modeling musical scores and classification tasks has a number of potential advantages, beyond the specific recognition task presented here.

1. INTRODUCTION

Graph Neural Networks (GNNs) have recently seen staggering successes in various fields. The MIR community has also experienced the influence of GNNs, principally in the field of recommender systems [1]. However, other sub-branches of MIR could potentially enjoy the graph representation and the benefits of graph deep learning.

Modeling musical scores in all their complexity has been challenging, with many approaches resorting to piano rolls [2], note arrays [3], or custom descriptors [4]. In this paper, we present a new representation of the score as a homogeneous graph with note-wise features to model aspects of the score. We use this representation to address the cadence detection task using graph neural networks, treating the task as a node classification problem. More specifically, our contribution is two-fold: a simple graph representation of scores extended with local features, and a Graph Convolutional Network (GCN) model to tackle heavily imbalanced classification tasks such as Cadence Detection. *Score modeling* itself has two aspects: (1) the construction of the graph, i.e., what are the nodes, and which connections do we define between them; and (2) the choice of score features, and how these relate to their respective graph nodes. The *classification model* is an adapted version of GraphSMOTE [5], a Graph Convolutional Network designed to deal with imbalanced classification problems, which we modified to deal with larger graphs and apply stochastic training. Henceforth, we call this model *Stochastic GraphSMOTE*. We employ this model on top of our score modeling with the intention of solving the Cadence Detection task.

The cadence detection setting is binary, i.e., there is a cadence (maybe of a specific type) or not. The current state of the art [4] uses an Support Vector Machine (SVM) classifier on a set of custom-designed cadence-specific features, based on three defined "cadence anchor points", and performs score/feature modeling and cadence classification at the level of beats. The model was tested on two annotated datasets: 24 Bach fugues and 42 Haydn string quartet expositions. Our new model proposed here will be shown to achieve comparable overall results; however, we will argue that it makes fewer task-related and musical assumptions, resulting in more general applicability. In particular, our empirical results suggest that by providing local features and applying a Graph Neural Network with neighbor convolution, we can learn nonlocal aspects that help improve prediction. This gives a more general approach for a variety of tasks where features are provided at the level of notes, but prediction may be note-wise, onset-wise, or beat-wise.

The rest of the paper is structured as follows. Section 2 discusses related work on cadence detection and music score modeling. Section 3 describes the score model and the graph construction from the score, section 4 introduces the corpora, and section 5 presents the proposed learning algorithm. Section 6 presents a series of three experiments and also takes a qualitative look at some examples. Finally, section 7 summarizes and concludes.

2. RELATED WORK

Graphs have emerged as a natural representation of music since the development of Tonnetz by Euler. Since then, there have been various proposals to use graph representations for addressing music analysis and MIR tasks. For instance (to name just two), [6] introduced relational *Klumpenhouwer networks* for music analysis, and [7] used *Tonnetz trajectories* for composer classification. One can distinguish between *heterogeneous* and *homogeneous* graphs [8]. Heterogeneous graphs may have multiple types of edges and nodes, while homogeneous graphs are simpler, containing only a single edge and node type. Recently, the creators of VirtuosoNet, a computational model for generating piano performances, used a heterogeneous graph representation of the score and trained their system using a Graph Neural Network [9]. However, in later publications, they reverted to a model without using graphs which achieved better performance [10]. In the present paper, we wish to show that a simple, homogeneous graph representation can form a natural and general basis for modeling a non-trivial music analysis task.

Automatic *cadence detection* is a challenging task. Although cadences are well established concepts, their definition or annotation in music can cause disagreements among musicologists. Previous work on automatic cadence detection has been done by [11] on Bach fugues and by [12] for a generalized classical music analysis system. A feature-based approach using standard Machine Learning classifiers is presented in [4] which represents the current state of the art. Recently, Sears and Widmer [13] highlighted the difficulty of detecting textbook voice leading schemata that occur near cadences in written music. However, to our knowledge, there exists no method employing deep learning models to solve the task.

3. MODELING SCORES AS A GRAPH

We model a score as a graph with individual notes and rests as nodes and simple temporal relations as edges. In addition, each graph node is associated with a vector of feature values that represent some basic properties of a note and its immediate context. Formally, let $G = (V, E)$ be a graph, where V is the set of nodes and $E \subseteq V \times V$ the set of edges and let A be the adjacency matrix of G. Each note and each rest in a score are represented as a node in the graph. We create three types of undirected connections between notes/rests: edges E_{on} between notes that occur on the same onset; edges E_{cons} between consecutive notes, and edges E_{dur} between a note of longer duration and notes whose onsets occur during this time:

$$
\begin{aligned}
E_{on} &= \{(i,j) \mid on(n_i) = on(n_j)\} \\
E_{cons} &= \{(i,j) \mid on(n_i) + dur(n_i) = on(n_j)\} \\
E_{dur} &= \{[(i,j) \mid on(n_i) + dur(n_i) > on(n_j)] \wedge \\
&\qquad [on(n_i) < on(n_j)]\} \\
E &= E_{on} \cup E_{cons} \cup E_{dur}
\end{aligned}
$$

where n_i is the i^{th} note. on denotes the onset of a note, dur the duration. All edges in E are undirected.

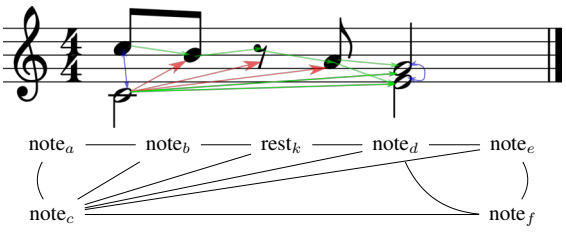

Figure 1. Example graph creation from a score following the process described in the text. E_{on} is denoted in blue, E_{cons} in green, and E_{dur} in red. Global attributes such as time and key signatures are added as node features.

3.1 Feature Overview

We use three types of features to further describe a note: [1] general-purpose note-level features to describe a note and its immediate rhythmic/melodic context; general graph topology features to capture aspects of local connectivity; and cadence-specific note features inspired by [4]. The third feature category is the only one that is designed with the specific classification target in mind; however, in contrast to [4], we restrict these to only consider the immediate local context of a note instead of using positional features relating to predefined past "cadence anchor points". In this way, we wish to demonstrate the generality of our representation and learning approach, which will hopefully learn more long-distance aspects automatically, as needed.

The first category, *general note-wise features*, is the largest one. For each note in the score, we extract onset time expressed in score-relative beats, duration in beats, and MIDI pitch, using the partitura package [14]. Furthermore, we translate global attributes such as time signature and assign them to each note. Also using partitura, we extract a set of generic note-wise features as defined in [15]. Finally, we extract features summarizing intervallic information at the time of onset of each note. These include *interval vectors* [16] and binary features activated when intervallic content is identical to the interval set corresponding to particular chord types, i.e., major, minor, diminished, etc.

Second, we add *graph-aware features* using the first 20 eigenvectors from the Laplacian of the adjacency matrix [17].

The final category contains *note-wise cadence-related features* similar to those in [4], such as voice leading information and voicing. However, our features are calculated at the note level only, considering the time of onset for each note and its immediate neighbors, such as adjacent past onsets or simultaneous onsets. In particular, we do not use any information about events that occur on previous beats. While these features are more restricted compared to [4] they are also more general, since we make no assumptions on and reference to "cadence anchor points" (e.g.,

[1] Code and a complete specification of all features is available on `https://github.com/manoskary/cadet`.

the occurrence of the preceding subdominant and dominant harmony), which in [4] are identified with specialized heuristics. In total, we store 135 features per node.

4. PROBLEM SETTING & CORPORA

In this work, we are interested in cadences of the Baroque and Classical periods. The main focus will be on detecting Perfect Authentic Cadences (PAC); where our annotated datasets permit, we will also consider root position Imperfect Authentic Cadences (rIAC) and Half Cadences (HC). The manual annotations in these datasets mark a cadence as occurring on the beat where the final I (i) arrives. Our precise task thus is to predict, for every note of the score, whether this note is contained in a cadence's arrival beat.

To benchmark our method, we used two datasets also used by Bigo et al. [4], and a third one annotated by Allegraud and al. [18]. The first set contains the 24 fugues from Bach's Well-tempered Clavier, Book I. The cadence annotations were presented in [11]. The second dataset contains 45 movement expositions from Haydn string quartets; the cadence annotations were produced by Sears and colleagues [19]. The last dataset contains 31 movements of Mozart string quartets with cadence annotations included. All the scores were retrieved from `http://kern.ccarh.org` and were parsed in python using the partitura package [14]. [2]

Cadences occur with low frequency in music. In particular, for the corpora we cover in this paper, cadences of all types combined account for less than 2% of the total notes in the score. Our produced score graphs range from approximately 25k nodes for the Bach fugues all the way to 70k nodes for the Mozart string quartets with more than 750k edges. Table 1 gives detailed dataset statistics.

5. MODEL

5.1 Graph Convolutional Network

The authors of [4] underline the importance of non-fixed positions for the cadence anchor points. We address this by employing a graph convolutional network. Graph Convolution Networks (GCNs) are based on the same principle as CNNs, but in the context of graphs we encounter the message passing concept, meaning convolution occurs only among nodes connected by edges. This theoretically allows local features to connect with distant features of their k-hop neighbors. Therefore, graph representation can learn, using local node information, higher lever information by sampling information from neighbors. Figure 2 illustrates the neighbor sampling concept.

For our model, we propose *Stochastic GraphSMOTE*, a Graph Convolutional Network with a built-in graph Auto-Encoder and Synthetic Minority Over-sampling for imbalanced node classification. The model consists of 4 parts, the encoder, a SMOTE layer in the encoder's latent space, the decoder, and the classifier. The structure of the model

[2] For reproducibility, we provide the generated graphs that were used for training on `https://github.com/manoskary/tonnetzcad`

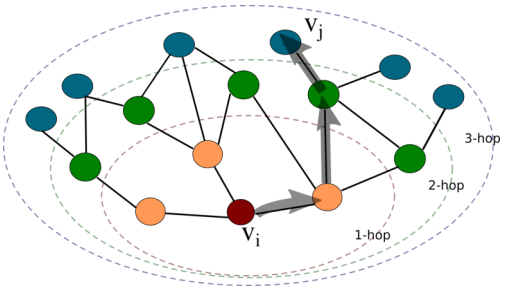

Figure 2. Multi-hop Neighborhood sampling. v_j is 3-hop neighbor of v_i. Color cues mark the k-hop neighborhoods occurring within the ellipses. The arrows demonstrate a random walk starting from v_i and ending at v_j.

follows GraphSMOTE [5] but with some major differences, mainly to adapt for stochastic training, which is needed because of the large size of our score graphs.

The encoder applied to a node i is defined as a standard GraphSAGE [20] stack given by:

$$\mathbf{h}_{\mathcal{N}(i)}^{(l+1)} = \text{mean}\left(\{\mathbf{W}_{pool}^{(l+1)} \cdot \mathbf{h}_j^l, \forall j \in \mathcal{N}(i)\}\right)$$
$$\mathbf{h}_i^{(l+1)} = \sigma\left(\mathbf{W}_{enc}^{(l+1)} \cdot \text{concat}(\mathbf{h}_i^l, \mathbf{h}_{\mathcal{N}(i)}^{l+1})\right)$$
$$\mathbf{h}_i^{(l+1)} = \text{norm}(\mathbf{h}_i^l)$$

where $h_i^{(l)}$ is the hidden representation of node i on layer l, σ is an activation function, norm is a normalization function, $\mathbf{W}$ are learnable weights, and $\mathcal{N}(i) = \{j \mid (i,j) \in E\}$ are the neighbors of node i. Let $B \subseteq V$ a subset of nodes denoting a batch sample. Then, given L the total number of hidden layers, $\mathbf{H}_B^{(enc)} = \{\mathbf{h}_u^{(L+1)} \mid u \in B\}$.

5.2 Dealing with Extreme Class Imbalance: Stochastic GraphSMOTE

Since cadences are very sparse, we need to introduce a balancing technique in order to avoid gradient convergence that will result in predicting only the majority class, i.e., absence of cadence. To counter this effect, we introduce a SMOTE layer that is applied in the *latent space* of the encoder. SMOTE generates synthetic samples with the same label as the minority class (see [21] for details). The main novelty of our model is that the SMOTE is performed for each batch separately.

In each batch, we count the occurrence, μ_i, for each of the classes $i \in I$. In the binary setting, let μ_M be the number of samples with the same label as the majority class and μ_m be the number of samples with the same labels as the minority class. By generating $(\mu_M - \mu_m)$ samples with the same label as the minority class, we force a $1:1$ binary class distribution. To generate these samples, in each batch, we randomly select a sample instance of the minority class as an anchor point and gather the k nearest neighbor samples of the same class within the batch. Finally, μ samples are generated as random linear interpolations between a randomly selected neighbor out of the k, and the selected anchor point in the euclidean space. Performing

Dataset	Pieces	Nodes	Edges	PAC	rIAC	HC
Bach Fugues	24	24,567	229,107	237	78	15
Haydn String Quartets	45	38,661	441,491	434	24	340
Mozart String Quartets	31	68,190	762,796	1,089	-	1,930

Table 1. Cadence nodes constitute less than 2% of all nodes.

SMOTE in the latent space assumes that a more appropriate representation for the generation of the synthetic minority samples is learned.

If $\mathbf{H}_B^{(enc)}$ is the hidden representation of the batch sampled nodes after the encoder layer, then $\mathbf{H}_B^{(smote)}$ is the SMOTE upsampling algorithm applied on $\mathbf{H}_B^{(enc)}$. Our Decoder layer is responsible for generating edges within the original nodes of the graph and the synthetic ones, created by SMOTE. The decoder output is described by the following equation:

$$\mathbf{A}_B^{(dec)} = \sigma\left(\mathbf{H}_B^{(smote)} \cdot \mathbf{W}^{(dec)} \cdot \text{transpose}(\mathbf{H}_B^{(smote)})\right)$$
$$\mathbf{A}_B^{(thr)} = \text{hardshrink}\left(\mathbf{A}_B^{(dec)}, \tau\right)$$

where $W^{(dec)}$ are the decoder's learnable weights, σ is a sigmoid activation function, and hardshrink is the hard shrinkage function with threshold τ. $\mathbf{A}_B^{(dec)}$ is the generated adjacency from the decoder and $\mathbf{A}_B^{(thr)}$ is a thresholded adjacency by a factor τ.

We define a regularization loss that aims at constraining the generated adjacency close to the original, defined by:

$$\mathcal{L}_B^{(dec)} = \text{BCE}\left(\mathbf{A}_B^{(dec)}, \mathbf{A}_B\right)$$

where BCE is the binary cross entropy loss, $\mathbf{A}_B^{(dec)}$ is the generated adjacency of the decoder for batch sample B and A_B is the adjacency matrix for batch sample B. Since we learn an edge generator which is good at reconstructing the adjacency matrix using the encoder's latent representations, it should also give adequate edge predictions for synthetic nodes.

The GNN classifier is composed of a GraphSAGE layer [20] with a linear layer on top. By adding a graph convolution layer such as GraphSAGE in the classifier, we can benefit from learning information from the generated adjacency and the neighbors of nodes. The GraphSAGE layer of the classifier is slightly different from the encoder because it performs directly on the generated thresholded adjacency of each batch sample:

$$\mathbf{h}_{\mathcal{N}(i)}^{(clf)} = \text{mean}\left(\mathbf{W}^{(pool)} \cdot \mathbf{A}_B^{(thr)}[i,:] \cdot \mathbf{H}_B^{(enc)}\right)$$
$$\mathbf{h}_i^{(clf)} = \text{norm}\left(\sigma\left(\mathbf{W}^{(clf)} \cdot \text{concat}\left(\mathbf{h}_i^{(enc)}, \mathbf{h}_{\mathcal{N}(i)}^{(clf)}\right)\right)\right)$$
$$\mathbf{h}_i^{(clf)} = \text{softmax}(\mathbf{W}^{(proj)} \cdot \mathbf{h}_i^{(clf)})$$

where $\mathbf{h}_i^{(clf)}$ are the predicted class probabilities of node i, $\mathbf{W}$ are learnable weights, $\mathbf{A}_B^{(thr)}$ is the generated thresholded adjacency from the decoder, $\mathbf{H}_B^{(enc)}$ are the batch encodings of the encoder and $\mathbf{h}_i^{(enc)}$ is the encoder's output for node i. During training, we use $\mathbf{H}_B^{(smote)}$ and $\mathbf{h}_i^{(smote)}$ respectively instead of $\mathbf{H}_B^{(enc)}$ and $\mathbf{h}_i^{(enc)}$. We define the *total loss* of our model for batch samples B:

$$\mathcal{L}_B^{(tot)} = \mathcal{L}_B^{(CE)} + \gamma * \mathcal{L}_B^{(dec)}$$

where $\mathcal{L}_{CE}$ signifies the cross entropy loss and γ is a hyper parameter.

Our model is trained stochastically, meaning that to create each batch a subset B of nodes are sampled. From these sampled nodes, given a pre-defined depth k, we retrieve the immediate neighbors of every $v \in B$ up to their k-hop neighbors in the graph G. We use neighbor sampling to reduce the cost of retrieving all up to k-hop neighbors of v by defining a maximum number ϕ_l of neighbors per depth layer l.

6. EXPERIMENTS

We conduct three main experiments. The first compares our model to the state of the art results in [4], using the same data and train/test setup. The second experiment focuses on multi-class learning of the particular type of cadence using different sets of features, in order to investigate how the model generalizes to a more complex setting and inspect the relevance of different feature sets. The third experiment investigates how neighbor convolution contributes to the model's performance. [3]

We fix our model with a hidden dimension of 256, with $L = 2$ hidden layers with $\phi_1 = 10$ and $\phi_2 = 25$ sampled neighbors for hidden layers 1 and 2 of the encoder, respectively, and one hidden layer of the same dimension for the classifier. The learning rate is set at 0.007, the weight-decay at 0.007, with a batch size of 1024, $k = 3$ for SMOTE, the decoder regularization loss multiplier $\gamma = 0.5$, and adjacency threshold value $\tau = 0.5$.

6.1 Quantitative Results

Table 2 summarizes the results of the first experiment, comparing our model's performance to the state of the art. [4] The reference model [4] can only classify at the beat level; our representation and classification model are more flexible in this regard, as they have access to, and describe, individual notes. In particular, our model can provide predictions at three different levels, note-wise, onset-wise and beat-wise predictions (the latter two simply by aggregation). In Table 2 we present the results of these predictions at all levels,

[3] All results, experiments, and the trained models are available on `https://wandb.ai/melkisedeath/CadenceDetection`

[4] In accordance with [4], we ignore the HC in Bach and rIAC in Haydn, because of their low numbers.

Dataset	Model	F1 Note	F1 Onset	F1 Beat	Prec. Beat	Recall Beat
Bach Fugues (PAC) (12 fugues)	Bigo et al. model	-	-	**0.80**	**0.89**	0.72
	SGSMOTE	0.85	0.75	0.73	0.70	0.77
	Pretrained SGSMOTE	**0.90**	**0.83**	**0.80**	0.74	**0.89**
Bach Fugues (rIAC) (12 fugues)	Bigo et al. model	-	-	0.68	0.71	0.65
	SGSMOTE	**0.87**	**0.75**	**0.73**	**0.75**	0.72
	Pretrained SGSMOTE	0.87	0.73	0.71	0.62	**0.82**
Haydn String Quartets (PAC) (21 pieces)	Bigo et al. model	-	-	**0.69**	**0.60**	**0.82**
	SGSMOTE	0.77	0.56	0.59	0.47	0.78
	Pretrained SGSMOTE	**0.81**	**0.63**	0.64	0.54	0.78
Haydn String Quartets (HC) (21 pieces)	Bigo et al. model	-	-	0.29	0.19	**0.56**
	SGSMOTE	0.65	0.32	0.30	0.33	0.27
	Pretrained SGSMOTE	**0.69**	**0.44**	**0.41**	**0.41**	0.41

Table 2. Results using half of the dataset for training, half for testing. Bach: fugues no.1-12 were used for training, no.13-24 for testing; Haydn: random 21:21 split. The pretrained network was trained on the other dataset, i.e. *Pretrained SGSMOTE* for Bach Fugues was pre-trained on string quartets, etc. Classification is binary, the presented $F1$ scores are for the positive class, i.e., the cadence (PAC: Perfect Authentic Cadence; rIAC: root position Imperfect AC; HC: Half Cadence).

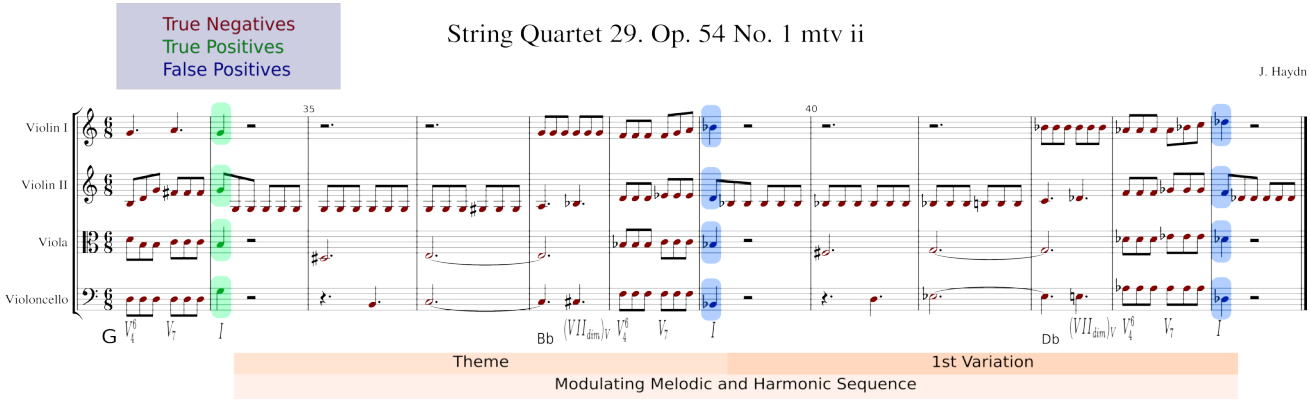

Figure 3. Haydn's String Quartet 29. Op.54 No.1 Mvt. II, mm. 33-45. Showing the output of the Stochastic GraphSMOTE Network for PAC prediction. True negatives are marked with red, true positives with green, false positives with blue. A partial analysis shows the chords towards the end of cadences and highlights a modulating sequence where every sequence ends with a cadential pattern, which counts as false positive predictions by the network.

in terms of F1 score. Only beat-wise scores are given for the reference model (taken from [4]). The last two columns of table 2 give the recall and precision for the beat-wise prediction. All metrics are presented for the positive, i.e. minority/cadence, class.

Our model matches or slightly surpasses the state of the art in rIAC detection in Bach fugues and on HCs in Haydn string quartets but does not reach the reference model's F1 results in PAC detection. We additionally present a pre-trained version of Stochastic GraphSMOTE, where the network was first trained on additional data and fine-tuned for the task. Specifically, the network for PAC prediction in Bach was pre-trained on the string quartets and vice versa. Pre-training, and thus the need for additional data, is the price we pay for the generality of the graph representation and the consequent size (number of parameters) of the deep network. Pre-training helps to (markedly) improve the results on HC, catch up with the reference on PAC in Bach, and narrow the gap on PAC in Haydn.

Generally, our results agree with [4] in implying that half cadences (HC) seem significantly harder to identify than authentic cadences, both perfect and imperfect. Another, more specific, observation concerns different ways in which the compared models achieve their overall F1 scores. In the PAC detection tasks, in particular, we observe comparable or higher recall of our model compared to the reference, but lower precision. This observation motivated us to check some of our model's false positive predictions; Section 6.2 below will show several instructive examples of 'almost correct' identifications.

The *second experiment* we conducted (Table 3) focuses on comparing the relevance of feature groups. For compactness we present here a multi-class classification scenario where we account not only for the existence of a cadence but also for the type of cadence present; that is, we have tree-class problems: no cadence, PAC, or rIAC (Bach) / HC (Haydn, Mozart). We compare two configurations: using all available features (as in the first experiment, feature set *all* in the table), or only feature sets 1 and 2, excluding the cadence-specific features (category 3 in Section 3.1; marked *general* in the table). Given this 3-class setting, we chose to report the macro averaged F1 score over all three classes.

Dataset	Features	F1 Note	F1 Beat
Bach Fugues	general	0.602	0.667
(PAC & rIAC)	all	0.653	0.702
Haydn String Quart.	general	0.542	0.610
(PAC & HC)	all	0.648	0.663
Mozart String Quart.	general	0.584	0.569
(PAC & HC)	all	0.588	0.606

Table 3. Three-class cadence classification with two different feature sets. Results were obtained by 5 fold cross validation (70% of pieces for training, 10% validation, 20% testing); no pre-training. Feature set *all* contains all features from Section 3.1; *general* excludes Category 3 cadence-specific engineered features.

(Macro averaging was chosen to counter the overwhelming effect of the majority class *no cadence*). The results (see Table 3) support the relevance of carefully devised cadence-related features à la [4]. However, also the general-purpose category 1 and 2 features alone support non-trivial cadence recognition and discrimination performance, which implies that the relational graph representation in combination with a convolutional approach manages to enrich highly local features with relevant non-local score context.

To investigate this latter aspect in more detail, we run a *third experiment*, to look at the effect of neighbor convolution depth on the obtainable classification score, again at three prediction granularity levels (note, onset, beat). Convolution depth refers to the number l of hidden layers of the encoder and the subsequent neighbor sampling up to l-hop neighbors. Our results (see Table 4) suggest that neighbor convolution clearly contributes to learning non-local features. Best results are achieved when using a convolution depth of 2. Increasing the receptive field beyond that level, we observed some instabilities emerging in the learning model, which could be attributed to the common vanishing gradient problem in deep GCNs [22].

Depth	F1 Note	F1 Onset	F1 Beat
None	0.833	0.671	0.667
1-hop	0.854	0.707	0.701
2-hop	**0.869**	**0.737**	**0.732**
3-hop	0.836	0.706	0.659

Table 4. Effect of neighbor convolution depth on PAC prediction in Bach fugues. The F1 Note/Onset/Beat scores presented are binary, i.e., for the PAC class. Depth refers to neighbor convolution depth. *None* means no graph convolution.

6.2 A Qualitative Look

Motivated by the fact that our model, while higher on recall, seems to be lower on precision than the model in [4], we take a closer look at some of the false positives in individual examples. Our findings suggest that many false positive predictions resemble cadences, in terms of tonal structure or implications, and could be considered and annotated as such, but lack some main components.

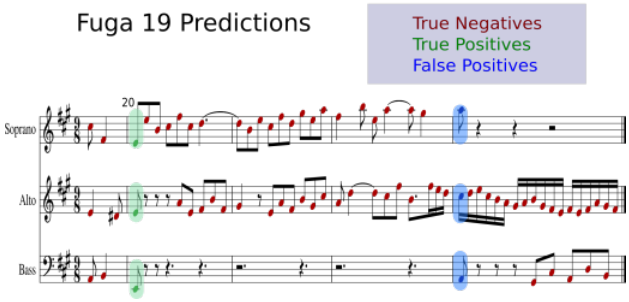

Figure 4. Predictions of Stochastic GraphSMOTE for fugue No.19, J.S.Bach, Well-tempered Clavier.

Figure 4 shows an example. The cadence prediction by our model on the downbeat of bar 23 is a false positive, according to the ground truth annotation. However, one could argue that the passage clearly has a cadence-like role, marking the end of the 2nd fugal episode and the return to the original tonality of A major [23].

Another example is the passage discussed in Fig.4 of [4], where a pattern occurs that has all the technical ingredients of a PAC, but was not annotated as such for (debatable) higher-level musicological considerations. Again, our model's PAC prediction there counts as a false positive.

As a final example, consider mm. 33-45 of Haydn's Op.54 No.1, 2nd mvt (Figure 3). We observe two false positive beat-wise predictions (8 if we count note-wise) in bars 39 and 44, respectively, following a true PAC on the beginning of bar 34. A harmonic analysis of these bars indicates a proper PAC preparation with text-book voice leading on the cadence arrival point in every occasion. These two false positive PACs form part of a modulating melodic and harmonic sequence; whether to classify them as cadences is a matter of higher-level musicological considerations.

We cite these few qualitative examples in an attempt to show that our prediction model can identify many more cadential patterns than the raw experimental figures suggest, but by design cannot consider high-level musical considerations such as, e.g., whether PAC-like patterns that occur in sequence should count as PACs or not.

7. CONCLUSION

We have presented a graph approach to effectively target the cadence detection task on symbolic classical scores. We demonstrated that our Graph Convolutional Network, Stochastic GraphSMOTE, can learn using only local note features, without the need for any musical assumptions about cadence anchor points. Furthermore, our network can produce fine-grained predictions at the level of individual notes.

Future work will address the performance of the model on different tasks, using the same graph representation. We hope to be able to show that this simple but general and natural representation of scores in terms of graphs can support a broad variety of symbolic music analysis and classification tasks.

ABSTRACT

The variational auto-encoder has become a leading framework for symbolic music generation, and a popular research direction is to study how to effectively *control* the generation process. A straightforward way is to control a model using different conditions during inference. However, in music practice, conditions are usually sequential (rather than simple categorical labels), involving rich information that overlaps with the learned representation. Consequently, the decoder gets confused about whether to "listen to" the latent representation or the condition, and sometimes just ignores the condition. To solve this problem, we leverage *domain adversarial training* to *disentangle* the representation from condition cues for better control. Specifically, we propose a condition corruption objective that uses the representation to denoise a corrupted condition. Minimized by a discriminator and maximized by the VAE encoder, this objective adversarially induces a condition-invariant representation. In this paper, we focus on the task of melody harmonization [1] to illustrate our idea, while our methodology can be generalized to other controllable generative tasks. Demos and experiments show that our methodology facilitates not only condition-invariant representation learning but also higher-quality controllability compared to baselines.

1. INTRODUCTION

In deep music generation, improving *controllability* has been a major challenge that gains increasing research attention [1–6]. In practice, controllability is typically implemented under a conditional architecture, where the generation process is biased by external condition inputs. For example, EC^2-VAE [7] learns a representation z_x of 8-beat melody x while the underlying chords are given as condition c. The system is controllable if the generated melody can adapt to variable chords properly. For such representation-learning architectures, however, the decoder tends to find a shortcut from z_x to x without attending to c, leading to "condition collapse". The reason for this, as we argue, is that z_x is inevitably intertwined with condition c in the representation space, as c is often an innate property of x. In the case of EC^2-VAE, the condition of chords is very much implied by the melody.

To address this problem, the representation z_x must be disentangled from condition c. A popular way to achieve this goal is to use an adversarial objective that predicts c from z_x, as shown in Figure 1. On the one hand, this objective is optimized by a discriminator; on the other hand, the encoder is trained to "fool" the discriminator by detaching c-related cues out of z_x. In this way, the decoder cannot find a shortcut in z_x but is forced to seek c to reconstruct x. Such a technique stems from *domain adversarial training* (DAT) [8], where the "domain" is interpreted as "condition" that controls the generation.

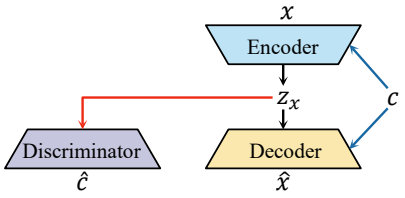

Figure 1: An illustration of domain adversarial training over a conditional generation architecture.

Apparently, DAT can be a powerful tool for controllable music generation. Previous studies [9, 10] have discussed simple scenarios where the condition is a global label (*e.g.*, note density). In music practice, however, local and sequential conditions [11] are more common. In such cases, c may not be fully implied by x, so the objective that simply predicts c from z_x does not necessarily hold.

In this paper, we focus on sequential conditions and develop a generalized form of DAT for controllable music generation. We illustrate our methodology with the task of *chord representation learning conditioned on melody*, where x stands for the chord progression, and c is the melody condition. In general, a chord progression can match many melodies, so we cannot directly predict c (melody) from z_x (chord) for the DAT objective. Instead, we leverage z_x to reconstruct c from a corrupted condition c^*. We rely on c^* to provide the melody context that cannot be hinted by chord x; on the other hand, the corrupted

Wang, "Domain Adversarial Training on Conditional Variational Auto-Encoder for Controllable Music Generation", in *Proc. of the 23rd Int. Society for Music Information Retrieval Conf.*, Bengaluru, India, 2022.

information reveals c's harmonic dependency on x, which we enforce the discriminator to learn. With proper corruption design, our DAT objective can be generalized to more scenarios with sequential conditions.

A well-trained model with good controllability can help us harmonize a new melody using the representation (style) of an existing chord progression. Experiments show that our model performs an excellent disentanglement of data representation from the condition, and the controllability outperforms the baselines. In summary, our contributions in this paper are as follows:

- **A general approach to controllability**: Based on a novel adversarial objective with condition corruption, we generalize domain adversarial training to music generation with sequential conditions;
- **A novel harmonization methodology**: We present a representation learning-based method for melody harmonization. Our current model harmonizes pop and folk melodies with the triad and seventh chords.

2. RELATED WORKS

2.1 Domain Adversarial Training

Domain adversarial training (DAT) is a representation learning approach initially proposed for domain adaptation tasks [12–14]. Through an adversarial process as described in Section 1, DAT enforces *domain invariance* to data representation so that it can be adapted to different domains flexibly. Such adaptability to new domains is analogous to controllability with new conditions. For generation tasks, DAT has been utilized to learn a condition-invariant data representation. Such invariance enforces the decoder to use condition information for reconstruction [15]. During inference, the decoder "listens to" new conditions as well and generates new data in a controllable way.

The first attempts that incorporate DAT with generation dealt with facial image generation conditioned on binary attributes (*e.g.*, male or female) [15, 16]. Such conditions cannot be explicitly supervised because we cannot find any pair of images that represents the same person both male and female. Fortunately, DAT enforces attribute invariance at encoding and learns attribute dependency at decoding, thus circumventing this problem. Recently, DAT has been extended to symbolic music generation conditioned on various attributes. Kawai *et al.* adopts DAT to a variational auto-encoder (VAE) for melody generation conditioned on statistical attributes (*e.g.*, note density) [9]. Later, Matsuoka *et al.* generalizes this methodology to generating polyphonic music with similar conditions [10].

For previous works, the conditions are particularly a global statistical label, which only represents a limited scenario of controllable generation. In our paper, we generalize the usage of DAT to sequential conditions. Conditioned on an 8-bar melody, we aim to learn a pitch-invariant representation of an 8-bar chord progression, which can later be adapted to varied melody conditions and to harmonize them. Our main novelty lies in a special design of the adversarial objective, which is to denoise corruption rather than make full prediction. This technique greatly helps us in dealing with the nuance of sequential conditions.

2.2 Controllable Music Generation

Controllable music generation takes various forms in terms of controlling technique and music representation [17]. For controlling technique, controllability can be achieved by sampling, interpolation, conditioning, and more ways [11]. For music representation, controls can be performed over statistical music properties (pitch variability, note density, etc.) [9, 10], compositional factors (chord progression, texture and rhythmic patterns, etc.) [7, 18–20], high-level semantics (emotion, cultural style, etc.) [21], and so on. With the development of representation learning, such properties can be abstracted and disentangled for flexible control.

In this paper, we are interested in chord representation learning conditioned on melodies, which falls into the category of controlling compositional factors via conditioning. Various conditional architectures, such as conditional VAE (C-VAE) [22], have been applied for similar purposes [7, 18–21]. However, as the condition is often easily implied by the representation, the decoder tends to skip the condition, and simply reconstruct the data for whatever conditions. To eradicate this problem, we introduce domain adversarial training and generalize it to sequential conditions (in our case, an 8-bar lead melody). Our model learns a pitch-invariant chord representation so that we can generate chord progressions harmoniously conditioned on varied melodies. Such control over compositional factors is common to broader music generation scenarios, and our methodology is generally applicable as well.

3. METHODOLOGY

In this section, we introduce our methodology with domain adversarial training on learning chord representation conditioned on the melody. An overview of our model is illustrated in Figure 2. We first describe our data representation and structure in Section 3.1. Then, we introduce our proposed model in Section 3.2. Finally, we elaborate on our novel design of condition corruption in Section 3.3.

3.1 Date Representation and Structure

3.1.1 Chord Representation

Our model generates an 8-bar chord progression conditioned on the melody. We quantize the chord progression at 1-beat unit and derive $T = 32$ timesteps. The maximum note count P for each chord is 4, which means we can flexibly represent any type of triad and seventh chords. Specifically, we treat chord progression as a piece of polyphony and follow [18] to represent it in both a surface structure (as model input) and a deep structure (for encoding).

The surface structure is a nested array of pitch attributes, denoted by $\{x_p^t | 1 \leq t \leq T, 1 \leq p \leq P\}$. Concretely, x_p^t is the p^{th} lowest pitch onset at time step t. We

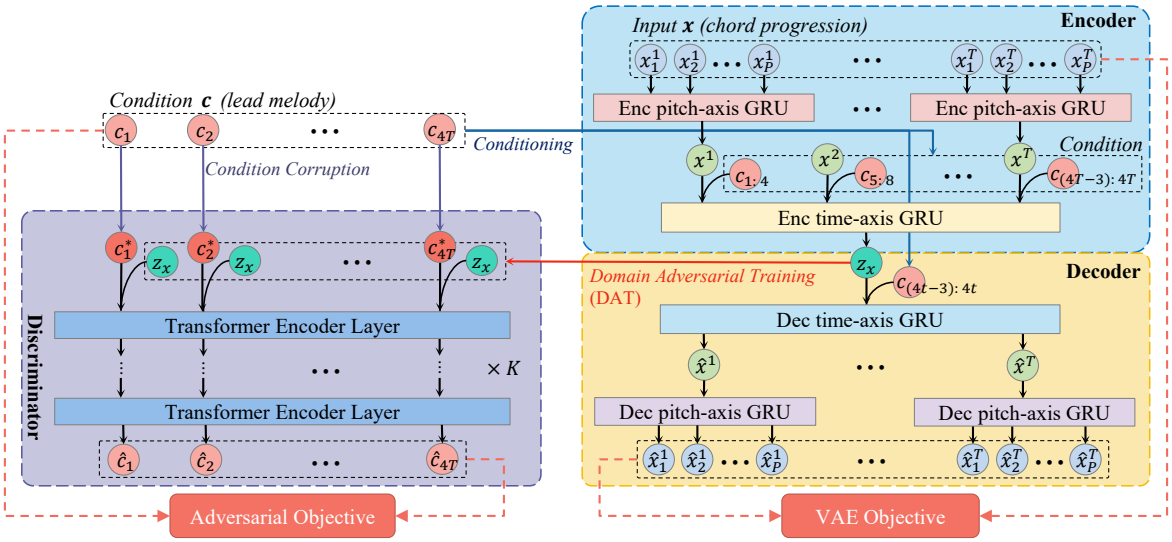

Figure 2: Chord representation learning with adversarial intervention for melody control.

represent x_p^t as a 13-D one-hot vector corresponding to 12 pitch classes plus a padding state. For most of our chord progression data, the offset of the last chord is precisely followed by the onset of the next one. Hence we do not explicitly consider the duration attributes.

For the deep structure, we build a syntax tree as in [18] to reveal the hierarchy from note via chord to chord progression. First, for $1 \leq t \leq T, 1 \leq p \leq P$, x_p^t itself constitutes the bottom layer of the tree. Then, for $1 \leq t \leq T$, we define x^t as the summary of $x_{1\leq p\leq P}^t$, which lies at the middle layer of the tree. Finally, we define z_x as the summary of $x^{1\leq t\leq T}$, which is the root of the tree. Such a deep structure is illustrated in Figure 3. Conceptually, while x^t is a compact representation of a single chord, z_x represents the complete chord progression.

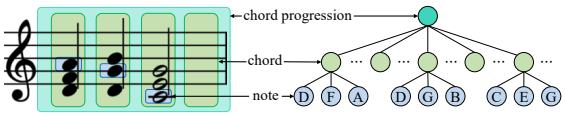

Figure 3: Tree-structure data representation of chord progression, reproduced from [18] with permission.

3.1.2 Melody Representation

Our model receives an 8-bar lead melody as the condition. we quantize the melody at $\frac{1}{4}$-beat unit and derive $4T = 128$ time steps. Following [7], we represent the melody as a sequence of note onsets plus a hold and a rest state. Each note onset consists of two one-hot vectors each representing 12 pitch classes and 10 octave ranges (registers). In our model, the melody pitch shares the same learnable embedding with the chord pitch.

3.2 Proposed Model

Our model applies a similar VAE architecture as PianoTree VAE [18], which learns representation for polyphonic music in a hierarchical manner. We use the surface structure of chord progression as the model input. The VAE architecture is built upon the deep tree-like structure.

We first illustrate the vanilla VAE design in the right half of Figure 2. Let x be the input chord progression and x_p^t be the p^{th} lowest pitch onset at time step t. The encoder first summarizes $x_{1\leq p\leq P}^t$ into an intermediate representation x^t (chord representation) for each time step t, and then encodes $x^{1\leq t\leq T}$ to the complete representation z_x. The decoder is basically a mirrored version of the encoder. The melody condition c, with its every four timesteps summed together, is concatenated to $x^{1\leq t\leq T}$ during encoding and to z_x during decoding. The loss function of our vanilla VAE architecture is:

$$\begin{aligned}\mathcal{L}(\theta_{\text{enc}}, \theta_{\text{dec}}) = &-\mathbb{E}_Q \left[\log P_{\theta_{\text{dec}}}\left(x \mid z_x, c\right)\right] \\ &+ \alpha \mathbb{KL}(Q_{\theta_{\text{enc}}}(z_x \mid x, c) \parallel \mathcal{N}(\mathbf{0}, \mathbf{1})),\end{aligned} \tag{1}$$

where $P_{\theta_{\text{dec}}}$ and $Q_{\theta_{\text{enc}}}$ refer to the VAE decoder and encoder. θ_{dec} and θ_{enc} are the learnable parameters. α is a balancing parameter for the regularization of KL loss [23].

Ideally, z_x should be a *relative* progression representation whose absolute pitch is controlled by melody c. However, as the input chord, x already has absolute pitch, this information is preserved in z_x as a redundant melody cue and confuses the decoder from attending to the condition.

To solve this problem, we assign a *discriminator* (left in Figure 2) to the VAE architecture. Instead of predicting c from z_x as conventional DAT objectives do, we bias the discriminator to denoise a *corrupted* melody condition. The corruption is done by transposing the melody to 12 keys with equal chance, which breaks the harmonic relation to the chord. In this way, we learn and extract the chord's dependency on its melody condition.

Formally, our discriminator leverages z_x to reconstruct melody condition c from a corrupted one c^*. Our DAT objective with condition corruption is trained in an adversarial manner. We optimize the discriminator by *minimizing* the reconstruction loss:

$$\mathcal{L}(\theta_{\text{dis}}) = -\mathbb{E}_Q \left[\log R_{\theta_{\text{dis}}}\left(c \mid z_x, c^*\right)\right], \tag{2}$$

where $R_{\theta_{\text{dis}}}$ is the discriminator with parameters θ_{dis}.

On the other hand, we optimize the VAE encoder by *maximizing* condition reconstruction error:

$$\begin{aligned}\mathcal{L}(\theta_{\text{enc}} \mid \theta_{\text{dis}}) = &-\mathbb{E}_Q \left[\log R_{\theta_{\text{dis}}} (\mathbf{1} - c \mid z_x, c^*)\right] \\ &+ \alpha \mathbb{KL}(Q_{\theta_{\text{enc}}}(z_x \mid x, c) \parallel \mathcal{N}(\mathbf{0}, \mathbf{1})),\end{aligned} \tag{3}$$

where $\mathbf{1} - c$ is a confusion criterion that encourages the encoder to "fool" the discriminator. $\mathcal{L}(\theta_i \mid \theta_j)$ means we optimize θ_i while fixing θ_j. The KL loss in Equation (3) and (1) ensures a consistent posterior regularization.

During domain adversarial training, Equation (2) and Equation (3) are iteratively optimized aside from the main VAE objective (1). In this way, the encoder is explicitly biased to disentangle z_x from c. The decoder learns to retrieve missing cues from c to reconstruct x, and thus guarantees controllability in the conditional architecture.

3.3 Condition Corruption

The main novelty of our architecture over previous applications of DAT [9,10,15] is that we incorporate a corrupted condition term to generalize this method to sequential conditions. The necessity of condition corruption is that, when c is not fully implied by x, the conventional DAT objective which predicts c from z_x no longer holds. In our case, x (chord) can be accompanied with various unique c (melodies), and a melody is largely independent of the chord in terms of sequential rhythmic patterns.

Condition corruption aims to reveal the dependency of c on x when a direct predictive inference from x to c cannot be established. The corrupted condition c^* serves as a *context* to fill in such prediction gap, and the *dependency* is highlighted when using z_x to denoise c^*. It may require field knowledge to design a proper corruption method for a specific scenario. Such corruption should keep the context part while blocking the dependency.

In our case, we corrupt the melody by transposing it to 12 keys with equal probability. The transposed melody c^* keeps the original rhythm and pitch curve shape while distorting the harmonic relation to the chord progression. Here the rhythm and the curve shape are the contexts, and the harmonic relation is the dependency. We compare our corruption method with a corruption-by-masking baseline in Section 4.6 to support the effectiveness of our design.

4. EXPERIMENTS

4.1 Dataset

We collect a total of 2K lead sheet pieces (melody with chord progression) for folk and pop songs from Nottingham [24] and POP909 [25] datasets. We only keep the pieces with $\frac{2}{4}$ and $\frac{4}{4}$ meters and slice them into 32-beat snippets at an 8-beat hop size, deriving a total of 35K samples. We quantize chords at 4^{th} note and melodies at 16^{th}. We randomly split the dataset (at song level) into training (95%) and validation (5%) sets. We further augment the training data by transposing each sample to all 12 keys.

4.2 Architecture Details

The VAE framework of our model is consistent with PianoTree VAE [18]. We implement the encoder with two bi-directional Gated Recurrent Unit (GRU) networks. The pitch-axis GRU and time-axis GRU each has a hidden dimension $d_{\text{p,enc}} = 256$ and $d_{\text{t,enc}} = 512$. The input embedding dimension d_{emb} and latent representation dimension d_{z} are both set to 128. The decoder mirrors the encoder with uni-directional GRUs, with hidden dimensions $d_{\text{t,dec}} = 1024$ and $d_{\text{p,dec}} = 512$. We set the KL balancing weight $\alpha = 0.1$ in Equation (1) and (3).

We implement the discriminator using BERT [26] with relative positional embedding [27–29], as our condition corruption is conceptually similar to language masking. For our model, we use 4 Transformer encoder layers with 4 heads [30] and 10% dropout [31]. The hidden dimensions of self-attention and feed-forward layers are $d_{\text{model}} = 256$ and $d_{\text{ff}} = 1024$. Our VAE and BERT discriminator each have 12.55M and 3.24M trainable parameters.

4.3 Training

Our model is trained using Adam optimizer [32], with a mini-batch of 256 samples and a learning rate from 1e-3 exponentially decayed to 1e-5. We use teacher forcing [33] for training the GRU-based decoder, with teacher forcing rate from 0.8 exponentially decayed to 0. We introduce domain adversarial training as an iterative process aside from the main VAE objective, as shown in Algorithm 1. We set $i = 10$, $j = 1$, $k = 5$, and $l = 5$. Our model is trained on a Geforce-2080Ti-12GB GPU. It takes 20 epochs (in around 15 hours) for our model to fully converge.

Algorithm 1: Domain Adversarial Training

```
while training do
    for i iterations do
        Optimize VAE with L(θ_enc, θ_dec),
    for j iterations do
        for k iteration do
            Optimize discriminator with L(θ_dis),
        for l iterations do
            Optimize encoder with L(θ_enc | θ_dis).
```

Figure 4 shows the trends of adversarial loss $\mathcal{L}(\theta_{\text{dis}})$ (in Equation (2)) and $\mathcal{L}(\theta_{\text{enc}} \mid \theta_{\text{dis}})$ (in Equation (3)). In the early stage, the discriminator learns to reconstruct c based on z_x, so the green curve decreases. However, as the adversarial procedure goes on, z_x is gradually disentangled from c-related cues. Consequently, the discriminator acquires less and less relevant information to reconstruct c well, and thus the green curve increases. The red curve exhibits an inverse trend, as it is supervised by $\mathbf{1} - c$. When each loss curve converges, we interpret it as an equilibrium that indicates a successful disentanglement of chord representation z_x from melody condition c.

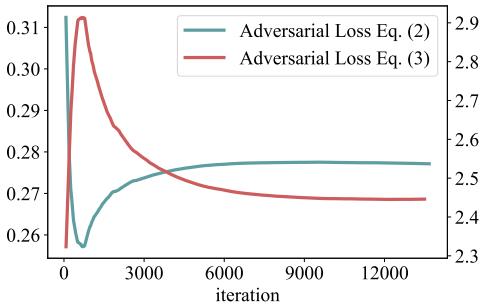

Figure 4: Adversarial loss curves with DAT. Such a trend is driven by the disentanglement of z_x from c.

4.4 Controllable Generation Results

Through domain adversarial training, our model gains reliable melody control over chord generation. Our model can harmonize a new melody using the representation of an existing chord progression. We hence develop a novel representation learning-based harmonization methodology. For example, Figure 5 presents two source lead sheets selected from our validation dataset. Both source samples are pop song phrases which share similar (but not exactly the same) chord progressions. However, the tonality and chromatic colours of these two pieces are quite different.

(a) Source A: a D major song accompanied by seventh chords.

(b) Source B: a B♭ major song accompanied by triads.

Figure 5: Source lead sheets.

Figure 6a is the result where we reconstruct chord A conditioned on melody B, i.e., to harmonize melody B with the harmonic style in A. Here the "style" includes tensions with seventh chords and a typical cadence progression of ii-V-I. We see these features properly fitted to melody B in the correct tone. In other words, the generation of chord progression is controlled by the melody. Figure 6b is the result where we reconstruct chord B conditioned on melody A. For this case, the original seventh chords in A are replaced by triads with a IV-V-I cadence. These results suggest that our learned chord representation can well discern relative progression and chromatic colour, while our model is controllable in terms of tonality.

(a) Reconstruction of Chord A conditioned on Melody B.

(b) Reconstruction of Chord B conditioned on Melody A.

Figure 6: Chord generation conditioned on exchanged melody conditions. This process can also be viewed as melody harmonization using exchanged harmonic styles.

4.5 Subjective Evaluation

In this section, we evaluate our model's performance on the task of *harmonization*. We first derive the following three baseline models for an ablation study:

Non-DAT: Compared with our model, Non-DAT has the same VAE framework but does not have a discriminator. It does not explicitly try to disentangle z_x from c using domain adversarial training (DAT);

Mask-CR: Mask-CR has the same architecture as our model but uses a different condition corruption technique. Specifically, it applies *masking corruption* (as in [26]) rather than pitch transposition;

Non-CR: Compared with our model, Non-CR uses the conventional DAT objective *without condition corruption*. It predicts c directly from z_x with a GRU discriminator.

To compare our model with the baselines, we survey on rating the harmonization quality of all models. Our survey has 10 groups of harmonization results and each subject is required to listen to 4. In each group, the subjects first listen to an original lead sheet A and a single melody B. Both A and B are 8-bar long (16 seconds) and are randomly selected from different musical pieces from our validation set. As in Section 4.4, we harmonize melody B with the harmonic style of A using our model and the baseline models. Subjects are then required to evaluate each version of harmonization. The rating is based on a five-point scale from 1 (very poor) to 5 (very high) over three metrics: harmonicity, creativity, and musicality.

A total of 38 subjects with diverse music backgrounds participated in our survey and we obtain 142 effective ratings for each metric. As shown in Figure 7, the height of the bars represents the mean value of the ratings. The error bars represent the mean square errors (MSEs) computed by within-subject ANOVA [34]. We report a significantly better harmonization performance of our model than all three baselines in each metric (p-value $p < 0.05$). Specifically, we note that our model achieves such performance based

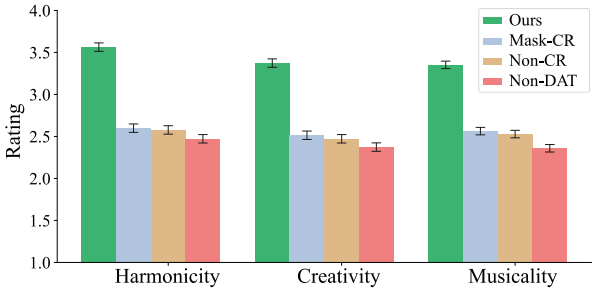

Figure 7: Subjective evaluation on the harmonization performance of our model and baseline models.

on a higher degree of representation disentanglement and controllability. We evaluate these methodological aspects with finer objective metrics in the following section.

4.6 Objective Evaluation

In this section, we objectively compare our model with the baselines in terms of *disentanglement* and *controllability*. The baseline models are as defined in Section 4.5.

4.6.1 Disentanglement

Our model disentangles chord representation z_x from melody condition c. In our case, the melody controls the absolute pitch of the chord progression. A satisfied disentanglement should derive a *pitch-invariant* representation. Following [7,35], we develop a similarity criterion to evaluate the performance on disentanglement.

Let $\mathrm{T}_i(\cdot)$ be a transposition operator with i semitones. We calculate cosine similarity $\cos(z_x, z_{\mathrm{T}_i(x)}), i = 1, 2, \cdots, 12$ for our model and for each baseline. In Figure 8, a higher similarity means representation z_x is less affected by the absolute pitch and thus is better disentangled. Our model outperforms all three baselines, including Mask-CR. This finding corroborates that a proper corruption strategy is crucial to applying domain adversarial training to concrete tasks. In our case, masking is not the best way to corrupt, as it is less aware of the harmonization context or dependency discussed in Section 3.3.

It is also worth noting that the similarity of z_x reflects human pitch perception. For each model, transposing a tritone ($\mathrm{T}_6(\cdot)$) derives the lowest similarity. Figure 8 shows that $z_{\mathrm{T}_6(x)}$ is literally orthogonal to z_x for Non-DAT and Non-CR. Interestingly, tritone is the most dissonant among all musical intervals in human perception. Such observation indicates that our model learns non-trivial music rules.

4.6.2 Controllability

A pitch-invariant representation helps us improve the model controllability by enforcing the decoder to rely on external conditions. In our case of harmonization, a good control generates harmonic chord progression conditioned on the lead melody. Aside from the subjective evaluation in Section 4.5, we introduce *harmony histogram* to objectively interpret the quality of control. Concretely, the harmony histogram is defined as the ratio of within-chord note positions on which the lead melody lies. For tonal music,

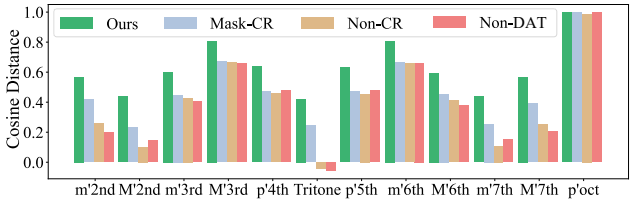

Figure 8: Object evaluation on representation similarity (invariance) against pitch transposition. A higher value denotes better disentanglement.

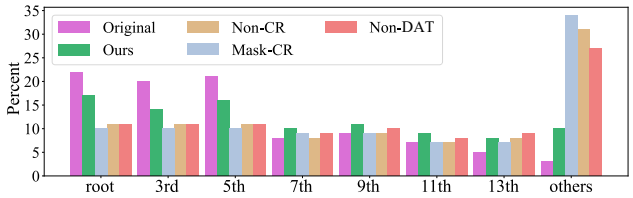

Figure 9: Objective evaluation on harmony histogram upon melody swapping. A higher ratio in root, 3rd, and 5th notes indicates a higher degree of controllability.

there should be more root, 3rd, and 5th notes appearing in the melody compared to 7th and higher, so that the music is considered harmonic.

In our experiment, we arrange our validation data into random pairs and reconstruct the chord progression with swapped melody conditions. We compare the harmony histogram of generated results from our model and all baselines. Additionally, we compute the histogram for the original (human-composed) data as ground truth. In Figure 9, we first observe that the histogram distribution has a larger portion in the root, 3rd, and 5th notes for the original data. For the baseline models, over 25% melody notes are beyond all chord notes and tensions (shown by "others" in Figure 9), which indicates excessive disharmony. Our proposed model, on the other hand, keeps a more consistent pattern with the ground truth.

5. CONCLUSION

In conclusion, we contribute a generalized form of domain adversarial training for controllable music generation, especially when complex sequential conditions are involved. The main novelty lies in the condition corruption objective, which contextualizes the exact dependency between representation z_x and condition c, and therefore assists disentanglement and control. Our method shows excellent performance in chord representation learning, where we learn a pitch-invariant representation conditioned on the melody and develop a novel harmonization strategy. Our improvement in disentanglement and controllability is elaborated with extensive subjective and objective evaluation. With the proposal of our methodology, we hope to bring a new perspective not only to music generation but also to more general scenarios of conditional representation learning.

ABSTRACT

The relationship between perceptual loudness and physical attributes of sound is an important subject in both computer music and psychoacoustics. Early studies of "equal-loudness contour" can trace back to the 1920s and the measured loudness with respect to intensity and frequency has been revised many times since then. However, most studies merely focus on synthesized sound, and the induced theories on natural tones with complex timbre have rarely been justified. To this end, we investigate both theory and applications of natural-tone loudness perception in this paper via modeling piano tone. The theory part contains: 1) an accurate measurement of piano-tone equal-loudness contour of pitches, and 2) a machine-learning model capable of inferring loudness purely based on spectral features trained on human subject measurements. As for the application, we apply our theory to *piano control transfer*, in which we adjust the MIDI velocities on two different player pianos (in different acoustic environments) to achieve the same perceptual effect. Experiments show that both our theoretical loudness modeling and the corresponding performance control transfer algorithm significantly outperform their baselines. [1]

1. INTRODUCTION

Sound *intensity* and *loudness* are two relevant but very different terms. Intensity is the physical feature of sound derived from sound pressure. Loudness, however, is the perceptual measure dependent on our auditory systems, where other physical factors also contribute to human perception. For example, a 1 kHz tone is measured louder than a 100 Hz tone of equal intensity, but softer than an equal-intensity white noise. Previous psychoacoustic studies provide knowledge of loudness perception via human subject experiments and various computational models have been proposed to account for loudness estimation [1–6].

However, existing theories mainly focus on synthesized tones and thus fall short of explaining natural tone loudness such as the piano tone. The generation of piano tone involves a complicated physical process [7] and the sound contains rich timbral variations hard to be synthesized from both frequency and time domain perspectives [8, 9]. On the other hand, recently we see a growing number of music information retrieval tasks involving feature extraction of piano tone loudness, such as automatic music transcription [10–12] and performance rendering [13, 14]. In most of these studies, loudness is sometimes confused with intensity or even the MIDI velocity. This motivates us to investigate loudness perception specific to piano tone, beneficial for various downstream applications.

In this paper, we investigate both theory and applications on loudness perception specific to piano tone. The theory is studied in a hybrid method containing a *psychoacoustic* procedure and a *machine-learning* procedure. In the psychoacoustic procedure, we measure the "equal-loudness contour" on piano based on a human subject experiment similar to the pure-tone equal-loudness measurement [1]. Since piano tones cannot be directly controlled by frequency and intensity, we instead study pitch and velocity, two corresponding discrete performance controls. In our experiment, the controls are executed by (acoustic) player pianos for accuracy and reproducibility. We show that different pianos (in different acoustic environments) have distinctive equal-loudness contour patterns, and existing methods have limited power to explain the measured pattern.

In the machine-learning procedure, we extend the piano-tone equal-loudness contour to a computational model, capable of inferring loudness purely from spectral features. Traditionally, loudness models are based on mathematical approximation of our auditory systems [3–6]. We argue such an approach is laborious and even intractable for natural tones such as the piano tone to take into account all contributing facets of sound. Instead, we propose a machine-learning approach including a loudness model trained on the human subject measurement in the previous experiment. The model takes in the spectrogram and outputs the estimated loudness, calibrated to standard loudness unit *sone* in post-processing.

[1] Code and models can be accessed via https://github.com/yangqu2000/ModelingPerceptualLoudnessOfPianoTone

We show our theory of piano tone loudness provides a more reasonable explanation of piano sounds in downstream applications. Specifically, we apply our loudness model to *performance control transfer* [14], in which we adjust the MIDI velocities on two different player pianos (in different acoustic environments) to achieve the same perceptual effect. The original intensity-based loudness estimator is replaced with the proposed method, and experimental results show a significant improvement in terms of transfer quality.

2. RELATED WORK

The study of the equal-loudness contour (ELC) of pure tone is a serious subject in psychoacoustics, since it reveals fundamental facts of human loudness perception with respect to frequency spectrum and intensity. The experiment settings have been modified throughout the century, including the tuning of listening conditions [1, 15, 16], the improvement of experiment procedures [1,17,18], and the extension of measured frequency range [1,16,19,20]. Suzuki *et al.* [2] provides a detailed literature review of the existing experiments. Our piano-tone ELC experiment is modified from the original one, including careful adjustment to account for discrete frequency and intensity control.

The psychoacoustic listening tests of pure tone and many others [1, 16–18, 21, 22] provide fundamental understanding of our auditory systems. In return, the study of *loudness models* takes in the auditory system hypotheses and yields loudness estimation of the different types of tone, including [1, 16–18] for pure tone, [21] for complex tone, and [22, 23] for complex tone with amplitude modulations. So far, the state-of-the-art loudness model ISO 532-3 [24, 25] has the theoretical power to estimate the loudness of arbitrary waveforms. In our paper, we validate and compare with this model particularly on piano tone loudness estimation.

The majority of research on piano tone mainly focuses on the relationship between instrument control and the physical attributes of the generated sound, either statistically [26–28] or via physical modeling [7, 29, 30]. However, there is a lack of formal theory to cover the perception of piano tone. In this paper, we provide the first approach to study the relationship between instrument control and piano tone loudness in a psychoacoustic approach.

3. PIANO TONE EQUAL-LOUDNESS CONTOUR

Unlike pure tone which is determined by frequency and intensity, piano tone is largely dependent on the environment including the instrument itself that generates the sound (e.g., upright or grand piano) and the surrounding acoustic environment (e.g., concert hall or small room). Given a fixed environment, a piano tone can be controlled by four factors, namely *pitch*, *velocity*, *duration* and *pedal* [31]. Simple as they are, the four control parameters interact with the acoustic environment and produce a wide spectrum of piano timbre, resulting in an unexplored loudness perception pattern. In this paper, we study how perceptual loudness is affected by the first two factors, i.e., pitch and velocity, which can be roughly understood as the "frequency" and "intensity" of piano tone, respectively. We leave the others for future study.

The piano tones in our experiment are produced by player pianos, which can execute the control parameter in a more accurate manner than human pianists. Pitch is controlled by 88 MIDI pitches in $[21..108]$ and velocity is controlled by 128 velocity levels in $[0..127]$.

3.1 Method of Measurement

The goal of this experiment is to measure the *equal-loudness contours* (ELC) of piano tone on a specific piano and acoustic environment, that is, a sequence of piano keys under possibly different velocities that have equal perceptual loudness.

The experiment is modified from the original pure-tone ELC experiments [1]. Specifically, we first select a reference tone, denoted by $(p_{\text{ref}}, v_{\text{ref}})$, where p_{ref} is a reference pitch and v_{ref} is the velocity level that we are interested in. Then, we enumerate piano pitches and for each pitch p_{var}, we ask subjects to listen to $(p_{\text{var}}, v_{\text{var}}), v_{\text{var}} \in [0..127]$ and choose the louder note until they find a velocity v^*_{var} such that $(p_{\text{var}}, v^*_{\text{var}})$ and $(p_{\text{ref}}, v_{\text{ref}})$ have equal loudness.

In psychoacoustic terms, the reference tone $(p_{\text{ref}}, v_{\text{ref}})$ is called a *reference stimulus*, and given the pitch, the candidate tones under multiple velocities to compare (i.e., $(p_{\text{var}}, v_{\text{var}})$) are called *variable stimuli*. The solution $(p_{\text{var}}, v^*_{\text{var}})$ is called the *point of subjective equality* (PSE). The curve that connects the PSEs at multiple pitches is the equal-loudness contour at reference velocity v_0.

To adjust the velocity of reference stimuli and search for the PSE of each pitch, we adopt *randomized maximum likelihood sequential procedure* (RMLSP) [1], a common procedure used in pure-tone ELC experiments consisting of a series of test rounds. At each test round, the subject is asked to compare the loudness of a pair of piano tones, including the reference stimulus and a variable stimulus. Then we fit an online logistic regression model to predict the PSE according to the subject's response so far. The velocity of the variable stimulus in the next test round is randomly selected within a velocity range centered at this PSE velocity. The algorithm ensures the procedure will converge to the correct PSE.

3.2 Experiment Setting

In our experiment, we use A4 in the middle of the keyboard as the reference pitch (i.e., $p_{\text{ref}} = 69$). We measure equal loudness contours at four velocity levels: $v_{\text{ref}} \in \{32, 44, 60, 80\}$. The four velocities lie in the common range of velocity usage and are evenly distributed with respect to the statistical distribution [11].

We measure equal-loudness contours on 9 variable pitches: $p_{\text{var}} \in \{21, 33, 45, 57, 69, 81, 93, 105, 108\}$. The pitches are the A's in all octaves together with the highest note C8. The measurement on all 88 keys is ideal though not affordable, since RMLSP normally takes 20 minutes to find the PSE with respect to one single variable pitch.

ID	Environment		Number of subjects assigned to each velocity level				
	Instrument	Acoustic environment	$v_{\text{ref}} = 32$	$v_{\text{ref}} = 44$	$v_{\text{ref}} = 60$	$v_{\text{ref}} = 80$	Total
Env. I	Grand Disklavier	Anechoic chamber	6	6	6	5	23
Env. II	Upright Disklavier	Non-anechoic chamber	7	7	7	7	28

Table 1: Experiment settings and subjects assignment in two environments.

We address the loudness modeling on the other pitches in section 4.

We set the number of RMLSP test round to be 32. In the first two test rounds, the subject always listens to two piano tones of constant variable velocities $v_{\text{var}} = 90$ and $v_{\text{var}} = 30$, respectively. After that, the model yields the next variable velocity uniformly sampled from a $[-6..+6]$ interval centered at the current-step estimation of the PSE. The order of the piano tone pairs between the reference stimulus and the variable stimulus is random at each test round.

The experiment is conducted on two player pianos located in different acoustic environments (as shown in Table 1). Environment I contains a grand YAMAHA Disklavier piano in an anechoic chamber, and Environment II contains an upright YAMAHA Disklavier piano in a non-anechoic chamber. Subjects are seated half a meter in front of the pianos where the pianists usually sit and use a laptop to respond.

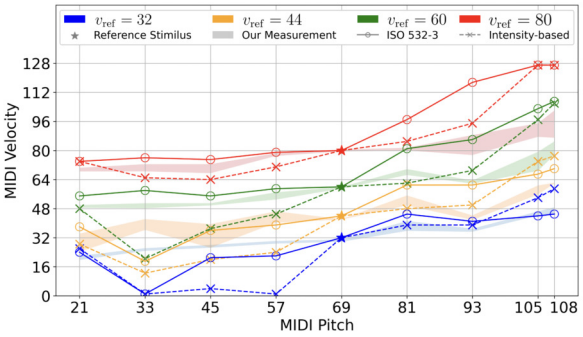
The subjects are 15 adults (18–35 years), 10 male and 5 female. All subjects have normal hearing sensitivity. 11 subjects participate in the experiment in Environment I and 9 subjects participate in the experiment in Environment II. Each subject is tested in a separate section.

The subject is tested at two or three of the four velocity levels randomly assigned (as shown in Table 1). For Environment I, 23 measurement results were collected. Each velocity level has a sample number of 6 except for velocity 80 with a sample number of 5. For Environment II, 28 measurement results were collected. Each velocity level has a sample number of 7.

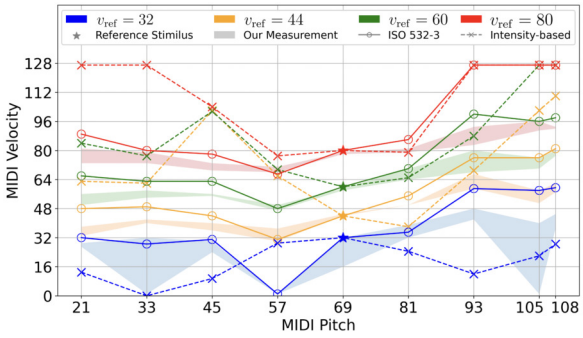
3.3 Result

Figure 1 shows our experiment results in Environment I and Environment II, respectively. Since MIDI velocity is an ordinal variable, it is improper to average the subjects' PSEs and show the mean equal-loudness curves. Instead, we present *equal-loudness ribbons*, where we replace the mean with the range of subjects' PSEs between the first and third quartiles among all data. Here, we use four different colors to indicate four reference velocities, and the diamond markers indicate the four reference stimuli on each graph. Note that in the lowest ($v_{\text{ref}} = 32$) ribbons, some of the variable pitches have PSEs equal to one, meaning that the variable pitches at the least audible velocity are still louder than or equal to the reference tone.

We see the patterns of equal-loudness ribbons are very different across the two environments. In Environment I, we see a gradual growth trend in all velocity levels, meaning higher pitches of the same velocity tend to be softer.



(a) Environment I.



(b) Environment II.

Figure 1: Measurement of equal-loudness ribbons of piano tone in two environments compared with ISO 532-3 [24,25] and intensity-based loudness computation [14,26].

In Environment II, the trend is less evident, and we see a valley at A3 (i.e., $p_{\text{var}} = 57$) at all reference velocity levels. Moreover, the range of equal-loudness ribbons varies, indicating the just noticeable difference in velocity change is uneven on different pianos, pitches and velocities.

3.4 Comparison with Existing Methods

We use the experiment result to validate two common loudness computation methods. The first method is ISO 532-3 by Moore *et al.* [24,25], the state-of-the-art loudness model based on the modeling of human auditory systems. The loudness value is computed as the maximum value of the predicted long-term loudness curve. The other method is used in [14,26] by naively computing the average intensity of the first 10 ms after the peak. For the two methods, we use the recordings of all the piano tones (discussed in section 4.3) and compute their corresponding loudness. The induced equal-loudness contours are shown in Figure 1 in solid lines with circles and dashed lines with crosses, respectively. Other popular methods such as applying A-

weighting is not considered since such methods are proved not generalizable to natural tone [32].

As shown in Figure 1(a) and Figure 1(b), in both environments, the results induced from ISO 532-3 are in general consistent with the equal-loudness measurement except for the pitch in the higher registers. The results induced from the intensity-based method fluctuate around the equal-loudness ribbons, failing to describe the perceptual effect.

4. LOUDNESS MODEL

In the previous section, we measure the equal-loudness contours (ELC) in two environments on 9 variable pitches and 4 reference velocities. In this section, we extend our findings to learn loudness models to account for loudness estimation of the remaining tones via a non-parametric approach as baseline (discussed in section 4.1) and a parametric approach (discussed in section 4.2). The parametric model is also capable of predicting loudness given the waveform of an arbitrary piano tone. We compare the prediction result with ISO 532-3 and the intensity-based method in section 4.3.

4.1 Non-parametric Method

We first propose a naive approach to predict the loudness of arbitrary piano tones in each environment via linear interpolation of the measured ELCs in section 3. First, we assign the loudness in *sone* to the tones of the reference pitch A4 under all the velocities using the calibration method discussed in section 4.2.3. Then, we linearly interpolate the ELCs measured on 9 variable pitches to all 88 pitches, and assign the same loudness level along each contour. Finally, for each pitch, we linearly interpolate between the ELCs. In section 5, we see such a simple method already yields satisfactory performance in downstream applications.

4.2 Parametric Method

Moreover, a parametric model is proposed to estimate the loudness using machine learning.

4.2.1 Model

We use $x = (p, v)$ to denote a piano tone, where p is the pitch and v is the velocity levels. We learn a parametric loudness model $\ell = f_\theta(x)$ to compute the loudness of a given piano tone x.

The loudness model is learned as a supervised classification problem (as shown in Figure 2). The input is a pair of piano tones (x_1, x_2), where $x_1 = (p_1, v_1)$ and $x_2 = (p_2, v_2)$. The target is the ground-truth label y, which is the indicator of whether x_1 is the louder one inferred from the ELCs. The difference between the estimated loudness ℓ_1 and ℓ_2 is used to predict the y. Specifically, the loss function is:

$$\mathcal{L}(\theta; x_1, x_2, y) = \text{BCE}(f_\theta(x_1) - f_\theta(x_2), y), \quad (1)$$

where $\text{BCE}(\cdot)$ is the binary cross entropy function.

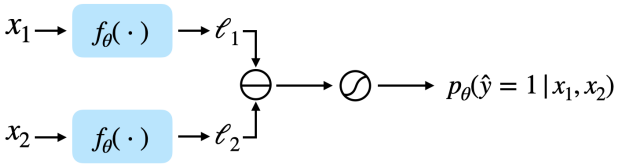


Figure 2: Illustration of the objective function.

The pairs (x_1, x_2) are sampled from all the tone pairs in each environment whose loudness comparisons are derivable based on the human subject results. Specifically, a pair must satisfy either of the two conditions:

(**C.1**) The two tones have the same pitch and thus can be compared based on velocity. The one with the larger velocity is assumed to be louder.

(**C.2**) The two tones have different variable pitches and the loudness comparison can be inferred from the equal-loudness ribbons in Figure 1.

4.2.2 Implementation

We define our loudness model $\ell = f_\theta(x)$ as the linear combination of the values on the mel-spectrogram of x (without an intercept term). The mel-spectrogram has 8 mel-frequency bins, a 2048 window size, and a 512 hop size under the sample rate of 22050 Hz. We select the 5 time frames (approx. 0.1s) right after the onset of the tone detected by [33]. In all, we have 80 input features of a pair of piano tones and the model can be optimized using logistic regression.

The small mel-frequency bin number in the current model can be understood as a constant convolution kernel to achieve better generalization on other non-variable pitches. In the future, the model can also be extended to neural networks given a larger amount of human subject results.

4.2.3 Calibration

The parametric method learns an unstandardized estimation of piano tone loudness based on classification, which needs to be further calibrated to the standard loudness unit in sone. We address the problem by matching the piano tones under reference pitch A4 to the corresponding equal-loudness pure tones and compute the corresponding pure tone loudness using ISO 532-3. The matching procedure follows from the *method of adjustment* [32].

4.3 Evaluation

4.3.1 Data Preparation

We record the piano tones of two Disklavier pianos in both environments for all pitches and velocities. The recorder is placed 0.5 meters in front of the piano (similar to the subjects' ear position) and is kept still during the recording procedure. For all piano tones, the MIDI duration is 0.3 seconds and each recording clip lasts 1.3 seconds.

To train the parametric model, we select all the piano tone pairs that satisfy the two conditions (defined in 4.2.1),

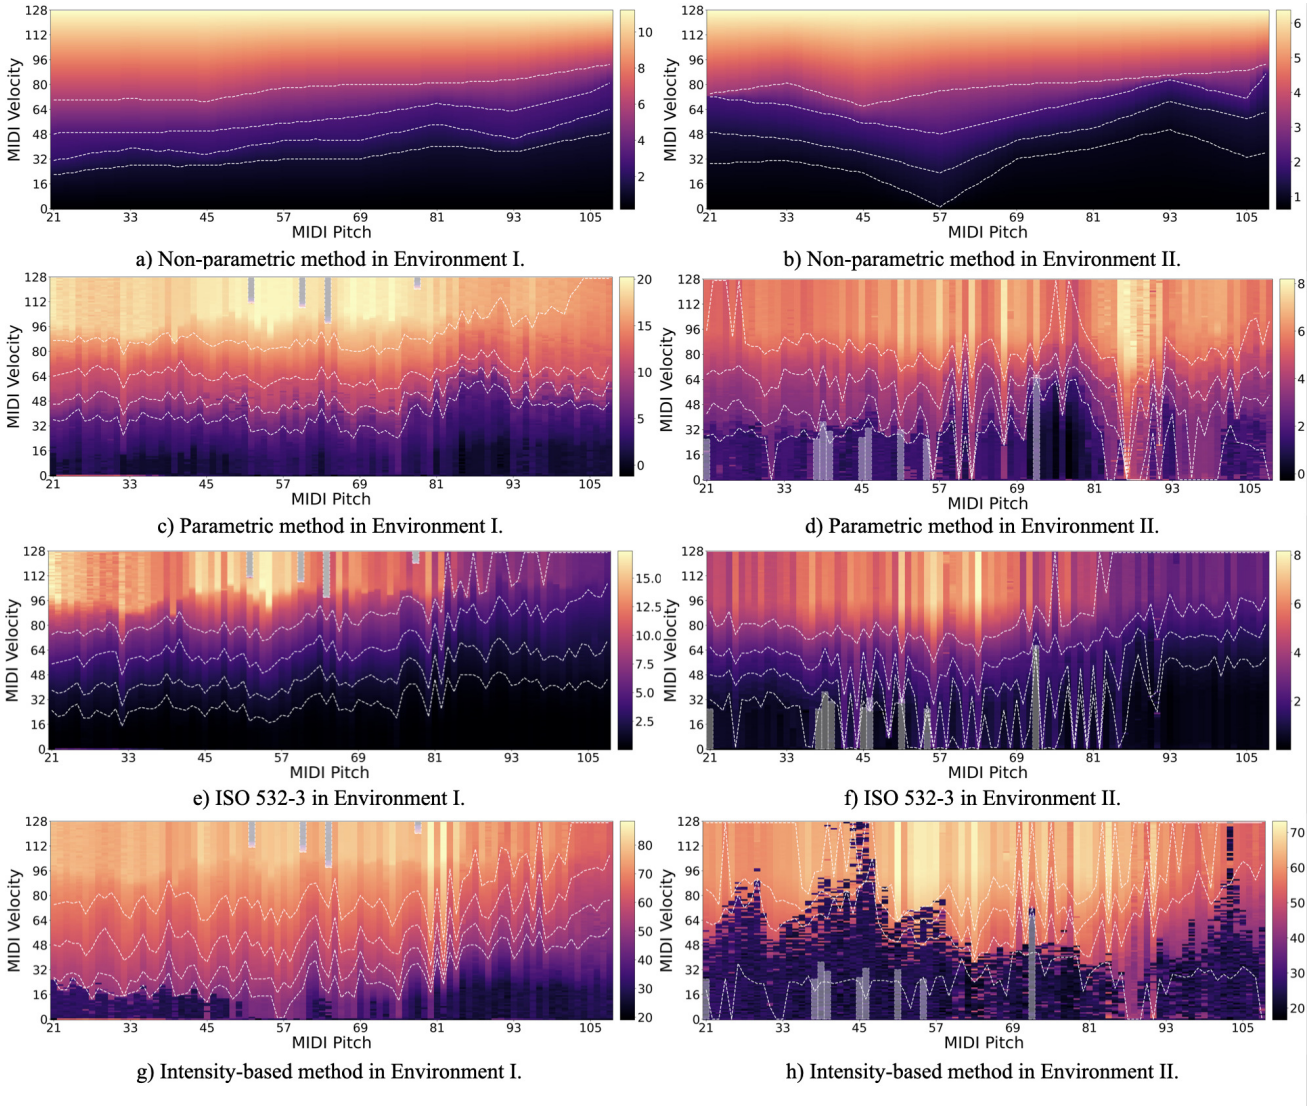

Figure 3: Visualization of calculated loudness value in Environment I and Environment II using our proposed loudness models, ISO 532-3 [24,25], and intensity-based method [14,26]. Points with a rectangular mask indicate mechanical failure of the player piano.

including 673,035 pairs satisfying the **C.1** and 427,633 pairs satisfying the **C.2** in Environment I, and 695,860 pairs satisfying the **C.1** and 422,386 pairs satisfying the **C.2** in Environment II. The dataset is randomly split into train set (80%) and test set (20%).

4.3.2 Results

Figure 3 shows the heatmaps of the predicted loudness of all piano tones in both environments by four methods: 1) our non-parametric method, 2) our parametric method, 3) ISO 532-3, and 4) intensity-based method. We show the ELCs derived from the heatmaps in dashed lines for better readability.

We see the non-parametric method presents a smooth interpolation of the measured ELCs. The result of the parametric method demonstrates a similar trend as ISO 532-3 except in the higher pitch range, which is more consistent with human subject measurement in Figure 1. Moreover, both parametric method and ISO 532-3 show more discontinuity than Figure 1, suggesting the MIDI velocity is not assigned in a uniform manner for different pitches. Finally, the result of intensity-based method are noisy and inconsistent with the human perception.

Table 2 shows the model accuracy on the test set of two conditions defined in 4.2.1 separately. The results demonstrate that our proposed method outperforms the two baselines in both environments, especially in the accuracy of **C.2**. We show the generalization ability in two ways. First, we apply the model trained in one environment to the other environment and achieves satisfactory accuracy (as indicated by the underlined numbers). Second, we combine the training data in both environments and train a hybrid model. The model outperforms the baselines and even achieves the best performance in environment II in both conditions. The evaluation result shows our proposed model capture certain features in the piano-tone mel-spectogram contributing to the perceptual loudness.

Methods	Acc. in Env. I		Acc. in Env. II	
	C.1	C.2	C.1	C.2
ISO 532-3	**0.9689**	0.9631	0.9037	0.9455
Intensity-based	0.9658	0.9290	0.8377	0.8555
PM - Env. I	**0.9689**	**0.9893**	0.8976	0.9614
PM - Env. II	0.9528	0.9607	0.9121	0.9793
Hybrid PM	0.9401	0.9785	**0.9370**	**0.9881**

Table 2: Evaluation of loudness comparison accuracy in Environment I and Environment II. The methods to compare are: 1) ISO 532-3: [24,25], 2) Intensity-based [14,26], 3) PM - Env. I: Parametric model trained on the data recorded in Environment I, 4) PM - Env. II: Parametric model trained on the data recorded in Environment II, and 5) Hybrid PM: Parametric model trained on the data recorded in both environments. Underlined data are tested by the parametric model training in the other environment.

5. PERFORMANCE CONTROL TRANSFER

In this section, we apply our theory of piano tone loudness to the downstream application of *performance control transfer*, in which we adjust the MIDI velocities on two different player pianos to achieve the same perceptual effect. An example scenario of the application is to reproduce a pianist's performance in the concert hall to one's living room.

5.1 Modification

Performance control transfer is originally proposed in [14], in which piano tone loudness is treated as a fundamental invariant property between the original performance and the transferred version. However, the study mistakenly uses the physical intensity as the loudness measure. Our approach replace the loudness estimator by the proposed loudness models (discussed in section 4) and keep the remaining algorithm the same. We also use ISO 532-3 as the loudness estimator as a baseline method.

5.2 Listening Test

We conduct a listening test to invite participants to evaluate the performance transferred by different algorithms, similar to the one conducted in [14]. Specifically, we prepare four pieces, including two monophonic pieces and two polyphonic pieces. The pieces are selected to cover classical and popular genres.

We invite two pianists to play the four pieces in Environment I and record both pianists' MIDI control and the performance audio. Then, we transfer the MIDI files recorded in Environment I to Environment II using different performance transfer methods, including 1) our non-parametric method, 2) our parametric method, 3) ISO 532-3, 4) intensity-based model (i.e., the original transfer method [14]), and 5) a raw transfer without any MIDI velocity editing. We play the transferred MIDI in Environment II and record them from the same microphone position discussed in section 4.3.

We invite people to subjectively rate the transfer quality through a double-blind online survey. During the survey, the subjects listen to four groups of samples. In each group, the original performance in Environment I is played, followed by the five transferred versions. Both the order of groups and the sample order within each group are randomized. After listening to each sample, the subjects rate them based on a 5-point scale from 1 (very low) to 5 (very high) according to three criteria: *faithfulness* (to the original performance), *naturalness* and *overall musicality*.

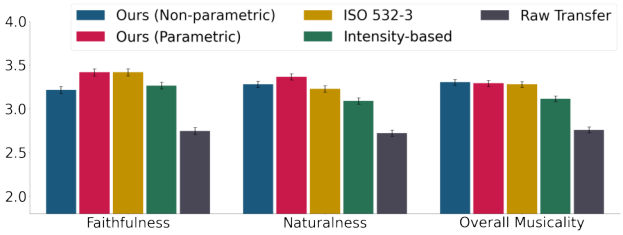

Figure 4: The subjective evaluation results of the five transfer methods.

5.3 Results

A total of 21 participants (14 male, 7 female) with different musical backgrounds have completed the survey. Figure 4 shows the result where the heights of the bars represent the means of the ratings and the error bars represent the confidence intervals computed via within-subject ANOVA [34].

The results show that all the loudness-based methods significantly outperforms the original intensity-based implementation and raw transfer (with p-value < 0.005). Moreover, our parametric method is marginally better than ISO 532-3 in terms of naturalness and overall musicality, and comparable with ISO 532-3 in faithfulness. Both our parametric and non-parametric methods demonstrate with only sparse human subject measurement data, we can achieve promising performance transfer results.

6. CONCLUSION

In this paper, we have contributed the first study to model the perceptual loudness of piano tones in a hybrid approach combining psychoacoustic experiments, and data-driven methods. Our theory include: 1) measurements of piano-tone equal-loudness contours on two player pianos, and 2) data-driven loudness models to estimate piano-tone loudness based on the measured contours. Experiments show our model provides more satisfactory estimation than existing loudness theories. Based on our findings, we validate the state-of-the-art loudness model ISO 532-3 on piano-specific tasks and argue that existing methods can be greatly improved if we have a more detailed human subject measurement and a deeper understanding of the timbral features of piano tone.

On the application side, we improve the existing performance control transfer method with the proposed loudness estimator. We believe the other downstream applications can also benefit from our study to propose a clearer problem definition and more accurate feature extraction.

ABSTRACT

Automatic music tagging systems have once more gained relevance over the last years, not least through their use in applications such as music recommender systems. State-of-the-art systems are based on a variant of convolutional neural networks (CNNs) and use some type of time-frequency audio representation as input, in a fitting combination, to predict semantic tags available through expert or crowd-based annotation. In this work we systematically compare five widely used audio input representations (STFT, CQT, Mel spectrograms, MFCCs, and raw audio waveform) using five established convolutional neural network architectures (musicnn, VGG-16, ResNet, a squeeze and excitation network (SeNet), as well as a newly proposed musicnn variant using dilated convolutions) for the task of music tag prediction. Performance of all factor combinations are measured on two distinct tagging datasets, namely MagnaTagATune and MTG Jamendo. A two-way ANOVA shows that both input representation and model architecture significantly impact the classification results. Despite differently sized input representations and practical impact on model training, we find that using STFT as input representations provides the best results overall. Furthermore, the proposed dilated convolutional architecture shows significant performance improvements for all input representations except raw waveform.

1. INTRODUCTION

Music tagging is a multi-label classification task to predict semantic high-level tags like "rock", "piano" or "fast" for music pieces. As for many music information retrieval (MIR) tasks, deep learning has become the state-of-the-art for music tagging [1]. Specifically, CNNs have provided the best results for this task, using either types of audio spectrograms or raw waveform as network input [2, 3].

The selection of audio input representations for neural networks is often decided heuristically or by falling back to standard spectrograms and usually not evaluated [4]. However, the choice of input representation can have a significant impact on performance, as shown in other tasks like natural language processing (NLP), justifying also an evaluation of different representations [5].

While existing work compares different aspects of neural network architectures and input representations (see section 2), an evaluation of their interplay is missing. In this work, as our first contribution, we systematically compare five different architectures and five different input representations in a full-factorial design. The baseline architectures are: *(i)* VGG-16 [6], *(ii)* ResNet [7], *(iii)* SENet [8], *(iv)* musicnn [9], and *(v)* a musicnn architecture with dilated convolutional layers. Five different input representations are tested on each of those architectures: *(i)* raw waveform, *(ii)* short time Fourier transformation (STFT), *(iii)* Mel spectrogram, *(iv)* Mel frequency cepstral coefficients (MFCCs), and *(v)* constant-Q transformation (CQT) [2, 3, 10]. All experiments are repeated on two different datasets and a statistical analysis is used to test if differences of results are significant.

Through this extensive evaluation, we can state that our second contribution is the introduction of dilated convolutional layers in a music tagging network architecture (musicnn). This observed improvement can be related to the fact that the dilated layers allow for a large receptive field when only using a limited amount of layers, cf. [10].

Next, in section 2, we review related work, followed by an outline of the five input representations, five neural network architectures, and datasets used in section 3. Section 4 describes the experimental setup, training, and evaluation strategy and presents the statistical evaluation and significance analysis of the results. Finally, conclusions on the results and findings are drawn in section 5.

2. RELATED WORK

In [2], the authors evaluate state-of-the-art CNN models for music auto-tagging either by using the audio waveform or Mel spectrogram as input representations. MagnaTagATune (MTAT), Million Song dataset (MSD), and MTG-Jamendo (MTGJ) serve as datasets for training and evaluation. Among others, the study considers the following model architectures: A fully convolutional network, *musicnn* (cf. section 3.2.4), a Sample-Level CNN to process raw waveforms using squeeze- and excitation blocks (cf. section 3.2.3), a convolutional recurrent neural network, as well as a self-attention based approach using an adaptation of the transformer architecture. Furthermore, the work fo-

Society for Music Information Retrieval Conf.,* Bengaluru, India, 2022.

cuses on effects of data augmentation like pitch shifting or time stretching to improve generalization abilities. Note that while we follow a similar strategy wrt. evaluated architectures in our work, we focus on the impact of different input representations on these different architectures and evaluate their interplay.

More recently, transformer networks have been applied for music tagging [11,12]. While these models improve the state-of-the-art performance, they are significantly more complex than plain convolutional models. Therefore, we consider them not a good match for the evaluation in this work. Other deep learning techniques like transfer-learning, data augmentation, and model aggregation which have been used in music tagging [13], are mainly model agnostic and can be applied on top of any input representation and model combination.

In [14], the authors tested the effect of training data size for music tagging. They trained models with dataset sizes ranging from 100k to 1.2 million training instances using the private 1.2M-Songs dataset. Two CNN architectures are used, one for raw waveforms and a second one for Mel spectrograms inputs. The Mel spectrogram-based model outperformed the raw waveform-based model in both datasets on all tested configurations, which encouraged the conclusion that domain knowledge can be beneficial for designing model architectures.

Using dilated convolutions has shown promising results in image segmentation- and classification over the last few years [15–17]. A similar trend can be observed for the audio domain [18–21]. Dilation can be used to increase the receptive field using only a few layers, which can be beneficial for tasks focusing on global properties of the input.

In [22], the authors use dilated convolutions for environmental sound classification. This task (similarly to music tagging) requires an architecture with a large receptive field. Previously this was achieved by using very deep CNNs. The evaluation shows performance improvements of up to 10% on different datasets compared to existing deep CNNs while reducing model size.

In [4], the authors compare the effects of several audio preprocessing methods for music auto-tagging when using a CNN. For this, the same neural network was trained on the MSD using either STFT or Mel spectrogram as input representations. The evaluation shows no significant differences in performance for the two input representations. However, using log-compressed magnitude spectrograms showed a significant performance increase for all tested configurations.

A more comprehensive comparison of spectrogram representations for audio was conducted in [10] in the context of environmental sound classification. Different configurations for STFT, Mel spectrogram, CQT, continuous wavelet transform, and MFCCs were evaluated in the experiments, using different CNN configurations for training. The evaluation shows that in nearly all configurations, shallower CNN models outperformed deeper ones. The authors suspect that overfitting of the deeper model is the cause of this. The results also show that Mel spectrograms performed consistently well, while STFT and CQT did not, while MFCCs performed worst.

The effects of the reduction of frequency and time resolution of Mel spectrograms for CNN architectures in the context of music auto-tagging were investigated in [23]. Two different state-of-the-art CNN architectures served as a reference for the comparison of Mel spectrograms with different frequency and time resolutions. The results show that while reducing the frequency bands from 128 to 48, the performance loss was negligible.

3. METHOD

This section covers the description of the input representations as well as the neural network architectures used in the evaluation. The experiments are implemented in Python, using librosa [1] for audio processing and TensorFlow as deep learning framework. The source code is available online, refer to the source code for all implementational details [2], there are also additional figures on the accompanying website [3].

3.1 Input Representations

In the following section, the used input representations are discussed and parameter settings are provided. In this work, standard parameter settings established in the literature are used. Figure 1 visualizes the 2D input representations using a 10s audio snippet.

3.1.1 Raw Waveform

In the context of this work, the audio material is resampled to 16kHz mono. This is used consistently also for the source of all spectrograms. As waveform input representation, 16kHz mono 32bit float pulse-code modulation (PCM) data is used.

3.1.2 STFT

A STFT is calculated by repeatedly applying a discrete Fourier transformation (DFT) to small frames of the audio signal. As a baseline spectrogram, in this work, the librosa STFT with default parameters is used: frame size of 2 048 at 16kHz, a hop length of 512, and a Hann window function.

3.1.3 Mel Spectrogram

A usual modification to plain spectrograms is to use psychoacoustically-motivated frequency scales. A common choice is the Mel scale, which has a logarithmic characteristic. In this work, 96-frequency-bin Mel spectrograms are used. A minimum frequency of 32Hz and 12 bins per octave are used. These or similar values are consistently used throughout the literature [23].

3.1.4 MFCC

MFCCs are a compact representation reducing the frequency dimension of the Mel spectrogram using the discrete cosine transform (DCT). MFCCs have been successfully applied in speech recognition and to some extend

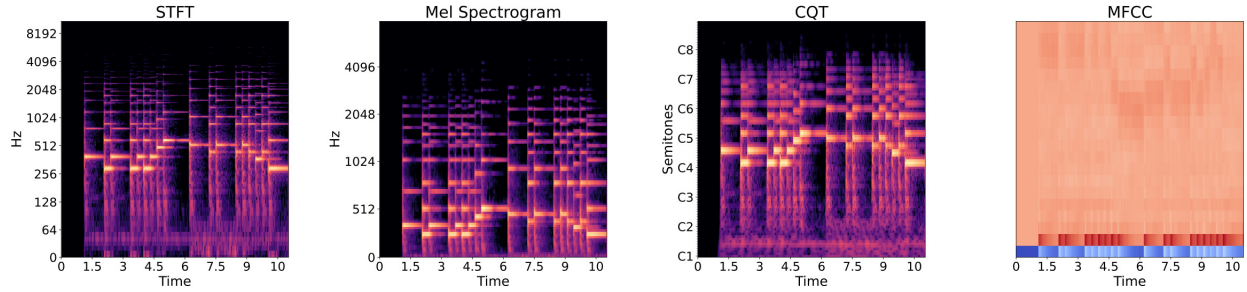

Figure 1. Different 2D input representations, from left to right: STFT, Mel spectrogram, CQT, and MFCC

also in MIR. The resulting coefficients describe the overall shape of the spectrogram columns [24]. Often the first 20 coefficients are used, which is also the default value in librosa, and therefore used in this work.

3.1.5 Constant-Q Transformation

Similar to the DFT, the CQT can be used to extract a time-frequency representation. The CQT results in a log-frequency scale and needs no further frequency transformation to match human audio perception. It is calculated similar to the STFT but enforces a constant ratio of the center frequency to resolution (constant-q) [25]. All parameters are chosen equal to comparable parameters of the Mel spectrogram: hop size 512, minimum frequency 32Hz, 12 bins per octave, and 96 frequency bins,

3.2 Network Architectures

In this section the five CNN architectures used for the experiments are discussed. Whenever kernel sizes are discussed, e.g. 3x3 filter kernels, these refer to two-dimensional inputs and imply 3(x1) filters for one-dimensional inputs. For more implementational details please refer to the original works, or the source code of the implementations.

3.2.1 VGG-16

The VGG-16 architecture introduced in [6] is used as a CNN baseline in this work. It consists of five convolutional blocks, each with 2-3 convolutional layers with 3x3 kernels and max-pooling with 2x2 kernels, followed by fully connected (FC) output layers. For each block the number of channels increases: 64, 128, 256, 512, and 512. For the FC layers (4 096 neurons each) the flattened output of the last convolutional block is used as input. Finally 50 sigmoid neurons form the output layer responsible for predicting the tags [6]. ReLU is used as an activation function for all hidden layers, and dropout- and batch-normalization layers are added after each block for regularization.

3.2.2 ResNet

Generally speaking, deeper networks have more processing power, but at the same time are harder to train because of the vanishing gradient problem. Residual networks implement so-called skip connections which are a solution to this problem and allow to train deeper networks [7]. A skip connection is a shortcut that adds the input to the output of a convolutional block or layer.

In this work, the ResNet-101 architecture (101 convolutional layers) [7] is used and reimplemented in TensorFlow. The basic building block is a bottleneck which consists of three convolutional layers (1x1, 3x3, 1x1) and a skip connection from the input to the output of the block. The 1x1 layers reduce the input dimensions by a quarter for the 3x3-layer and increase it again afterwards, which is done to reduces the memory footprint of the network. After the first convolutional layer (7x7) to downsize the input, the architecture consists of 3 blocks with 64 channels, 4 with 128, 23 with 256, and 3 blocks with 512 channels, followed by the sigmoid output layer.

3.2.3 Squeeze and Excitation Network

This architecture is based on the sample-level CNN architecture proposed in [26]. It uses one-dimensional raw audio-data as input. A basic block consists of a convolutional layer (3x3), followed by batch-normalization and max-pooling (2x2 for 2D and 3 for 1D). After that, the squeeze and excitation (SE) part is applied. The squeeze operation consists of a global average pooling to compress each channel. The excitation operation consists of two fully-connected layers (ReLU, sigmoid). Finally, the output of the basic convolutional part gets scaled with the output of the SE part by channel-wise multiplication. The squeeze and excitation network (SENet) consists of nine of these blocks, where the outputs of the last three blocks are max-pooled globally and concatenated to serve as input for two FC output layers, which use sigmoid outputs [26].

To make this architecture work for 2D input representations the frequency dimension is reduced gradually using 2D filters throughout the network.

3.2.4 Musicnn

Musicnn is a CNN designed specifically for music tagging and has been re-implemented and slightly adapted for this work. The original architecture uses Mel spectrograms with a length of three seconds and 96 Mel-bins as input [9]. The architecture is divided into three parts: *frontend*, *midend*, and *backend*. The *frontend* uses one convolutional layer with different kernel sizes motivated by music-domain knowledge. In the original work, 7x38, 7x67, 128x1, 64x1 and 32x1 filters are used. These filters are scaled relatively to the size of the frequency dimen-

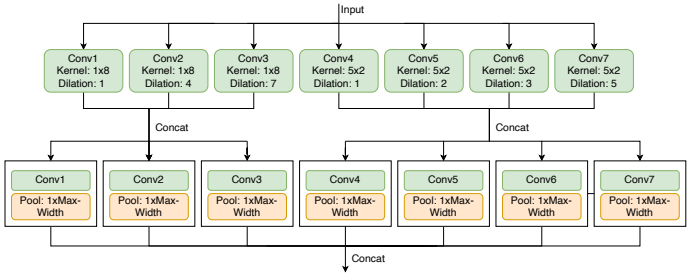

Figure 2. Dilated CNN frontend architecture for 2D-input

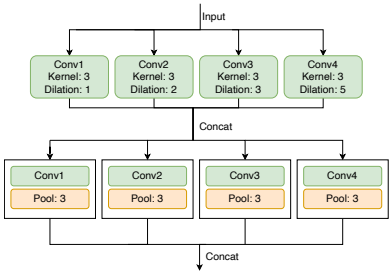

Figure 3. Dilated CNN block for frontend for 1D-input

sion for the other input representations used in this work. For the one-dimensional input, the frontend architecture from [14] is used, consisting of seven 3x1 convolutions, combined with max-pooling layers. The *midend* consists of three convolutional layers (7xN kernels) supposed to extract higher-level representations from the low-level features of the frontend. In the original work, midend and frontend layers are connected by summation of each input with the previous outputs (quasi-residual connections, inspired by dense connections [27]). The output layer concatenates all previous layers of the midend. The *backend* uses temporal pooling for the final output. It combines average- and max-pooling over the time dimension of the output of the midend, concatenates their outputs and then uses two dense-layers with sigmoid outputs for the final prediction [14].

3.2.5 Dilated CNN

This section presents an extension of the musicnn using dilated convolutions in the frontend. Dilated convolutions spread out the filters over a wider area, thus achieving a larger receptive field without increasing resource consumption [21, 28, 29]. As discussed in the introduction, a large receptive field is desirable since music tags depend on global properties of the audio signal. Figure 2 displays the architectural layout of the frontend for the dilated CNN. Three convolutional layers are used to extract temporal features, while four layers span the frequency axis. Then, all outputs are concatenated and serve as input for the midend. Convolutions in the first block have 26 channels and 51 in the second one. As described for the stacked dilated convolution block in [29], the outputs are concatenated after the first block of convolutions and are used as input for the second block.

For the one-dimensional input, the musicnn frontend was adapted differently. It consists of seven sequential stacked dilated convolutions to reduce the input size sufficiently. Each of those blocks consists of four parallel convolutions stacked in two blocks, as displayed in Figure 3.

3.3 Datasets

The two music tagging datasets used in this work are: MagnaTagATune ("MTAT") [30] and MTG-Jamendo ("MTGJ") [31]. Both these datasets contain tags belonging to the three categories "genre", "instrument" and "mood" identified relevant for the tag grouping in this work [32, 33].

3.3.1 MagnaTagATune

The dataset was created using the game-with-a-purpose called TagATune [30, 34]. MTAT consists of 5 223 songs, segmented into 25 863 song-snippets with a length of 29 seconds. Each snippet comes with associated tags from a set of 188 tags. Some of the tags in the dataset are synonyms for each other, therefore similar tags such as "choir" and "choral" or "horn" and "horns" are merged. Since some tags only yield an insufficient number of training examples, only the top 50 tags by occurrence are used, which is a common practice [26, 35, 36]. This results in 17 genre-, 22 instrument-, 9 mood- and two uncategorized tags. To be consistent on the two datasets, a 60:20:20 train/validation/test data split is used. When generating the splits, snippets of the same song are always put in the same split to counteract overfitting.

3.3.2 MTG-Jamendo

MTGJ consists of royalty-free music, and contains 55 709 full-length songs from 3 565 different artists. Every song is at least 30s in length and 224s on average, resulting in 3 777 hours of audio. In order to be consistent with the MTAT, only the first 29s of each audio segment are used, which reduces training- and test-data size. In total, there are 195 different tag annotations for each song, each belonging to one of the three categories "genre", "instrument", or "mood". The set of tags has already been cleaned up and does not contain tags with the same meaning [31]. The distribution of the number of examples per tag is comparable to MTAT. Again, only the top 50 most frequent tags are used for the experiments, which is consistent with the literature [31]. There are 31 genre-, 14 instrument- and 5 mood-tags. For train-, validation, and test-splits, the first split definition from the dataset repository is used [31]. The split ratios are approximately 60:20:20. The split definition ensures that tracks of the same artists are only present in one subset and that tags, tracks, and artists are equally distributed.

4. EVALUATION

4.1 Experiment Setup

For each combination of network architecture, input representation, and dataset, a model is trained and evaluated. For MTAT seven runs with random initialization, and for MTGJ five runs are performed and results are averaged over the runs. As evaluation criteria ROC-AUC was used

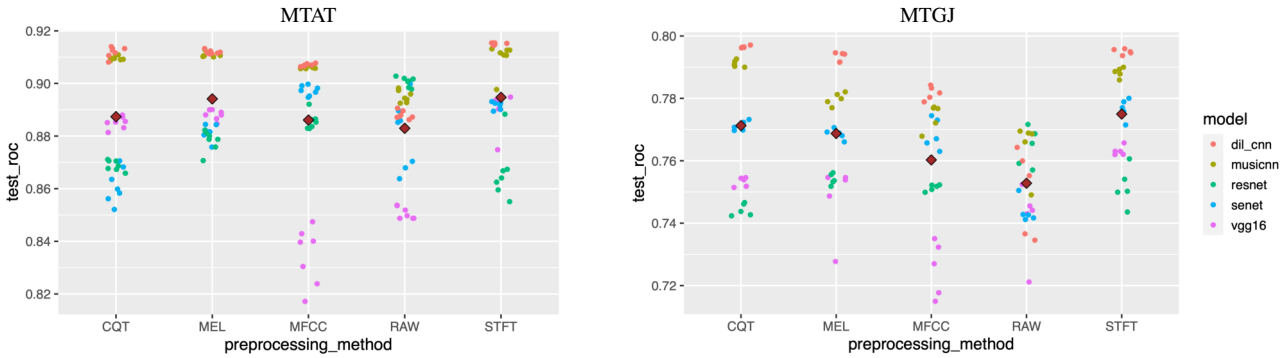

Figure 4. ROC-AUC scores for input representations and architectures on MTAT and MTGJ.

[35]. For training, early stopping was applied: training is stopped as soon as no further improvement on the validation split is achieved. As optimizer, ADAM in combination with a simple learning-rate schedule was used. Because of the smaller size of MTAT, additional refinement using stochastic gradient descent (SGD) with a reduced learning rate (1/5) was performed [37].

4.2 Results and Statistical Analysis

Figure 4 displays the ROC-AUC scores for the seven runs on MTAT (left) and the five runs on MTGJ (right) of input and architecture combinations. Different colors represent architectures, additionally, the average performance per input representation is shown in brown. The results for MTAT are on-par with state-of-the art results: dil_cnn+STFT: 0.915 v.s. 0.913 in [2]. For MTGJ, results are slightly below state-of-the-art (0.793 v.s. 0.832 in [2]), however, for compatibility reasons with MTAT in this work only 29s of each track are used v.s. full tracks in [2].

A two-way ANOVA is used to check if network architecture and/or input representation have a significant influence on the performance. Assumptions for ANOVA (independence and homoscedasticity of observations, normal distribution of residuals) are ensured: Since each run-configuration uses a different architecture and input representation combination, independence of observations is given. Homoscedasticity (equality of variances) of values is checked using the Levene test which indicates that this assumption is not met for MTAT. Therefore, a data transformation is applied to the result values on MTAT, which was not necessary for MTGJ. Residuals are found to be approximately normally distributed, which satisfies the last assumption [38].

Table 1 displays the results for the two-way ANOVA analysis. The p-values for the input representation and the architectures individually as well as combined indicate a strong influence on the performance. Due to the data transformation, the sum of squares (SS) and the mean squares (MS) for MTAT are not interpretable.

Tukey-HSD tests are used to check for significant differences of mean values between individual input representations as well as network architectures on both datasets. Table 2 shows the results with and without the data transformation to see absolute difference between groups while

MTAT	DF	SS (E+10)	MS (E+10)	F	P
input	4	2.83	70.8	57.64	<1E-5
arch.	4	31.6	7.89	642.13	<1E-5
input&arch.	16	15.1	94.5	76.86	<1E-5
residual	150	1.84	123		
MTGJ	DF	SS (E-5)	MS (E-5)	F	P
input	4	800	200	63.61	<1E-5
arch.	4	2600	650	205.51	<1E-5
input&arch.	16	1010	60	20.04	<1E-5
Residual	100	320	3.16		

Table 1. Two-way ANOVA results on MTAT and MTGJ. SS is sum of square, MS is mean square, DF is degrees of freedom, F is f-value, and P the p-value.

	diff (t)	p-value (t)	diff	p-value
MEL-CQT	13926.88	4.92E-06	0.0068	5.11E-07

Table 2. Tukey-HSD ROC-AUC results for input representations on MTAT with transformations (t) and without.

being able to validate or reject those results. The overall worst performing input representation is the raw waveform. It is 0.44% worse than the CQT transformation with a p-value of 0.0024 and significantly worse for the transformed input with a p-value of 1.18e-08. Compared to the MFCCs, the raw waveform performs 0.0031% worse, but with a p-value of 0.0651, so this difference is insignificant for the untransformed input. However, with the transformed input, there is a strong significance with a p-value of 7.63e-09 that the MFCCs outperform the raw waveform to an equal extent as the CQT transformation does. Comparing the MFCCs with the CQT transformation, neither of both outperforms the other for the transformed input and the untransformed with very high p-values of 1.00 and 0.8135. As displayed before in Figure 4, the former performs better in combination with all architec-

tures except for the VGG-16 model than the latter, where it shows a very poor performance compared to all other input representations. Mel spectrograms in average perform 0.8% better than MFCCs with a p-value of 2.05e-09 and 0.68% better than the CQT transformation with a p-value of 5.11e-07. These strong significance levels are also validated with the transformed inputs. There is no significant difference between the Mel spectrogram and the STFT with high p-values of 0.9869 and 0.2569 for untransformed and transformed inputs, respectively.

	diff (t)	p-val (t)	diff	p-value

vgg16-dil_cnn	-100118.83	0.0000	-0.0370	0.0000
resnet-musicnn	-79977.60	0.0000	-0.0264	0.0000
senet-musicnn	-73856.87	0.0000	-0.0238	0.0000
vgg16-musicnn	-95283.87	0.0000	-0.0365	0.0000
senet-resnet	6120.73	0.1475	0.0026	1.93E-01
vgg16-resnet	-15306.27	4.24E-07	-0.0101	1.32E-13
vgg16-senet	-21427.00	1.95E-12	-0.0127	1.54E-14

Table 3. Tukey-HSD ROC-AUC results for network architectures on MTAT with transformations (t) and without.

Table 3 shows the results for the Tukey-HSD range test on the different architectures. VGG-16 performs significantly worse than all other models. On average, it performs 1.01% worse than ResNet and 1.27% worse than SENet with p-values of $< 1e-06$ for both transformed and untransformed scores. There is no significant difference between the latter two because the p-value is 14.75% for the transformed input. Musicnn and the dilated CNN significantly outperform all other models with $> 2.4\%$ difference. As already discussed previously, there is no significant difference between those two architectures with p-values of 99.38% and 36.34% for untransformed and transformed scores, respectively.

The results on MTGJ have been found to be consistent with those on MTAT, due to space restrictions, the tables are only available on the accompanying website. For audio representations, the raw waveform again performs worse than all other inputs, but now the significance for MFCCs outperforming the raw waveform is much stronger, with a p-value of 8.22e-05 for having a 0.75% higher ROC-score. On average, the Mel spectrogram significantly performs 0.85% better than the MFCCs, and the CQT transformation performs 1.1% better than the latter. In contrast to the previous dataset, the Mel spectrogram and the CQT transformation perform equally well. The STFT performs 0.62% better than the Mel spectrogram. However, the performance difference between STFT and CQT is not statistically significant, with a p-value of 0.1472.

Regarding architectures, there is no significant difference between the musicnn and the dilated CNN, which perform best overall. VGG-16 performs worse than other architectures, followed by ResNet and SeNet.

Additionally, the same evaluation is performed separately for the three tag categories "genre", "instrument" and "mood". The motivation for this is the assumption that tag categories may depend on different properties of music which might be captured differently by individual input representation and network architecture combinations. On MTAT the results for genre and instrument are comparable to the overall results, while for mood the MFCC input representation performed surprisingly well, however, this could not be reproduced on MTGJ. Due to space restriction the detailed results are not provided here, but can be obtained on the accompanying website.

4.3 Discussion

The evaluation shows that both architecture and input representation significantly impact the classification results during all experiments. The STFT provides the best overall results on almost all tested configurations. This comes to the price of higher resource consumption due to the larger size of this input representation. Raw waveforms show the worst results on all configurations which might be because the architectures are originally designed for two-dimensional inputs and are adapted. Despite their small size, MFCCs perform well across almost all architectures, so they might be a good choice for tasks requiring low resource consumption. Mel spectrograms show solid performances across all architectures but are still significantly worse than the STFT. However, due to their around ten times smaller size, they are much less resource-consuming which might be the reason why they are a commonly used input representation. The dilated CNN significantly outperforms the original musicnn on two-dimensional input representations and performs worse on the raw waveform.

On MTAT the CQT transformation has the second-worst results but on MTGJ it performs equally well as the STFT. Therefore, no general conclusion can be drawn about the performance of this input representation which is comparable in terms of size to the Mel spectrogram. The evaluation on individual tag categories was inconsistent between the two datasets making further conclusions difficult. For genre tags, similar results can be observed on MTAT and MTGJ, but there is no particular trend identifiable compared to the evaluation across all tags. The results suggest that mood classification differs the most from the other tag categories. For example, MFCCs perform the second-worst for genre- and instrument classification but the second-best on mood tags. However, this was not the case for MTGJ, where MFCCs only show slightly better results than the raw waveform.

5. CONCLUSIONS

In this work, five CNN architectures and five input representations have been evaluated on two commonly used music tagging datasets. A thorough statistical analysis of the results, identifies significant performance differences between all combinations, where the combination of STFT inputs and the newly introduced dilated variant of the musicnn performs best. The evaluation on tag categories does not yield any consistent trends, but points to some interesting hypothesis, e.g., that for mood tags compressed input representations like MFCC might be sufficient.
